Toxic Cirrhosis. (*Postnecrotic Cirrhosis, Nodular Cirrhosis*). A toxic cirrhosis follows many forms of poisoning by drugs or chemicals and sometimes acute infectious hepatitis and occasionally in a patient who recovers from acute or subacute yellow atrophy In this form of cirrhosis ascites occurs late in the course of the disease if at all.

Cirrhosis of the Liver in Children. Cirrhosis in children is rare Among 82,866 admissions to the St Louis Children's Hospital there was a total of 40 cases of cirrhosis

Defined as a diffuse fibrosis of the liver, the condition can be brought about in a variety of ways, some of which depend on inheritance and some on major derangement in some other organic system A variety of toxins are capable of causing necrosis in the liver which, if it is not too extensive, is followed by fibrotic repair There seems to be nothing distinctive about this sequence as it occurs in children Two typical cases of hepatolenticular degeneration, which have been described, are indistinguishable, so far as the liver is concerned, from ordinary nodular cirrhosis

Keller and Nute classified the disease, according to causes, in the 40 cited cases There were 8 cases of obstructive biliary cirrhosis, which is due almost always to congenital anatomic anomaly Clinically it is distinguished by an obstructive jaundice in the newborn infant and pathologically by interlobular fibrosis, bile stasis and moderate inflammatory infiltration Eleven patients had nodular cirrhosis, which develops in childhood rather than in infancy and is insidious in onset Jaundice and hepatosplenomegaly are the most constant observations The atrophic stage is rare The liver shows extensive perilobular fibrosis, focal regeneration and mononuclear cell infiltration without bile stasis Diffuse fibrosis of the liver, in addition to the usual clinical and pathologic findings, was observed as a rare sequela of erythroblastosis fetalis in 5 cases Congestive cirrhosis is the result of repeated severe passive congestion of the liver that alternates with periods of relative compensation Clinically it is overshadowed by the primary disease of the heart Six cases of this type are reported There was only 1 case of postnecrotic cirrhosis of the liver.

The manifestations of cirrhosis of the liver in children are similar to those present in adults who have a comparable form of the disease

Biliary Cirrhosis. (*Hanot's Cirrhosis, Cholangiolitic Cirrhosis, Noncalculous Cholangitic Cirrhosis*) Biliary cirrhosis occurs in a primary and a secondary form. The *primary* form occurs in youth and early adult life It may be familial It is characterized by persistent jaundice and enlargement of the spleen and the liver, fever, leukocytosis and mild abdominal pain

The *secondary* form of the disease seems to be a sequel of a persistent obstruction of the common bile duct This disease is suspected if jaundice does not subside after the obstruction of the common bile duct has been relieved

Vascular Diseases of the Liver. Cirrhosis of the liver due to chronic passive congestion has already been considered Hemangioma likewise has been mentioned Other vascular diseases of the liver are rare and are seldom diagnosed prior to death

The portal vein may become occluded and in rare instances a complete collateral circulation ensues When the portal vein is occluded and collateral circulation is not adequate or not established, there is sudden onset of hematemesis, ascites and swelling of the spleen

The hepatic veins are subject to occlusions, periphlebitis, suppurative phlebitis and endophlebitis A widespread occlusion of the hepatic veins which results in an excessive collateral circulation about the umbilicus is known as Chiari's disease

(endophlebitis hepatica obliterans). Diseases of the hepatic veins are even rar than disease of the portal vein.

The hepatic artery may be involved by atherosclerosis, by infarcts or by aneurysm. All of these conditions are rare and usually are not diagnosed clinicall

Tumors of the Liver. *Benign Tumors.* Benign tumors of the liver are ra lesions which occur more frequently in men of middle age than in men of oth ages or in women. These growths may be either solid or cystic. The solid tumo include angioma (hemangioma and lymphangioma), adenoma (fibro-adenoma benign teratoma (mixed tumor), hamartoma, leiomyoma, lipoma and teratoma

Hemangioma, the most frequent benign tumor of the liver, occurs in the left lob These tumors are usually single, demarcated and often pedunculated, but they var through wide limits in size and locations in the liver

Adenomas arise either from liver cells or bile-duct cells and may be single c multiple. They too vary in size and location

Teratomas are solitary tumors of variable size and consistency.

Growths composed of all the cellular elements of the hepatic parenchyma have bee given the name *hamartomas* The mass is composed of liver lobules, bile ducts an blood vessel networks which, though fairly well differentiated, may not show any pur poseful arrangement or attain the complete pattern of the normal organ. Hamartoma which occur in the lungs are not composed of hepatic tissue but of a network of newl formed blood vessels

Leiomyomas in the liver are exceedingly rare lesions.

The symptoms of benign solid tumor of the liver arise when the mass reaches size sufficient to interfere with the normal function of neighboring organs Thus th symptoms produced are variable The most definite symptoms arise when there i sufficient pressure on the common bile duct or the intestine to occlude the lumer of the structure involved

On examination there is a palpable, nontender, smooth mass connected with the liver The mass, most commonly, is palpable in the midepigastrium Hemangioma may present as a palpable mass in the left upper quadrant Some hemangiomas may be compressible, and occasionally a bruit or hum may be heard over them An enlarged spleen, ascites, and other evidences of portal hypertension and decompensation may be observed when the tumor, especially an adenoma, is associated with cirrhosis of the liver

Benign solid tumor of the liver is diagnosed on biopsy of a specimen removed by the surgeon or at postmortem examination The diagnosis may be conjectured if there is a mass associated with the liver or directly connected with the liver, and if the mass has been known to exist for a long time without any serious deterioration in the health of the patient

Surgical removal when possible, is the only treatment.

There are *parasitic and nonparasitic cysts* of the liver As a matter of enumeration the following cysts may be identified solitary (simple, retention), multiple (in polycystic disease), echinococcal (hydatid), cystadenoma, pseudocyst, teratomatous, lymphatic (lymphangiomatous), and endothelial These cysts are identifiable only by biopsy

The echinococcal cyst is the only important *parasitic cyst* affecting the liver, and the resulting disorder is the only important acquired cystic disease of that organ (see Infection of the Intestines by Higher Animal Parasites, p 939).

Hepatic nonparasitic cysts, solitary or multiple, are rare.

Solitary cysts have been observed in fetuses and in persons of all ages Nonparasitic cysts remain symptomless unless they attain sufficient size to compress adjacent viscera, or unless complications develop Medical advice is sought because of painless abdominal swelling Abdominal pain, when present, is epigastric or is situated in the right upper quadrant.

Rupture and infection are frequent complications in nonparasitic cysts. In addi-

tion, sudden intracystic hemorrhage may occur with an accompanying acute abdominal pain. Much the same manifestations are seen in the rare case in which the pedicle of a large pedunculated cyst suddenly becomes twisted

Physical examination reveals an abdominal tumor In polycystic disease both kidneys are nearly always palpable as well as the enlarged liver.

When some complication occurs in cystic disease of the liver, the findings depend on the complication present

A correct diagnosis is not made prior to operation or death. Sinuses may persist for years when treatment by external drainage has been employed.

Malignant Tumors (Primary). The clinical features of malignant tumors of the liver are the same for all types

Among the factors thought to be of importance in the genesis of primary cancer of the liver are previous or existing inflammatory processes, parasitic infection, chemicals, dietary deficiencies, congenital defects, hereditary predisposition, trauma and venous congestion An evaluation of the importance of these factors, singly or combined, is not possible

Cirrhosis of the liver is associated with primary carcinoma of the liver in 8 of 10 who have malignant hepatomas and in half of those who have malignant cholangiomas. Thrombosis of the portal vein is common in primary carcinoma of the liver. Thrombosis of the hepatic veins occurs occasionally, and even thrombosis of the inferior vena cava may be present

Pathologists describe sarcomas, malignant teratomas and carcinomas. The primary carcinomas of the liver are divided into three groups (1) the hepatocellular carcinomas (hepatomas), (2) carcinomas of the gallbladder or bile passages (cholangiomas) and (3) the atypical or mixed carcinomas Hepatomas are the most frequent form of primary cancer of the liver All of the carcinomas of the liver are often associated with cirrhosis

In sarcomas of the liver, the liver is usually much enlarged and the lesions may be massive, nodular, or conglomerate and diffuse Cirrhosis, as in carcinomas, is frequently associated if the sarcoma arises primarily in the liver

Intrahepatic metastasis is so common as to be almost the rule in fatal primary malignant tumor Extrahepatic metastasis occurs in one half of all cases The sites most frequently affected in extrahepatic metastasis are the regional lymph nodes and the lungs

Primary hepatic carcinoma may occur in persons of any age, including children. It is commoner in the pigmented races than in the white race

SYMPTOMS In children the attention of the parents is often initially attracted by a large abdomen or the appearance of an abdominal mass In others loss of weight, vomiting, nutritional disturbance, anorexia, or abnormal stools arouse concern Jaundice and ascites are not nearly so common in children as in adults

In adults there commonly are, in retrospect, loss of strength and progressive loss of weight which are more rapid than should be attributed to the cirrhosis of the liver, which is responsible for the ascites, peripheral edema, collateral venous development and hematemesis In others the symptoms are those of malignant disease which is responsible for the loss of weight, asthenia, pain and hepatic enlargement without the features of cirrhosis

Three out of 4 patients who have primary hepatic malignant disease have abdominal pain which is localized to the right upper abdominal quadrant and not infrequently is felt in the back as well It is unrelated to meals, and rarely is severe until the disease is well advanced Asthenia, as a rule, is delayed in appearance until the disease is well advanced

Hematemesis or melena, or both, from ruptured esophageal varices, and epistaxis, frequently recurrent, are common. Occasionally pruritus is intense and constitutes one of the important complaints. Hypoglycemic episodes with hunger, diplopia, nervousness and even coma may occur

Fever is not a feature of the disease and rarely is present

(endophlebitis hepatica obliterans). Diseases of the hepatic veins are even rarer than disease of the portal vein.

The hepatic artery may be involved by atherosclerosis, by infarcts or by an aneurysm. All of these conditions are rare and usually are not diagnosed clinically

Tumors of the Liver. *Benign Tumors.* Benign tumors of the liver are rare lesions which occur more frequently in men of middle age than in men of other ages or in women These growths may be either solid or cystic The solid tumors include angioma (hemangioma and lymphangioma), adenoma (fibro-adenoma), benign teratoma (mixed tumor), hamartoma, leiomyoma, lipoma and teratoma

Hemangioma, the most frequent benign tumor of the liver, occurs in the left lobe These tumors are usually single, demarcated and often pedunculated, but they vary through wide limits in size and locations in the liver.

Adenomas arise either from liver cells or bile-duct cells and may be single or multiple. They too vary in size and location

Teratomas are solitary tumors of variable size and consistency

Growths composed of all the cellular elements of the hepatic parenchyma have been given the name *hamartomas* The mass is composed of liver lobules, bile ducts and blood vessel networks which, though fairly well differentiated, may not show any purposeful arrangement or attain the complete pattern of the normal organ Hamartomas which occur in the lungs are not composed of hepatic tissue but of a network of newly formed blood vessels

Leiomyomas in the liver are exceedingly rare lesions

The symptoms of benign solid tumor of the liver arise when the mass reaches a size sufficient to interfere with the normal function of neighboring organs Thus the symptoms produced are variable The most definite symptoms arise when there is sufficient pressure on the common bile duct or the intestine to occlude the lumen of the structure involved

On examination there is a palpable, nontender, smooth mass connected with the liver The mass, most commonly, is palpable in the midepigastrium Hemangioma may present as a palpable mass in the left upper quadrant Some hemangiomas may be compressible, and occasionally a bruit or hum may be heard over them An enlarged spleen, ascites, and other evidences of portal hypertension and decompensation may be observed when the tumor, especially an adenoma, is associated with cirrhosis of the liver

Benign solid tumor of the liver is diagnosed on biopsy of a specimen removed by the surgeon or at postmortem examination The diagnosis may be conjectured if there is a mass associated with the liver or directly connected with the liver, and if the mass has been known to exist for a long time without any serious deterioration in the health of the patient

Surgical removal when possible, is the only treatment

There are *parasitic and nonparasitic cysts* of the liver. As a matter of enumeration the following cysts may be identified solitary (simple, retention), multiple (in polycystic disease), echinococcal (hydatid), cystadenoma, pseudocyst, teratomatous, lymphatic (lymphangiomatous), and endothelial These cysts are identifiable only by biopsy

The echinococcal cyst is the only important *parasitic cyst* affecting the liver, and the resulting disorder is the only important acquired cystic disease of that organ (see Infection of the Intestines by Higher Animal Parasites, p. 939)

Hepatic nonparasitic cysts, solitary or multiple, are rare

Solitary cysts have been observed in fetuses and in persons of all ages Nonparasitic cysts remain symptomless unless they attain sufficient size to compress adjacent viscera, or unless complications develop Medical advice is sought because of painless abdominal swelling. Abdominal pain, when present, is epigastric or is situated in the right upper quadrant

Rupture and infection are frequent complications in nonparasitic cysts In addi-

Hourglass gallbladders are common. Irrespective of whether they are of congenital or acquired origin, they are symptomless However, a gallbladder containing an hourglass deformity may become diseased.

A *diverticulum* of the *neck* of the gallbladder is usually a persistent fetal cysthepatic duct or rest. Diverticula found in the *fundus* may be due to a constricting band of fetal origin. A diverticulum of the gallbladder responds in unison with the gallbladder to disease and stone formation.

A gallbladder having within it small partitions which communicate with each other is a *trabecular gallbladder.* Such an organ originates from a vesicular outgrowth of hepatic tissue.

The *malpositions* of the gallbladder in the horizontal plane comprise transposition of the vesicle to the left when it is situated on the undersurface of the left lobe of the liver, and situs inversus viscerum in which the gallbladder is moved to the left side as a part of the general malformation. The malpositions in horizontal transverse planes comprise deep embedment of the vesicle in the liver and retrodisplacement, in which the gallbladder does not rest in its own fossa, and the fundus extends back and adheres to the liver or hangs free and retroperitoneally.

The gallbladder is normally intrahepatic during early developmental stages, but it becomes *extrahepatic* during development. When intrahepatic in man, the vesicle usually is found partially or completely embedded. Diagnosis is made at surgical operation or at necropsy

Acquired anomalies of the gallbladder may resemble true diverticula. For instance, there may be eventrations of the wall of the gallbladder and cul-de-sacs which are multiple and contain calculi. Hydrops and displacements due to disease of the liver or adjacent structures are commonly observed.

Acute Cholecystitis. Acute inflammation of the gallbladder is commonest among stocky, stoic, obese persons. More women are affected than men Negroes are infrequently affected.

Acute cholecystitis most frequently arises from an obstruction to the outlet of the gallbladder by an impacted gallstone in the proximal end of the gallbladder or in the cystic duct. Rarely are obstructions present such as torsion of the cystic duct at its junction with the gallbladder, or obstruction of the cystic duct by congenital narrowing or by an anomalous blood vessel More commonly, when acute cholecystitis occurs in the absence of gallstones, it is from obstruction of the cystic duct from acquired fibrosis or from extrinsic compression from enlarged lymph nodes or from an adjacent tumor.

There are many gallbladders which remain bacteriologically sterile throughout the course of acute cholecystitis Occasionally, acute cholecystitis is due to bacterial infection, but such occurrences are rare and then they may be associated with stagnant bile in the gallbladder

The gallbladder in acute cholecystitis of moderate degree is enlarged The peritoneal surface is covered with an inflammatory exudate, and there may be adhesions to surrounding structures In the more severe infections gangrene may be present with some exudation of bile-stained fluid to the outside of the gallbladder. In some instances the fundus of the gallbladder may be embedded in the hepatic parenchyma and is surrounded by a localized necrosis Occasionally there is a free perforation of the gallbladder with an associated generalized chemical peritonitis If the gallbladder has become adherent to the duodenum or colon, free perforation into the bowel may be present.

Symptoms. The symptoms may commence at any time, during the day or night with pain in the epigastric or in the right hypochondriac regions. There may be nausea and vomiting of varying degrees of severity from the beginning of the attack or these symptoms may be postponed until after the patient has had an opiate administered for the pain The vomiting often is retching and almost continuous.

When first seen by the physician, 7 or 8 of every 10 patients will mention that they have had similar attacks before. In the severe attacks pain is constant, sharp and severe However, variations in intensity of pain occur during an attack. The pain in acute cholecystitis usually returns after the effect of an injected opiate wears

EXAMINATION. In both children and adults enlargement of the liver is rapid and tremendous The liver may be fixed and may not display mobility either on palpation or with respiration In those who have cirrhosis of the liver prior to onset of carcinoma of the liver, the spleen is palpable and ascites is present. Edema of the legs may ensue Jaundice is present late in the course of the disease.

Studies of the blood reveal anemia Liver function tests, analyses of the feces and the urine, and roentgenologic examination do not reveal any worthy diagnostic data.

DIAGNOSIS. A very rapid enlargement of the liver in the absence of failure of the right side of the heart and without any other evidence of hepatic disease may be due to a primary tumor Diagnosis of primary malignant neoplasm of the liver is seldom made prior to necropsy or biopsy.

Primary malignant neoplasm cannot be distinguished from *hepatic metastasis* from a silent primary focus elsewhere in the body.

The prognosis is hopeless

Enlargements of the Liver and Spleen. During examination of the abdominal viscera the spleen may be found enlarged Such enlargement may or may not be associated with enlargement of the liver Under the ordinary conditions of an examination by physical means a palpable spleen is significant. In many instances the enlargement of the spleen may be extreme and may be the first and only symptom of serious disease

The causes of splenomegaly are enumerated as follows: (1) infectious, (2) circulatory, usually mechanical in origin, (3) hemic and lymphatic, (4) metabolic and (5) cystic and neoplastic (see Chapter 12).

THE GALLBLADDER AND BILE DUCTS

THE GALLBLADDER

The gallbladder reaches the surface at the anterior end of the right ninth costal cartilage, just to the outer edge of the rectus muscle. This is the upper end of the right linea semilunaris Normally the gallbladder is not palpable. Many dubious claims are made in regard to the ability to palpate the distended gallbladder. However, at times, it can be palpated. *Hydrops* is the common cause for a palpable gallbladder.

Congenital and Acquired Anomalies and Malpositions. In the embryo which is 15 mm long the gallbladder is represented by an elongated mass. The bile ducts already have patent lumina The bile ducts and the lumen of the gallbladder develop by a process of vacuolation If vacuolation is disordered structural defects or congenital absence of the ducts or gallbladder may result Splitting, as an aberration of vacuolation, may produce a double, a bilobate, or an hourglass gallbladder, or a diverticulum of the gallbladder

Agenesis or absence of the gallbladder is a rare condition which occurs twice as frequently in women as in men. Absence of the gallbladder is compatible with digestive comfort.

Anteroposterior bends in the developing gallbladder are situated at the distal end and at the junction between the body and the fundus. The latter fold normally disappears, but when it persists, it participates in the formation of a folded-fundus gallbladder or *phrygian cap* The phrygian cap does not interfere with function of the gallbladder

There are two varieties of *double gallbladder*· one in which each duct empties independently into the same part or different parts of the extrahepatic biliary duct system, and one, the lambda type, in which the two ducts open into a common cystic duct The vesicles may appear as two distinct organs at variable distances apart or may be invested with a common peritoneum.

The *bilobate gallbladder* consists of a completely divided gallbladder with a common cystic duct.

Acute perforation of the gallbladder usually is preceded by an obstruction by a stone of the cystic or the common bile duct which produces distention of the gallbladder and interference with circulation of the blood, and gangrene ensues. The wall of the gallbladder, weakened by gangrene, ruptures. Occasionally there is thrombosis of the cystic artery, and sudden rupture follows A rare cause of rupture of the gallbladder is bacterial infection which weakens the wall of the gallbladder, as in typhoid fever.

Perforation of the gallbladder usually occurs at the fundus It is found in persons from 40 to 60 years of age. A history of previous attacks of cholecystitis is generally recorded unless the perforation occurs secondary to atherosclerosis or an infection.

The symptoms of acute free perforation in a patient who has acute cholecystitis are difficult to recognize until generalized peritonitis develops. There is pain in the right hypochondrium, in the epigastrium, or in the right lower abdominal quadrant. The pain progressively increases in severity and in extent until it becomes generalized throughout the abdomen

On examination the pulse is rapid and fever is present. Shock and peripheral vascular collapse are prominent when bile peritonitis is present The abdominal wall is tense, and muscular rigidity, at first most marked in the right side of the hypochondrium, gradually advances so that the entire abdomen becomes involved Acute tenderness in the right upper and right lower abdominal quadrants becomes widespread as the peritonitis progresses Abdominal distention develops and may become prominent

Free perforation should be suspected in any patient who presents signs and symptoms indicating acute inflammation of the gallbladder, who has persistent pain, and who shows a progressive increase in the degree and extent of abdominal tenderness, rigidity and shock A correct diagnosis of free perforation is not usually made in acute cholecystitis

One half of the persons who die from acute cholecystitis have acute free perforation of the gallbladder The commonest causes of death after surgical operation for acute perforation of the gallbladder are peritonitis and pulmonary embolism An acute hepatic insufficiency with the added features of shock may develop and cause death

Bile Peritonitis. Among the known causes of bile peritonitis are perforation of the gallbladder, rupture of any of the bile ducts after surgical operation on the biliary tract, traumatic rupture of the bile ducts, leakage from injured accessory hepatic ducts in the bed of the gallbladder subsequent to cholecystectomy, and malignant invasion of the gallbladder or bile ducts with perforation

In some patients there are no objective findings which will account for the leakage of the bile This group of patients who have idiopathic bile peritonitis is sizable

There is often in the abdomen an increased amount of free fluid which varies in color from amber to light green The peritoneum is congested and is covered with numerous plaques of fibrinous or fibrinopurulent material Gallstones in the bile ducts or free in the abdomen have been reported in more than half of those who have perforation of the gallbladder

The manifestations are those of acute peritonitis

The diagnosis of bile peritonitis is seldom made The diagnosis of general peritonitis is usually made prior to operation or necropsy

The therapy of bile peritonitis is prompt operation [illegible] ule, repair of any perf [illegible]

The mortality [illegible] or absence of infectic [illegible] of illness prior to operation The average mortality rate is 50 per cent

Chronic Cholecystitis and the Calcified Gallbladder. If roentgenologic examination fails to reveal evidence of stone, impairment or loss of concentrating function, or pericholecystitis, the surgical removal of the gallbladder which has been

off, or the pain may recur every few hours. More often, a constant dull or severe aching pain may continue for several days.

The pain is situated in the right upper quadrant of the abdomen in about one half of those who have it, and in the remainder the pain is in the epigastrium Reference of pain to the midscapular region or to the right infrascapular region occurs in approximately one half of these patients. In some the pain is referred to the shoulder tip, in others, to the left upper abdominal quadrant, or to the loin.

Chills or chilly sensations may occur at the onset of an attack. The temperature may be within the limits of normal or rarely exceeds 100 F (37.8 C)

EXAMINATION On examination, abdominal distention of variable degrees is present in about 1 of every 5 of those who have acute cholecystitis From time to time severe ileus (the so-called gallbladder ileus) may attend the acute pain, with great distention of the abdomen. There is tenderness in the right upper quadrant of the abdomen. Also, tenderness may be elicited by jolting the lower margins of the ribs on the right side of the back In mild attacks the patient may be aware of tenderness on deep inspiration or on descending a stairway. In an occasional patient a tense, tender, distended gallbladder or a tender mass may be palpated in the right upper portion of the abdomen

Jaundice can be detected in about 1 of every 4 during the acute phase of cholecystitis Jaundice may occur in association with acute cholecystitis without there being a stone in the common duct

The leukocyte count may be increased. In about 1 patient of every 5 the count will exceed 15,000 cells per cubic millimeter of blood A single leukocyte count is a poor index of the character and extent of the associated pathologic process in an acutely inflamed gallbladder The general trend of several counts is a useful indication in following the progress of the disease

The erythrocyte sedimentation is increased

The routine determination of serum-bilirubin concentration is of some value *Small degrees of hyperbilirubinemia are not diagnostic of stones in the common* duct Serum-bilirubin concentrations as high as 3 mg per 100 ml are often observed during the course of acute cholecystitis in the absence of a stone in the common duct.

There is usually *bile* in the urine Glycosuria which appears for the first time during an attack of acute cholecystitis may indicate a participation of the pancreas in the process.

DIAGNOSIS A sudden onset of nausea, vomiting, and acute, mild or severe pain in the upper right abdominal quadrant, going through to the back, occurring in a *patient about 40 years of age and overweight,* is *diagnostic* in most instances Often there is a history of previous attacks of pain which required hypodermic injections of opiates for relief.

Among the common disease conditions which may produce similar symptoms are acute appendicitis, subacute perforation of a peptic ulcer, and renal colic.

If jaundice becomes prominent, there is usually a *stone in the common duct*

The patient who has the manifestations of peritonitis, or fever, rapid pulse, marked leukocytosis and a large, tender gallbladder suggesting imminent *perforation,* should be operated on promptly If there is jaundice and the forementioned symptoms are mild or absent, it may be well to postpone surgical treatment until the patient can be properly prepared for operation

Even in the presence of mild symptoms, diagnostic studies are postponed until all signs of acute inflammation have subsided

Acute Perforation of the Gallbladder. Acute free perforation of the gallbladder is found at the time of operation in 1 of every 200 cases of gallbladder disease in which surgical exploration is made. Of the perforations of the gallbladder which occur as complications of acute cholecystitis, about 1 of 4 is free.

symptoms. This incidence of symptoms does not include dyspeptic symptoms occurring day after day in those who have, and those who do not have, uncomplicated cholelithiasis Symptoms of gallstones must be limited to the syndrome of gallstone colic or biliary colic This syndrome is characterized by attacks of pain indistinguishable from the pain in the presence of acute cholecystitis. The pain increases and decreases slowly in intensity, it is not a true colic. The belching associated with "gallbladder dyspepsia" is due to air swallowing, overeating, anxiety, fear and tension. It is not due to gallbladder disease and it will not be relieved by removal of the gallbladder. It may be relieved for a while after the gallbladder is removed, but will return as soon as the patient returns to her regular daily routine and becomes tense The so-called qualitative food distress of gallbladder disease, for instance, an intolerance of fats, fruits and uncooked vegetables, is commonly associated with an accompanying psychoneurosis. However, these symptoms may be due to gallbladder disease A patient who has headache followed by nausea and vomiting often attributes the complaint to biliousness Bilious attacks should not be presumed to be due to gallbladder disease Often so-called bilious attacks are accompanied by vomiting and retching After retching, a pain and soreness may appear in the upper part of the abdomen. Such soreness and pain, as described by the patient, are very much like the discomforts of biliary colic. Often the so-called bilious attacks are migraine. Migraine is not relieved by cholecystectomy

The most important genuine symptom to be related by the patient who has gallstones is the change of color of stools and urine, the stools being lighter than normal, and the urine very dark Of more significance than the color of the urine is the history of the passage of light-colored feces, for the color of the urine may be deepened by concentration of the urine, which may be the result of dehydration caused by abstinence from food or drink and by vomiting A slight transient icterus may occur from many causes, but when it follows biliary colic it is usually due to acute cholecystitis and stone in the cystic duct or in the common duct

Examination The patient who has gallstones often has not had symptoms. Therefore the results of abdominal examination are negative for evidence of the cholelithiasis If the patient is examined during an attack of pain, the findings are the same as those during an attack of acute cholecystitis. There are tenderness and often muscle guarding in the right upper part of the abdomen The results of examination shortly after such an attack may be negative Often there is residual tenderness, however, which may be elicited over the upper right abdominal quadrant or by light pounding with the ulnar side of the hand over the back.

Diagnosis The diagnosis of gallstone disease often can be made with a reasonable degree of accuracy from the history and the findings on physical examination If jaundice attended the attack of pain, the diagnosis can be made with more certainty A diagnosis of gallstones without confirmation by positive roentgenologic examination is rarely necessary

The important complications of cholelithiasis are empyema, gangrene and free perforation of the gallbladder, pericholecystic abscess, hepatitis, cholangitis, pylephlebitis and septicemia The common complication, which is often important because of its frequency, is jaundice

Any patient who has had an attack of biliary colic in association with jaundice or without jaundice, and who has demonstrable gallstones on roentgenologic examination, or any patient who has had such an attack who has a nonfunctioning gallbladder, proved by the usual technic of roentgenologic examination of the gallbladder, should undergo cholecystectomy. Any patient who has gallstones and evidence of impairment of liver function may be considered for cholecystectomy. The occurrence of manifestations of cardiac dysfunction following the onset of symptoms of cholelithiasis requires consideration for removal of the gallbladder.

clinically diagnosed as having chronic cholecystitis usually will not give lasting relief from the subjective complaints.

In contrast to the gallbladder which does not contain stones is the calcified gallbladder which may be causing symptoms. Calcium may be diffusely deposited throughout the gallbladder or it may occur in discrete patches Calcified gallbladders are often enlarged and functionless, and may be associated with obliteration of the cystic duct.

A calcified gallbladder may be proved to be nonfunctioning by roentgenologic examination A nonfunctioning gallbladder is significantly diseased. If the gallbladder is functioning and free from stones, and only a primary shadow is present in the roentgenogram, the gallbladder is not significantly diseased.

Cholelithiasis. Gallstones vary greatly in size and number Although most stones in a gallbladder seem to be of a single age, stones of different ages may occur

Calculi are found with great frequency in both the gallbladder and the common duct They rarely are confined to the intrahepatic ducts, but when so confined, the stones are almost always the black so-called pigment (bilirubin-calcium) stones

The exact mechanism of the genesis of gallstones is unknown The predisposing factors of gallstone formation are (1) metabolic, (2) chemical and (3) local.

During the last trimester of pregnancy the intra-abdominal pressure interferes with the outflow of bile It has been postulated that the biliary stasis thus created in pregnancy may be a factor in the production of gallstones. Postulations associating the formation of gallstones to endocrine disturbances have been made without good evidence that such occurs

It has been demonstrated that bile salts are concerned with keeping cholesterol in solution The precipitation of cholesterol occurs whenever there is significant lowering of the bile-acid content in the gallbladder in proportion to the cholesterol The normal gallbladder acidifies hepatic bile and perhaps in this way prevents calcium carbonate and other ingredients of gallstones from precipitating Any factor which alters the normal acidification of bile in the gallbladder is concerned in gallstone formation

It seems probable that infection and associated inflammatory changes within the gallbladder may be secondary to interference with gallbladder function brought about by mechanical obstruction of the cystic duct or the common duct, or both, by the calculi Infection, however, usually is not a major factor in the genesis of most gallstones, pathologic changes in the gallbladder, like the infection, are secondary to the presence of stones, the stones having been formed by aberrations in normal chemical reactions which maintain the constituents of bile in solution

No direct relation has been established between the concentrations of cholesterol in blood and in bile in the obese who have gallstones.

Repeated attacks of acute or subacute cholecystitis originated by stones eventually cause severe inflammatory changes in the vesical wall, which may become thickened and contract firmly on the contained stones The inflammation extends and there is pericholecystitis with adhesions to the liver, duodenum, hepatic flexure of the colon or omentum. Choledocholithiasis occurs in approximately one fourth of the cases of cholelithiasis Of rare occurrence are fistulas of the biliary tract, and the passage into the intestine of a stone or stones which obstruct the intestine Pancreatitis is a frequent complication of cholelithiasis

The recorded incidence of gallstones is mainly determined by the presence of symptoms, but since symptoms are often absent, estimates of the incidence are worthless

The occurrence of cholelithiasis with symptoms is commoner among middle-aged women than among men, and it steadily increases with age. However, gallstones do occur in infants, children and young adults In these a common cause is congenital hemolytic, or some other form of hemolytic, anemia. All races of men and many species of animals have gallstones

SYMPTOMS. Despite the dubious origin of the figures on the incidence of gallstones, it may be stated that about 1 in every 10 patients who have calculi has

digestive health after the gallbladder has been removed Likewise the postcholecystectomy syndrome does not affect those who have strictured common bile ducts or stones in the common bile duct which were not removed at the time of removal of the gallbladder.

The gallbladder is not a nuisance organ like the appendix, for it does have functions. However, these functions can usually be dispensed with, without manifest discomfort, as evidenced by the 9 of every 10 patients who have the gallbladder removed and are comfortable thereafter so far as the loss of the gallbladder is concerned

The gallbladder has two main functions. (1) It regulates bile pressure in the bile ducts by serving as an overflow reservoir and tension bulb. (2) The contraction of the gallbladder is regulated by the neuroregulatory mechanism which controls opening and closing of the sphincter. Postcholecystectomy syndromes may be associated with loss of these functions or may develop secondarily to a loss of the biochemical properties of the concentrated gallbladder bile

When the tension-regulating mechanism of the gallbladder which amounts to 150 to 200 mm of water is lost, the unchecked changes of bile pressure during active digestion may give rise to feelings of fullness, pressure, and cramplike pain resembling gallstone colic in the right upper quadrant of the abdomen The diameter of the lumen of the common bile duct is a factor in the production of these symptoms, for patients who have cholecystolithiasis without involvement of the common duct are much more likely to have symptoms than those patients who have had ampullar obstruction (Pribram) with dilatation of the common bile duct.

The postcholecystectomy syndromes which have been enumerated by Pribram are as follows (1) the pressure syndromes due to the missing tension-bulb function of the gallbladder and their secondary complications, cholangiohepatitis and pancreatitis, (2) the lowered tolerance for food, especially fatty food, due to the missing digestive aid of concentrated gallbladder bile and the hormone secreted from the wall of the gallbladder, (3) paralysis of the sphincter, leading to diarrhea and enteritis.

As a result of studies of the alteration of intraductal pressure after cholecystectomy, it has been agreed that the pressure may rise from 25 mm of mercury to 50 and 55 mm The influence of drugs on the changes of pressure in the common duct due to contraction of the sphincter has been studied by McGowan, Butsch and Walters and by Doubilet and Mulholland. It was observed that injections of morphine cause contraction of the sphincter followed by an increase of intraductal pressure from 150 to 200 mm. of water to 250 to 300 mm Antispasmodics like atropine cause the pressure to drop or at least prevent a rise in pressure after simultaneous administration of morphine. Inhalation of amyl nitrite produces a relaxation of the sphincter with an immediate drop of intraductal pressure Spasm of the sphincter does not cause pain The region of the sphincter [illegible]
duct
quie

entirely due to the *increased intraductal pressure* Among the complications related to the increased intraductal pressure and stasis of bile is *cholangiohepatitis*

Bile pressure and stasis of bile due to spastic conditions of the sphincter may increase after removal of the gallbladder, and cholangiohepatitis, not present before operation, may ensue Similar conditions prevail in the development of certain forms of *pancreatitis*

However, there are cases in which pancreatic conditions related to disease of the biliary tract disappear after cholecystectomy Reflux of bile into the pancreatic duct constitutes only one and probably not even a common cause in the pathogenesis of pancreatitis

The gallbladder concentrates bile, which increases its digestive aid It secretes a hormone-like substance (cholecysmon), a coenzyme which activates the fat-

The Nonfunctioning Gallbladder. The roentgenologic examination, when properly performed, may not reveal evidence of the presence of a gallbladder. If the gallbladder has not been surgically removed or has not been transposed through error in development to a place in the liver away from its usual situation, the absence of its shadow on the roentgenogram is significant The absence of the gallbladder on the roentgenogram is reported as a nonfunctioning gallbladder

A nonfunctioning gallbladder in a patient who has symptoms and findings of gallbladder disease usually contains calculi which are not radiopaque. The report of a nonfunctioning gallbladder is one of the most positive of radiologic findings.

The Primary Shadow. The gallbladder may cast a shadow on the roentgenogram without the administration of a radiopaque substance. Such a shadow has no particular diagnostic significance

Calculi in Dilated Stump of the Cystic Duct. After cholecystectomy the cystic duct may be dilated A pouch thus formed may vary from 1 to 2½ inches (2.5 to 6 4 cm) in length and may be of an average caliber of the little finger and contain stones within the dilated stump Peterson has recorded 42 such instances He considered the term re-formed gallbladder a misnomer and correctly concluded that the so-called re-formed gallbladder was the dilated stump of the cystic duct. In his experience the stump of the cystic duct assumed a shape like that of a normal gallbladder but, except in rare instances, was much smaller. It contained mucosa like that of the cystic duct with, in some cases, mucosa in the fundus suggestive of origin from the gallbladder. Its wall showed inflammatory signs Its lumen often contained stones. On histologic examination the excised structures were reported as showing chronic cholecystitis

Painful seizures which are either identical with or very similar to those experienced prior to cholecystectomy may occur Roentgenograms give positive evidence

Postcholecystectomy Syndromes. There is a group of clinical syndromes which with or without good reason have been attributed directly or indirectly to some missing functions of the gallbladder and which therefore have received the name postcholecystectomy syndromes

The relief of symptoms of biliary colic after cholecystectomy occurs in 9 of every 10 who have the operation if the diagnosis is correctly made, and proved by operation This statement is made with the assumption that the diagnostician and the surgeon are aware that aerophagia and, to a large extent, the so-called qualitative food distress often associated with gallbladder disease are not a part of the *syndrome of biliary colic* Aerophagia and qualitative food distress have as their origin psychoneurosis and not gallbladder disease.

Cholecystectomy performed for chronic cholecystitis without gallstones results in failure to obtain symptomatic relief in a number of patients Patients who have little or no relief of symptoms after cholecystectomy may have undergone operation because there was nonvisualization of the gallbladder on roentgenograms following the single-dose oral administration of the dye which may have been vomited A lesser number have been operated on because the gallbladder did not empty after a fatty meal Some of these patients are psychoneurotic individuals and removal of the gallbladder will not alleviate their discomforts

However, the 1 of every 10 who have had the gallbladder removed for gallstones and biliary colic who does not obtain relief will usually be found to have (1) calculi in the biliary duct, or common bile duct, (2) stricture of the common bile duct, (3) stones in remnants of the cystic duct or in remnants of the *gallbladder* [illegible] or (4) chronic cholangitis, which may [illegible] biliary colics and jaundice, and [illegible] the latter group of patients may have a chronic pancreatitis or pancreatic stones

It is emphasized that 9 of every 10 patients who undergo cholecvstectomy enjoy

stones are not present. Many of these gallbladders, however, contain stones which cause the symptoms for which the patients are submitted to surgical operation

The roentgenologic findings are not conclusive The diagnosis is made on opening the resected gallbladder.

Torsion of the Gallbladder. In rare instances the gallbladder is completely surrounded by peritoneum and has a mesentery-like attachment to the liver. In still rarer instances the gallbladder lies completely free except that it is attached to the liver through a pedicle composed of the cystic duct and its attendant structures. It is the pedicellate gallbladder which becomes twisted; torsion takes place. The condition is commonest in old women

The onset of symptoms is sudden The pain is constant and severe, and is like the severe pain of biliary colic Vomiting is present and sometimes is extreme Jaundice is variable but generally is absent. About 48 hours after the onset, there are fever, fast pulse and exhaustion, these may be the first indication of the seriousness of the disease in the aged patient

The abdominal wall is ordinarily rigid and there is distinct local tenderness over the region of the gallbladder There are no palpable masses

Tenderness over the gallbladder increases after about 48 hours The abdominal signs indicative of peritoneal irritation become more pronounced with increasing rigidity and more widespread involvement of the abdominal wall. The leukocyte count tends to increase and a pronounced leukocytosis may develop.

Diagnosis of torsion of the gallbladder cannot be made clinically. The usual preoperative diagnosis is cholecystitis

Torsion of the gallbladder requires immediate cholecystectomy. The prognosis is good

Tumors of the Gallbladder. Walters found *papillomas* in 8 per cent of the gallbladders which he removed. Small papillomas are often found in association with cholesterosis Large papillomas are rare. They may be pedunculated and all are benign

Adenomas are second in incidence to papillomas Adenomas occur singly and may be cystic, papillary or semisolid *Myomas, lipomas, myxomas* and *mixed types* have been occasionally reported *Fibromas* occur very rarely

Benign tumors are usually symptomless

The roentgenologist regularly diagnoses the papillomas correctly These tumors are not usually treated The other benign tumors are not diagnosable except by histologic study

Malignant Tumors. *Primary Carcinoma.* Primary carcinoma of the gallbladder is rare Often it is first discovered at necropsy It more commonly occurs in those who have gallstone disease

The relationship of carcinoma of the gallbladder to antecedent gallstones is not understood, for there is a very low incidence of carcinoma in the total number of patients who have cholelithiasis

The sex incidence shows a ratio of women to men averaging about 4.1. Women of 60 to 70 years of age may be affected, rarely men of these ages are affected.

Carcinoma is the common malignant tumor of the gallbladder Histologically there are adenocarcinomas and squamous cell carcinomas of the gallbladder. These tumors metastasize early to the regional lymph nodes and to the liver. The liver is the commonest seat of extensive secondary growth The colon, duodenum, stomach or jejunum may become involved by virtue of adhesion and subsequent extension of cancerous cells by contiguity Perforation of the carcinomatous gallbladder directly into these organs is common.

There is often a history of biliary colic which commences after the development of the cancer in those who do not have gallstone disease. In those who have gallstones too, a long history of biliary colic may be obtained.

Pain in the region of the gallbladder is more constantly present in carcinoma

splitting lipases. Concentrated bile with its salts is an important aid in the digestion of food. Bile salts activate digestive enzymes, form conjugated products with poorly soluble and therefore poorly absorbable substances, and help the latter to pass through the intestinal wall into the blood and lymph stream The bile salts act as catalysts both in the breaking down and in the absorption of foodstuffs. The gallbladder empties the highly efficient concentrated bile by active contraction in response to the stimulation of food during digestion and the formation of cholecystokinin in the intestines. The lack of these biochemical functions in cholecystectomized patients may well account for the observed *lowered tolerance for food,* especially fatty food.

With removal of the gallbladder the nervous plexuses of its serous and muscular wall also are removed These nervous plexuses control the opening and closing of the sphincter. The reflex of the sphincter after cholecystectomy may become uncontrolled or disorderly and dyskinetic disorders may ensue Dyskinetic disorders and spasm may not have been present before operation, but after cholecystectomy they may greatly aggravate the pressure syndromes

Spastic contraction of the sphincter following cholecystectomy occurs in only a few patients In others a pronounced atony or even a complete paralysis follows the removal of all of the nervous plexuses when cholecystectomy is performed Judd and Mann, in measuring the intraductal pressure after cholecystectomy, recorded in some instances, following an initial rise, a gradual diminution of pressure to zero, indicating the development of total paralysis of the sphincter This means a continuous drainage of bile into the duodenum instead of the rhythmic and interrupted emptying regulated by a functioning sphincter and related to the contraction of the gallbladder Continuous drainage of bile into the duodenum, particularly when the patient is in a fasting state, may be followed by diarrhea. Such diarrhea may be due to the purgative effect of the excess of bile salts pouring continuously into the duodenum

It is well to mention that postcholecystectomy syndromes occur commonly in young women who have a pronounced irritability of the digestive apparatus, hyperacidity and constipation There is a low incidence of postcholecystectomy syndromes when the patient really needs to have the gallbladder removed. There is low incidence of postcholecystectomy syndromes in complicated cases, and relatively high incidence in cases in which cholecystectomy has been performed in the presence of a mildly diseased and still somewhat functioning gallbladder.

Examination There are no findings either on physical examination or on roentgenologic studies which are characteristic of a postcholecystectomy syndrome

Diagnosis The diagnosis can be established only by time and observation and the exclusion of all other possible organic diseases. Many of these patients have all of their digestive complaints labeled by the surgeon, after the gallbladder has been removed, as being of neurotic origin Diets low in fat content with small meals and weight reductions if overweight may be helpful in improvement of the general health The asthenic, sitophobic patients may be helped by encouraging them to eat regularly and to partake of sufficient amounts of food to improve the general health

Milk of Calcium Bile. Milk of calcium bile (limy bile) is a rare condition due to deposition of lime salts within the gallbladder The symptoms are the same as those produced by gallstones Roentgenologic study is diagnostic The treatment is cholecystectomy.

Cholesterosis of the Gallbladder. Strawberry gallbladder is a term chosen by MacCarty to describe the gross appearance of the mucosa in advanced cholesterosis or lipoid gallbladder. Strawberry gallbladder is much commoner in women than in men

There are no definite symptoms caused by cholesterosis of the gallbladder if

A biliary obstruction in association with choledocholithiasis often initiates cholangitis. Suppurative cholangitis is but a further stage of cholangitis and seldom can be diagnosed prior to death

Acute cholangitis and suppurative cholangitis are suspected but not diagnosed if recovery ensues If death follows, a diagnosis is made at necropsy.

Chronic Cholangitis. The term cholangitis lenta describes a type of chronic infective nonsuppurative cholangitis which involves the intrahepatic bile channels, is due to infection with the streptococcus (usually a viridans strain), and often is associated with, or actually causes, endocarditis. Chronic low-grade icterus and swelling of the liver and spleen together with intermittent fever are present in association with the bacterial endocarditis.

The prognosis is bad even if antibiotics are correctly used.

Choledocholithiasis. Judd and Marshall recorded 5.5 per cent of gallstone disease restricted to the common duct. In 25 per cent of all cases of gallstone disease there are stones in the common duct. A ductal origin of calculi can occur but it must be rare as compared to origin in the gallbladder. The presence of the calculi in the ducts is more correctly explained as due to a migration of calculi from the gallbladder.

In about 4 of every 5 patients who have choledocholithiasis the gallbladder is diseased, and often it is fibrotic and functionless (Walters and Snell). Hepatic damage is a frequent concomitant, slight to moderate damage is mentioned in about two thirds and marked structural hepatic changes in about one third of the reported cases of obstructive jaundice caused by stones in the common duct (Snell). Chronic inflammatory changes with fibrosis are to be seen in the pancreas in about 25 per cent of persons who have choledocholithiasis. Pylephlebitis and thrombosis of the portal vein are encountered rarely The age and sex incidence are the same as for stones in the gallbladder.

Stones present in the common bile duct have passed into the duct from the gallbladder and have entered it through the cystic duct. The manifestations of stones in the common duct are the same whether the gallbladder has or has not been removed In Weir's experience with common duct stones the asymptomatic period following removal of the gallbladder averaged 3 years and 8 months. Often there is a feeling of epigastric distention and pain. In one half to two thirds of patients suffering from common duct stone the pain is referred to the back. In an occasional

the common duct, chills and fever rarely occur in the latter if jaundice is present However, a stone in the common bile duct in the presence of a hepatitis may be associated with recurrent chills and fever, generalized aches and pains, progressive anemia, jaundice and enlargement of the liver In these patients the manifestations due to a stone in the common duct are very much the same as those of chronic cholangitis.

A stone present in the common duct without jaundice is termed a silent stone.

The liver is often palpable and tender. If obstructive biliary cirrhosis, as the result of long-standing jaundice, is present, the spleen is enlarged and palpable, and in a few who have palpable spleens there will be ascites During and for a short time after an attack of colic there is tenderness in the right upper quadrant of the abdomen. In rare instances the gallbladder will be palpable if it has not been removed.

A diagnosis is based on the findings at operation, a stone in the common bile duct or stone in the extrahepatic ducts, with removal of the calculus

of the gallbladder than in biliary colic. The pain is often followed by jaundice, loss of body weight, vomiting, anorexia and weakness.

In about three fourths of all of those who have cancer of the gallbladder examination reveals a palpable, hard, tender tumor which seems to be a part of the liver Jaundice usually is continuous, although intermittent jaundice may occur. The jaundice results from obstruction of the common duct Fever is present sometime during the course of the illness Ascites is often a late development

The diagnosis is not established prior to operation or necropsy.

Primary Sarcoma Primary sarcoma in the gallbladder is extremely rare Clinically there are no features which serve to distinguish between sarcoma and carcinoma of the gallbladder However, sarcoma may occur in younger patients than carcinoma

DISEASES OF THE BILE DUCTS

Anomalies and Abnormalities of the Common Bile Duct. The main portion of the hepatic diverticulum elongates into the ductus choledochus and hepatic ducts Bile ducts within the liver arise secondarily, beginning in the embryo at 8 weeks The main ducts are subject to agenesis, duplication and sacculation.

The common bile duct may open into the stomach near the pylorus, or join the duodenum independently of the pancreatic duct The common bile duct may be duplicated, so that two separate ducts enter the duodenum or one branch may enter the duodenum and the other enter the stomach

The bile duct may be dilated, and associated with a choledochus cyst Often choledochus cysts are associated with partial or complete obstruction of the common duct These cysts are retroperitoneal, either ventral or dorsal to the duodenum They are usually small, but may reach a capacity of several liters. The gallbladder is of normal size or smaller than normal

Agenesis is a rare abnormality of the common duct In agenesis the duct or ducts may be absent or may be represented by a fibrous cord Frequently icterus is present at birth or it appears within 48 hours Eventually, about the second month, a diagnosis of obstructive jaundice is made

The cystic duct may join the hepatic duct in devious ways For instance, it may join the hepatic duct at an angle, run parallel with the hepatic duct and be enclosed in the same sheath before joining it, or it may seem to circle around the duct

Cholangitis (Catarrhal Jaundice) Bacterial inflammations of the biliary passages are secondary to disease of the gallbladder, liver, pancreas or adjacent structures Inflammations of these structures are either acute or chronic. They often produce a truly catarrhal

If there is an appearar

swelling and tenderness of

of any disease of the biliary passages, gallbladder, liver or pancreas, cholangitis is suspected as the cause

Viral infections are responsible for the occurrence of epidemic hepatitis, which is unrelated to the catarrhal jaundice enumerated here The presence of bacteria in the biliary passages has no pathogenic significance and usually does not give rise to disease of the biliary tract Infectious cholangitis may be either enterogenous or hematogenous in origin In cholangitis of the enterogenous type, the organisms most frequently recovered are *Escherichia coli, Salmonella typhosa* and *Salmonella paratyphi*

In hematogenous cholangitis the commonest causative organisms are those which often are present in septicemia, for instance, *Streptococcus viridans, Streptococcus hemolyticus, Staphylococcus aureus,* pneumococci, Friedlander's bacilli and influenza bacilli The commoner acute infections accounting for these organisms are tonsillitis, appendicitis, pneumonia, diphtheria and typhoid fever For these acute infections to be of etiologic significance the cholangitis must occur during the active infection or immediately thereafter.

stricture. The onset of obstructive jaundice due to stricture occurring late after operation is insidious. There are fever, jaundice, and often enlargement of the liver and the spleen.

The diagnostic procedures are the same as those employed in diagnosis of stones in the common duct However, the diagnosis is never certain until proved by surgical exploration

Strictures at the Ampulla of Vater. Obstructions and strictures of the common bile duct at the ampulla or the sphincter of Oddi are usually attributed to stone or spasm, but may be due to fibrosis at the papilla Fibrosis of the bile duct at or near the sphincter of Oddi appears to be a disease mainly of patients from 50 to 70 years of age. The characteristic manifestation is an obstructive type of jaundice, the cause of which, prior to operation or necropsy, is not recognizable or distinguishable from any other cause of an obstructive jaundice.

Biliary Fistulas. Biliary fistulas usually are complications of gallstone disease or of surgical operation for gallstones Less frequently there is empyema of the gallbladder with formation and drainage of abscess All biliary fistulas are rare, but spontaneous external fistulas and postoperative internal biliary fistulas are very rare.

The persistence of an external biliary fistula after operation is manifested by persistence of acholic stools after the tube inserted in the ducts by the surgeon for the drainage of bile, has been clamped prior to its removal or by persistence of copious drainage of bile from the sinus tract after removal of the tube for bile drainage Cholangiography performed before the removal of the drainage tube enables detection of the cause for persistence of acholic stools or the loss of large amounts of bile externally and the situation of fistulas if they are present.

Balfour and Ross pointed out that the commonest cause of external biliary fistula is incomplete surgical intervention or injury to the biliary tract at the time of operation

Under normal conditions, after the removal of a drainage tube from the common duct, bile flow should cease within 10 days

In most instances an external fistula of the gallbladder which is draining mucus is due to obstruction to the cystic duct by a stone or by chronic inflammation This condition is easily recognized and is completely remedied by cholecystectomy.

After cholecystostomy, if there is continued drainage of bile from the gallbladder and if little or no bile enters the intestinal tract, a stone usually is present in the common duct However, malignant lesions obstructing the terminal bile duct may be present.

Practically all of the bile secreted may be drained off for a long period without the development of a serious deficiency state In infection of the biliary tract and secondary hepatitis, nutritional deficiencies develop more rapidly because of a lack of the action of bile in digestive processes In these patients there may be an associated osteoporosis, avitaminosis, electrolyte imbalance, and disturbances in water and salt metabolism.

[illegible] *ulas* are biliary-duodenal,

[illegible] oduodenal, is found as a sequela of acute cholecystitis with empyema, involving the gallbladder containing stones A less common cause for [illegible]

[illegible]

The sequence of symptoms of choledochoduodenal fistulas is obstructive jaundice, with the disappearance of the jaundice after a severe attack of pain. The presence of a choledochoduodenal fistula in a patient who has not had antecedent jaundice should suggest the possibility of a primary duodenal lesion

Rapid loss of weight, chills, fever, and severe diarrhea are often present in

After cholecystectomy for cholelithiasis, recurring colics and jaundice are strong evidence for a stone in the common duct. A persistent biliary fistula following drainage of the gallbladder for stones is good enough evidence for a presumptive diagnosis of stone in the common duct.

Plain roentgenograms of the right upper quadrant of the abdomen may reveal calculi in 1 in every 7 cases. In cholecystectomized patients the frequency with which opaque calculi in the region of the ducts are disclosed by a plain roentgenogram is small

Treatment of common duct stone is surgical removal.

Rupture of Bile Ducts. Infection after surgical operation or infection alone or infection associated with the reflux of activated pancreatic juice in the absence of stone may cause rupture of the common bile or hepatic ducts. Rupture of bile ducts may also result from a blow to the abdomen or from a puncture wound

During the immediate postoperative period after operation on the biliary tract, perforation of the bile duct may be suspected if bile appears around the external drain The occurrence of spontaneous rupture of the bile ducts late after operation may not be recognized.

The symptoms of rupture of a bile duct or ducts may resemble those of an acute freely perforated peptic ulcer

Stricture of the Common Bile Duct. Cicatricial stricture of the common bile duct occurs as the result of gallstone disease and from a benign fibrotic process of unknown origin The stricture occurring as the result of gallstone disease is primarily traumatic or inflammatory in origin Traumatic strictures occasionally but rarely follow surgical injury to the common bile duct

Stricture of the bile ducts in the absence of gallstone disease or operative trauma occurs. Stricture of this type appears well away from the sites liable to direct surgical trauma, which lends credence to the belief that these strictures often occur primarily and independently of surgical trauma

The symptoms of primary acquired inflammatory stricture of the common bile duct may be indistinguishable from those of tumor of the main bile duct or the head of the pancreas. The incidence of carcinoma of the pancreas which causes obstruction and jaundice is much greater than that of cicatricial stricture of the common duct. This increased incidence of carcinoma of the pancreas over that of carcinoma of the common bile duct is diagnostically helpful when obstructive jaundice is present in the absence of calculi.

The conditions which predispose the common bile duct to stricture following surgical intervention are anomalies in the origin and course of the cystic artery, such as a long cystic artery coursing parallel to the common bile duct or an abnormally short cystic duct Probably a commoner cause for accident during surgical operations is obliteration of anatomic landmarks, interfering with identification and exposure of the ducts during operation (Walters)

Jaundice is the characteristic manifestation of postoperative occlusion of the common bile duct. If complete occlusion of the common duct occurs at the time of cholecystectomy, jaundice occurs within 12 to 48 hours If jaundice does not appear until several days after operation and is associated with a fever, there is an infection from leakage of bile from an injured duct, or soiling from an acutely inflamed gallbladder, or a stone remaining in the common duct Spastic closure of the papilla of Vater is rare, but when it is responsible the jaundice clears within a few days to a [illegible] and progres-

[illegible] t be mani-

[illegible] truction of

[illegible] biliary ducts occurring later than 6 months after operation on the biliary tract is rarely due to stricture unless more than one operation has been performed for

purative cholangitis develop Pericholangitic fibrosis and changes characteristic of obstructive biliary cirrhosis have been described

The commonest sites of metastatic spread are the liver, regional lymph nodes, pancreas and lungs.

The onset is usually insidious, with jaundice. Progressive obstructive jaundice and loss of body weight are the usual manifestations There may be present pain, pruritus, anorexia, fever, vomiting, dyspepsia and constipation or diarrhea

A preoperative diagnosis of a tumor of a biliary passage is not essential. Mechanical obstruction of the main bile duct requires surgical operation. The diagnosis is established by biopsy at the time of operation

FUNCTIONAL DISORDERS OF DIGESTION

A functional disorder of digestion implies a physiologic disturbance not due to any known primary structural changes. There is no general agreement on this concept, however, since the scope and limitations of functional disturbances cannot be defined and, more particularly, since often a clinical distinction between what is functional and what is structural cannot be made

Disturbances of function occurring in association with or subsequent to proved organic diseases of the gastrointestinal, respiratory, circulatory, generative and urinary systems, or in conjunction with diseases of the brain and spinal cord, or in relation to various systemic infections, intoxications, and deficiency states, are not regarded as functional in nature unless such symptoms existed prior to the onset of the organic disease Physiologic disturbances which occur in relation to causes such as endocrine and metabolic disturbances are likewise not diagnosed as functional disorders

In a description of functional disorders of digestion it is necessary to consider the influence of the following conditions on digestion (1) heredity, (2) changes in the autonomic nervous system; (3) emotional conflicts; (4) personality, (5) anxiety, (6) hormones; (7) convalescent states from infections or other illnesses, physical fatigue, and infections, (8) the allergic state; (9) nonallergic foods; (10) laxatives, (11) motor disturbances; (12) the coexistence of gastrointestinal disease and psychoneurosis, (13) achlorhydria, (14) gastroenterostomy; (15) fecal impaction and (16) sprue (tropical and nontropical)

Heredity A *hereditary* tendency may be of significance. A full genealogic history may reveal a high incidence of similar digestive dysfunctions

Autonomic Nerves The terms vagotonia and sympathicotonia designate autonomic nerve imbalance Such oversimplicity in explanation of disease of the autonomic nervous system in relation to digestion has not proved to be of value in either diagnosis or treatment of disorders of the autonomic nervous system or of the digestive system

The intrinsic nerve structures of the intestines comprise the myenteric plexuses of Auerbach and the submucous plexus of Meissner, which are influenced by the two major divisions of the autonomic nervous system For instance, hypertonicity and increased peristalsis and spasticity of the sphincters follow increased vagal activity

Pain may originate in the gastrointestinal tract as a result of either overdilatation or overcontraction of hollow viscera, and from stretching of the capsules of the solid organs

Emotional Conflicts. In the evaluation and thus the diagnosis of digestive disease brought about by emotional conflicts or abnormal psychic tensions, it is well to recall that the principal relay station for emotional components of disease appears to be the diencephalon It is responsible for the correlation of psychic and somatic disorders. and it has a regulating influence on both of the major divisions of the

cholecystocolonic fistula. The patient has had symptoms of disease of the biliary tract, in which a more lasting severe attack is associated for the first time with diarrhea. Immediately following the onset of the diarrhea there is disappearance of the jaundice. Cholecystocolonic fistula often can be diagnosed by means of roentgenologic studies of the colon

Biliary-gastric fistula is commonly due to gallstone disease.

Bronchobiliary fistula is rare but develops as a complication of gallstones, echinococcus disease, and amebic abscesses of the liver or liver abscesses as a result of external trauma. The establishment of a bronchobiliary fistula commences with an acute exacerbation of chronic disease of the biliary tract or hepatic disease followed by an irritating cough with embarrassment to respiration. If these symptoms are followed by the expectoration of large amounts of bile, the diagnosis is established The usual physical signs characteristic of minimal basal pneumonitis, atelectasis or diaphragmatic pleurisy may be present

Roentgenologic examination may be diagnostic in all *internal fistulas* which communicate with the alimentary canal

The prognosis is usually poor in all types of biliary fistulas. It is good in those readily amenable to surgical resection and repair.

Functional Disorders of Bile Flow. Various terms have been used to describe functional disorders of bile flow They [illegible]
atonic dyskinesia, spastic and atonic d[illegible]
tonica, postcholecystectomy syndrome [illegible]

Biliary dyssynergia capable of causing symptoms occurs in patients who have had severe gallbladder disease or who have undergone surgical operation on the biliary tract

Often adequate roentgenologic survey of the biliary tract will disclose causes other than dyssynergia to explain the complaints Pains in the hepatic region occurring in association with gastrointestinal neuroses or profound derangements of the autonomic nervous system are not due to biliary dyssynergia

Tumors of the Bile Ducts. In the experience of Walters and Snell benign tumors of the bile ducts have little clinical importance They are exceedingly rare and are usually so small that they do not give rise to symptoms

Adenomas make up the greatest number of benign tumors, and many of these are described as papillomas Other rare benign tumors of the bile ducts include lipoma, fibroma, adenomyofibroma, neuroma and carcinoid tumor

Benign tumors of the bile ducts are rarely suspected clinically They are discovered either at surgical operation or roentgenologically. Symptoms, if present, simulate those of obstructive jaundice of other origins If colic, fever and jaundice are present, calculi are usually suspected.

Primary Malignant Tumors of the Extrahepatic Bile Ducts. Primary malignant tumors of the extrahepatic bile ducts are somewhat commoner than are benign tumors of these ducts These malignant growths occur oftenest in men between 50 and 70 years of age. They are not related to gallstone disease The most frequent sites are the common duct and the junction of the cystic and common hepatic ducts. There are three anatomic varieties, villous, nodular and diffuse The villous type is rare

According to Judd and Gray, the grade of malignancy in two thirds of cases observed by them was 3 or higher (Broders' classification on a basis of 1 to 4, in which 1 represents the lowest, and 4 the highest grade) [illegible] empyema [illegible] the duct [illegible] become enlarged and may be the seat of advanced hydrohepatosis Atrophy and necrosis may be noted in the hepatic lobules, usually confined to the central zones R[illegible]

goiter accounts for a very small number of instances in which there are symptoms of colonic neurosis

A low metabolic rate has been frequently observed in instances of functional digestive disorders of the colon. However, low metabolic rates (—10 to —20 per cent) are common in many who have various sorts of psychoneuroses without digestive complaints

Vitamin deprivations cause intestinal disorders.

Convalescent States, Physical Fatigue and Infections. Derangements of digestion simulating functional disorders may follow serious or inconsequential *bacterial and viral infections* and other irritants acting within the alimentary tract, or generalized infections such as those of the upper part of the respiratory tract

Infections within the alimentary tract may cause chronic diarrhea. It may be difficult bacteriologically to identify certain bacteria such as streptococci or *Clostridium perfringens* as the causative agents However, at times these may originate a chronic diarrhea Bacillary dysentery is an acute infectious disease of the intestines, but this infection may linger and cause a chronic diarrhea of several months' duration *Salmonella typhosa, Salmonella paratyphi, Salmonella schottmuelleri, Salmonella hirschfeldii, Salmonella typhimurium, Salmonella gallinarum* and *Salmonella pullorum* all may cause prolonged diarrheas. In some instances a gonorrheal proctitis may cause frequent bowel evacuations

Lymphopathia venereum infections often produce strictures of the rectum, and such strictures while ulcerated and secondarily infected may cause frequent emptying of the bowel Ordinarily lymphopathia venereum infections are associated with stricturing, constipation or obstipation

Tuberculosis of the intestine is a common bacterial infection associated with a chronic diarrhea

Syphilitic infections of the intestines are difficult to delineate, and certainly a chronic diarrhea cannot be attributed to syphilis.

Intestinal actinomycetes may infect the intestines and cause chronic diarrhea which may resemble that of tuberculosis Intestinal nocardiosis is less common The fungi imperfecti, except for *Candida albicans*, rarely originate disease *Candida albicans* is found in quantity in the stools of patients who have chronic diarrhea due to such causes as sprue and pernicious anemia. It would be difficult to prove that fungi imperfecti cause chronic diarrhea.

Histoplasma capsulatum may infect the intestine causing a chronic diarrhea resembling that observed in patients who have tuberculosis or actinomycotic infections

The protozoan parasites, *Endamoeba histolytica,* and the flagellates *Giardia lamblia, Trichomonas hominis* and *Chilomastix mesnili* may be associated with chronic diarrhea However, it is not diagnostically safe to assign any of these organisms for the cause of a chronic diarrhea except *Endamoeba histolytica* The infusorian, *Balantidium coli,* causes a serious acute colitis when the bowel becomes obstructed It is not a cause of chronic diarrhea

Infection with *Leishmania donovani* may be complicated by chronic diarrhea.

Helminthes usually do not cause diarrhea

The so-called special methods of isolating a particular intestinal bacterium and then testing the skin for hypersensitivity to this bacterium or its products, and the therapeutic results obtained by the treatment of intestinal disease by means of vaccines or the removal of foci of infection, are scientifically dubious procedures.

Physical fatigue and exposure to cold may be important causes of functional digestive attacks Weakness following long febrile illnesses or infections of the upper part of the respiratory tract may aggravate or initiate the symptoms of alimentary neuromuscular instability. A painful abdominal crisis may leave as an aftermath the irritable colon syndrome

autonomic nervous system which also centers there. The diencephalon also has direct influence on most of the endocrine glands, on metabolism as well as on all homeostasis. The diencephalon receives impulses from and sends impulses to the cerebral cortex In primary somatic disease the diencephalon receives abnormal impulses and registers them in the viscera, especially in the abdomen. Disorders in which there is either a lack or an increase of normal and abnormal constituents of the blood may affect the center directly or centripetally via the autonomic nervous system In states of emotional conflict and abnormal tension the diencephalon may be influenced from the cerebral cortex and then set up impulses *responsible for secondary changes in function* and even in structure of the viscera A consideration of these factors requires as criteria for diagnosis first, the absence of any primary physical or chemical changes, and, second, the finding of satisfactory psychologic causes to account for the clinical manifestations

In those who have functional gastrointestinal disturbances due to psychologic causes, there is a change of affect and this is termed the subjective phase There are often disturbances of the special senses such as sensations of appetite, hunger and pain The objective phase, due to psychologic disorders of digestion, includes disturbances in the neuromuscular, autonomovisceral, and secretory functions These disturbances are termed objective because they can be observed clinically

Personality. Changes in the affect are related to the personality of the patient In order to identify these disorders and to treat them satisfactorily, the physician is asked to have a basic concept of the structure of personality, types of personality, and the various types of reaction in relation to disease processes

The several personality reaction types include (1) the *organic reaction* types, such as occur in association with structural diseases of the brain due to vascular and degenerative changes, neoplasms, infections, intoxications and deficiency states—*these reactions are predominated by intellectual disturbances; (2) the affective reaction* type, which consists of hypomania and involutional melancholia; (3) the *schizophrenic reaction* type, which consists of the many bizarre modes of thinking, feeling and acting observed in schizophrenia. The most important reaction type in this discussion is the *psychoneurotic*.

Anxiety This is the central symptom presented by the patient in nearly all neuroses and psychoneuroses Anxiety may be defined as one of the clinically important major emotions recognized introspectively as an unpleasant feeling, accompanied by fear without any, or without adequate, cause It is manifested objectively by abnormal changes in the neuromuscular and secretory functions which are emotional expressions All psychoneurotic symptoms are derived from anxiety arising in the conscious or unconscious parts of the personality These symptom complexes include either definite anxiety or conversions and substitutions for anxiety reflected in *disturbances in the physiologic or emotional spheres*. Anxiety gives rise to hostility which, in turn, generates more anxiety. Indeed, certain patients seem to have the ability to create anxiety in the family and finally in the physician Once this has been done, neither the physician nor the patient may realize that hostility toward each other is the prevailing mode The existence of both anxiety and hostility helps to explain the reasons why the neurotic patient is driven imperatively toward *dominating* everyone, toward complying with others but at the same time imposing his will on them, toward detachment from people but at the same time toward a craving for their affection These conflicts may be the dynamic center of the neuroses and the *physician-patient relationship. They are often the bases for* iatric disorders

Hormones. The *hormones* of the *endocrine glands* are not essential to the function of the alimentary tract In the case of the pituitary it is well known that hypophysectomy does not cause any well-defined change in digestive functions.

Hyperthyroidism may be associated with gastrointestinal hypermotility causing diarrhea and symptoms resembling those due to an irritable colon. *However*, toxic

The administration of mercury is a cause for chronic diarrhea in certain instances of poisoning by this agent Arsenic likewise may give diarrhea. Lead, on the contrary, causes chronic constipation

Motor disturbances as a result of a psychoneurosis consist of pyloroduodenal irritability, hyperperistalsis, hypertonicity and hypermotility or hypomotility. A duodenal ulcer-like syndrome may alternate with or accompany the irritable colon symptoms in many psychoneurotic persons It is well to be aware that there is a generalized derangement of motility of the alimentary tract in those who have irritable colon syndrome Disturbances in the motor behavior of the small intestine may be the main manifestations in some instances of the irritable colon syndrome. In these disturbances of the small intestine the roentgenologist may report that the barium meal arrives in the colon in from one-half hour to 4 hours after its ingestion. It seems that the main seat of the dysfunction is in the small intestine

The *coexistence of organic gastrointestinal disease and psychoneurotic symptoms* requires evaluation of the degree of each which is present The evaluation of the etiologic relationship between symptoms is often difficult even after extensive investigation. The presence of an organic lesion may not be discovered Likewise it may be impossible to find an adequate psychogenic cause for the presenting symptoms

It is the consensus that the symptoms of digestive, or any other, psychoneuroses and neuroses imply the absence of any primary structural or chemical disease, the existence of a certain constitutional make-up, the occurrence of precipitating or exciting causes, and the formation of symptoms which may originate in the psychic or in the physiologic sphere or in both The symptom may begin synchronously with the action of some exciting cause which may be an injury, an infection, a chemical disturbance, or some emotional stress

Achlorhydria once was thought to occupy a prominent place in the production of chronic diarrhea At times and under conditions which cannot be elaborated, this may be the cause of loose bowel movements It is well to realize that achlorhydria rarely is accompanied by frequent bowel movements

Chronic diarrhea may follow *gastroenterostomy* This type of diarrhea may be attributed to rapid emptying of the stomach, to gastrojejunitis, or to gastrocolic fistula Occasionally a gastrojejunostomy, a gastroileostomy or an entero-enterostomy between widely separated segments of the intestines may cause diarrhea The continuous elimination of dejecta from an ileac stoma is not considered a diarrhea A diarrhea from an ileac stoma is manifested by a greatly increased volume of dejecta Likewise a diarrhea from a colic stoma is manifested by an increased volume of dejecta

In aged individuals and in those who have congenital megacolons, *fecal impaction* may occur, but a channel is left open through the impaction and chronic diarrhea characterized by the frequent passage of small amounts of feces occurs

Similar mechanical conditions may be produced in the colon by diverticulitis, colonic polyps, factitial sigmoiditis and malignant lesions

Sprue Both tropical and nontropical forms are characterized by frequent bowel movements In these disorders the volume of the feces is increased and it contains increased quantities of fat

The Irritable Colon Syndrome. The terms irritable colon and unstable colon are used to embrace all of the manifestations of the colonic neuroses. The disturbances of the *motor activity* of the colon are the commonest. The *mixed neuroses* are next in frequency. The *secretory neuroses* occur the least frequently.

In the irritable colon syndrome there is present a colonic dysfunction in asso-

complaints

be present

[illegible]ng laxatives

and colonic irrigations are poorly tolerated

Allergic State. Allergy and the *allergic reaction* or allergic digestive symptoms may occur in any person who has been endowed through heredity with the allergic state. In such a person the oral ingestion of specific antigens or antigenic substances may induce allergic symptoms. These symptoms are the manifestations of intestinal hyperemia, edema and increased mucus secretion occurring during the allergic manifestations Since allergic manifestations may be localized or generalized through the alimentary tube the symptoms may be localized or generalized digestive manifestations which simulate functional disorders.

The localized symptoms of digestive allergies perhaps occur more frequently in the colon than elsewhere in the alimentary tract. An allergy may contribute to or entirely account for the so-called irritable colon syndrome in an insignificant number of patients who have this disorder. Colonic dysfunction of allergic origin is more often manifested as isolated attacks of diarrhea and abdominal pain than as severe episodes of abdominal pain associated with vomiting and diarrhea and accompanied by systemic symptoms and signs of shock.

In order to attribute gastrointestinal symptoms to allergy, the first diagnostic requirement is the presence of the allergic state. There should be a genealogic history of allergy There should be a history of definite reactions to the eating of certain foods, drinking certain beverages, or taking certain drugs, or a reactivity to certain extraneous substances In the absence of known reactions to such substances, the presence of hay fever or asthma may be confirmatory evidence. In all instances there should be a periodicity of the symptoms like that present in hay fever and asthma The attacks of abdominal pain or diarrhea should be partially or totally relieved by the administration of epinephrine (0 5 ml. of 1 to 1,000 solution) The presence of an eosinophilia during the attack is important diagnostically.

The ability to relieve symptoms of abdominal pain, diarrhea, and mucus discharge by the withdrawal of foods to which patients seem to be sensitive and the subsequent reappearance of symptoms following the ingestion of those foods are diagnostically helpful, but time and repetition of this sort of diagnostic tests are necessary before a definite diagnosis of an intestinal allergy can be made A psychic colonic disorder will often respond well to the withdrawal of certain foods for short intervals

Nonallergic Foods The ingestion of *various foods* by patients who have a gastrointestinal neurosis may be responsible for the aggravation of symptoms and perhaps, less frequently, for their initiation. Roughage is poorly tolerated by the patient who has an unstable digestion If fibrous foods are ingested, they often aggravate the symptoms In susceptible subjects, the taking of ice-cold or hot food and drink may initiate diarrhea and abdominal pain

Laxatives. The continuous use of *laxatives, enemas* and *irrigations of the colon* for the relief of constipation may cause symptoms similar to those of a colonic neurosis In some instances laxatives or enemas have been administered by charlatans for the relief of auto-intoxication, headaches, constipation, abdominal pain and discomfort, and gaseous dyspepsia These symptoms will cease on discontinuation of the cathartics if a colonic neurosis is not present prior to the employment of intestinal irritants In reality, laxatives and enemas do not contribute to the presence of colonic neurosis and they are not important *etiologically. They* act to stimulate the intestines, and a continuous stimulation will serve to annul the normal colonic reflexes for defecation. If a psychoneurosis is not present, the intestinal symptoms immediately cease on the discontinuance of the use of laxatives and enemas

A common cause of loose bowels is the self-prescription and administration [illegible] cathartics. It is well to inquire in regard to prescribed [illegible] history is being taken in an instance of chronic diarrhea.

Man, possessing an alimentary volume midway between these two animals and eating a sufficient amount of food for maintenance, invalidates the general statement concerning the influence of dietary factors on the development of constipation.

The important cause for constipation is *improper training and neglect* in very early childhood When a child is trained to have bowel movements at a specified time or simply is left alone, there will be no constipation In later life if an individual does not have time for bowel movements and to allow the bowels to act normally, the physician cannot be of any help to him

The lack of *adequate facilities* may be given as the reason for the frequent *neglect to move the bowels after fecal matter has entered the rectum and initiated the* desire to defecate Usually this sensation soon passes off although the fecal matter remains in the rectum It is not until a fresh increment of feces further distends the rectum that the desire to defecate recurs. After a time, because of the constant residence of feces in the rectum, the defecation sense may be blunted and finally may disappear entirely. If toilets are not available, patients may be advised to provide themselves with suitable vessels which can be emptied later.

In the minds of many people there is the idea that a weekly cleaning out by a strong purge is beneficial to the body economy. This practice goes back many centuries and will continue for many more centuries, and its detrimental effects have not been proved It may destroy normal bowel habit

Constipation occurs in persons of all ages who do not or are not allowed to leave the act of defecation to normal controls. Constipation produces no other subjective complaint or objective evidence of disease In cases of simple constipation symptoms are rare except in hypersensitive subjects. Constipation as a symptom of organic disease or of fecal impaction is accompanied by various discomforts depending on the nature of the disease or the cause of the impaction

The history of the manner of onset of constipation will often serve to indicate its

digital, endoscopic and roentgenographic examinations of the anus, rectum and colon

Examination On general examination there is no evidence of loss of weight unless anorexia or sitophobia, functional vomiting, or diarrhea is present There are often found (1) cold, moist hands and feet, (2) dry mouth and lips, (3) variable pulse rate, (4) variable blood pressure, (5) tenseness, (6) tender abdomen and (7) hyperactive tendon reflexes.

Diagnosis A consideration of the possible presence of a functional disorder of digestion to account for digestive symptoms is required in most of those who have symptoms of abnormal digestion The findings on roentgenologic and roentgenographic examinations are the most helpful evidence in addition to the presence of a particular type of temperament and the findings on physical examination In cases of chronic diarrhea the following examinations should be executed in the order given here, the results of examination should be negative. (1) feces for ova and parasites (three examinations on successive days of liquid stools obtained by the administration of 1 ounce of epsom salts to the fasting patient); (2) proctosigmoidoscopic examination; (3) roentgenographic examinations of the stomach, colon and also occasionally the small intestines, (4) composition of the gastric contents (presence of hydrochloric acid); (5) basal metabolic determinations if the presence of hyperthyroidism is suspected, and (6) examination of the blood and urine for evidences of poisoning by certain chemicals such as arsenic and mercury and the presence or absence of leukocytosis and anemia.

In many instances a period of observation is required before a diagnosis can be made

In various places in the medical literature statements will be found that the irritable colon syndrome, including both diarrhea and constipation, is due to the tensions of present-day civilization There are no data to prove that psychic diarrheas and constipation are any more prevalent in modern civilized men and women than they were or are in savages. During the seasons of fresh berries and other fruits most savages have diarrhea When food supplies are scarce, the savages probably are constipated. So far as psychic tension is concerned, the savage, racked by fear of his enemies, torn between the exigencies of strife for his personal existence and the signs and implications of the presence of demons, spirits and gods ready to bring disaster on him, had and has more to be tense about than the present-day civilized men and women.

The shape of the formed stools is frequently displeasing to the patient who has irritable colon The passage of small, hard pellets or scybala may precede or follow an episode of abdominal discomfort Often there are present diarrhea or constipation

Diarrhea. The *history* will often separate a chronic diarrhea due to organic disease from one due to irritable colon In a patient who has organic disease the symptoms will have a definite onset. Often there will be, or will have been, present fever, bloody dysentery, loss of weight, and symptoms which disturb sleep The history in a diarrhea of psychogenic origin will reveal a constancy of symptoms dating indefinitely. There will be no disturbance of sleep from the diarrhea and no loss of weight without the presence of sitophobia Rectal bleeding will be absent unless there is an anal fissure or hemorrhoids.

Mucous colitis is the clinical manifestation of a functional colonic derangement characterized by the discharge of excessive quantities of mucus in the stools in the absence of demonstrable colonic disease

Constipation. Constipation may be defined as an abnormal retention of fecal matter in the intestinal canal or an undue delay in the discharge of excreta from the rectum. Constipation may be a manifestation of the irritable colon syndrome In this syndrome there may be alternating constipation and diarrhea However, there are a great number of stable and stoic individuals who are constipated from causes not necessarily a part of the etiology of this syndrome Some of these causes are made apparent by the following discussion

The causes of constipation are (1) The passage of the food residue and excreta along the colon is abnormally slow (2) The food residue reaches the rectum without delay but defecation is inefficient or difficult The natural *posture for defecation* is the squatting position, with the thighs flexed upon the abdomen In this posture the *capacity of the abdominal cavity is reduced and intra-abdominal* pressure increased, thus aiding the expulsion of the fecal mass The modern toilet seat in many instances is too high Unless the toilet seat is low enough that the feet may rest firmly on the floor and some flexion of the thighs is possible, the accessory muscles which aid in defecation normally have little opportunity to fulfill their function Four muscular structures responsible for the expulsion of the fecal mass are the muscles of the abdominal wall, the diaphragm, the levator ani muscles and the smooth muscle of the intestinal wall, and these should be aided by posture during the act of defecation

If the *upright position of man,* as has been claimed, causes constipation, it is because there is an increase in the distance that the intestines must raise the intestinal chyme against gravity Measurements of this distance are comparable in man and the quadrupeds Likewise it is erroneous to assume that there is lack of support of the intestines of man while in the upright position The ruminant quadrupeds have relatively a much longer alimentary tract, they eat a much greater quantity of food, carry it for longer periods and have no more support of the intestines than does man

The *colon of man* is midway between the size of the colon in the herbivora and the carnivora The herbivora are not constipated. The carnivora may be constipated

category of disorders may be mentioned genetic dwarfism and gigantism, certain instances of hirsutism, obesity, mongolism, Laurence-Moon-Biedl syndrome and mental retardation of children.

The endocrine glands are so intimately associated with the normal psychic, psychosomatic and somatic constitutions and behavior of the normal person that aberrations in their function permit of wide interpretations. It is for this reason that the literature on endocrinopathies is extensive and often difficult to evaluate. The physician has to be as careful as it is possible to be in the selection of a consultant to help in the diagnosis of the patients who may have an endocrine disorder.

THE PANCREAS

The pancreas lies beneath the stomach and transverse colon, stretching across from the duodenum on the right of the spinal column to the spleen on the left Its body lies over the first and second lumbar vertebrae, its lower edge about 2 inches (5.1 cm) above the umbilicus. Normally the pancreas is not palpable.

The pancreas secretes an external secretion referred to as pancreatic juice or the exocrine secretion It also secretes an internal secretion, insulin. Both the external and the internal secretions are active because of their hormonal content The exocrine secretion passes through the pancreatic ducts into the duodenum and it is concerned with intestinal digestion It contains the digestive enzymes amylopsin, trypsin, steapsin (lipase) and rennin The internal secretion of the pancreas, insulin, is concerned with the control of carbohydrate metabolism

Many diseases of the pancreas are expressed as acute, subacute or chronic localized conditions limited to the pancreas without disturbances of either the exocrine or the endocrine functions These localized diseases at any time may cause disturbances in one or the other or both of the secretory functions of the pancreas Finally a localized disease may extend to involve the pancreas sufficiently to cause a combined disturbance of both the exocrine and the endocrine functions of the organ

The diseases of the pancreas which interfere with the production of the pancreatic juice and its delivery to the intestines give rise to manifestations referable to the digestive system The incidence of these diseases is rare indeed in comparison with the incidence of the diseases due to the interference with its endocrine function, the production of insulin, namely, diabetes mellitus and hyperinsulinism

EXOCRINE DISORDERS OF THE PANCREAS
(Pancreatic Insufficiency)

There are no known examples of disease due to an overproduction of the exocrine secretion of the pancreas.

Deprivation of the Exocrine Secretion (Pancreatic Insufficiency) Deprivation of the pancreatic juice is followed by bulky stools, light in color, soft and watery, passed one to three times daily The total weight of these stools is increased three times normal The increase in weight is due to the increased excretion of fats and proteins Normally 5 to 6 gm of fat are lost in the stools from a 100 gm. daily intake whereas 35 to 45 gm are lost in the feces on deprivation of the pancreatic juice

Normally about 10 gm of protein are lost from a 100 gm. intake. On deprivation of pancreatic juice 25 to 50 gm of protein are lost in the feces

The digestion and absorption of carbohydrates proceed normally when there is deprivation of pancreatic juice

Pancreatic insufficiency occurs when there is injury, destruction or abolition of sufficient amounts of pancreatic tissue to prevent it from secretion of a sufficient amount of pancreatic juice or pancreatic digestive hormones to initiate and complete intestinal digestion. When this is present the symptoms of deprivation of pancreatic

14

DISEASES OF THE ENDOCRINE SYSTEM

The term endocrine gland refers to a ductless gland which delivers its secretions directly into the blood stream The secretory products of endocrine glands are variously termed internal secretions, hormones and sometimes autacoids The most appropriate name for the active principles secreted by endocrine glands is hormones. A hormone is the substance carried to the different parts of the body which acts for the good of the organism It is realized that the intracellular hormones are of a separate class from those of the endocrine glands Likewise, the vitamins are hormones derived from plant and animal sources

An endocrine gland may consist of secreting cells, or it may have cell types for an endocrine secretion and another type of cell for the secretion of an exocrine substance Those glands which contain elements for the secretion of an exocrine substance also have a system of ducts or channels for delivery of secretions to the outside The pancreas is an example of the latter type of gland

The process of glandular secretion may range from the separation of a specific substance of the blood to the elaboration of a new specific chemical compound or even the formation of cells as in the case of the formation of ova or spermatozoa

Hormones are numerous and complex, and characteristically their presence initiates very complex chemical actions or enables them to proceed at normal body temperatures They are therefore catalysts in their own rights or they may utilize other catalysts for their activation In the extremes of body temperatures hormones may be inactivated or destroyed

It is known that there are other mechanisms for hormone inactivation Certain trophic hormones seem to be inactivated by their respective target glands For example, thyroid tissue inactivates thyrotropin (lymphoid tissue may act in a similar manner), gonadal tissue inactivates gonadotropin and the liver too can and probably does inactivate gonadotropin.

The mechanism for activation of hormones is buried if possible in more obscurity than that of inactivation

The hormones have not been accorded a regular system of terminology The hormones with known chemical structure are either small molecular weight amines, steroids, or proteins The steroids are secreted by the testes, ovaries and adrenal cortices These structures have their origin from the celomic mesothelium The protein hormones are secreted by the anterior pituitary, thyroid, parathyroid and pancreas These glands originate from the alimentary tract and are therefore of epithelial derivation The adrenal medulla and the neurohypophysis arise from the nervous system and they secrete hormones of a small molecular weight and of the structure of the amines These amines and the steroids are remarkably similar in chemical structure

The clinical manifestations of endocrine disease are observed, not in the gland involved but in the structures susceptible to its hormones. Special studies are required in order to demonstrate that the gland in question is performing its allotted tasks There are many patients who are regarded as having an endocrinopathy by certain endocrinologists who tend to overestimate the diagnostic reliability of the tests employed. Among the disorders so diagnosed are the syndromes of pseudohypoparathyroidism, pseudodiabetes insipidus, pseudo-Addison's disease and that all-inclusive syndrome of hypometabolism The disorders which have heredity as their etiology may be the most difficult to differentiate from endocrinopathies. In this

Acute Pancreatitis. Acute pancreatitis is a rare but a serious and often fatal disease, particularly when there is hemorrhage and necrosis in the pancreas

The acute pancreatitis which may accompany infectious diseases is usually not serious and it is rarely recognized Likewise the pancreatitis which may be diagnosed by the surgeon as an enlarged, indurated head of the pancreas is not a serious disease if the surgeon is able to treat the accompanying biliary disease adequately.

ORIGINS There are three theories to explain the occurrence of acute pancreatitis: (1) the theory of infection, (2) the theory of the common channel (Opie) and (3) the theory of obstruction of the small pancreatic ducts.

Theory of Infection Bacteria present in the bile regurgitated into the pancreas are said to activate the pancreatic enzymes, which cause the initial autolysis of tissue. In infectious parotitis, typhoid fever and scarlet fever bacterial invasion of the pancreas by way of the blood stream or of infection through the lymphatic channels has etiologic significance. Acute pancreatitis occurring in association with such an acute infectious disease is mild and tends to disappear without any serious consequence.

Theory of a Common Channel (Opie) A common channel is formed by the confluence of the common bile duct and the pancreatic duct at a point ahead of their entrance into the duodenum. Such a confluence of these ducts is frequent enough to be considered a normal anatomic arrangement. Bile usually does not enter the pancreatic duct because the secretory pressure of the pancreatic juice is greater than that of the bile Bile, therefore, can enter the pancreas only when there is some sort of obstruction at the ampulla which obstructs the flow of bile into the gut and thus forces the bile into the pancreatic duct and the pancreas When this occurs, activation of pancreatic enzymes either in the biliary passages or within the pancreas takes place and acute pancreatic necrosis ensues Pancreatic enzymes may be activated in the common ampulla or in the biliary passages and then may pass into the pancreatic duct. Many observers have produced acute pancreatitis in experimental animals by injecting bile into the pancreatic ducts

Obstruction of the Small Pancreatic Ducts. Rich and Duff suggested that an obstruction to the small pancreatic ducts, and thus an obstruction to the outflow of pancreatic juice, resulting from pancreatic lithiasis, gallstones, stricture, edema and tumor accounts for some cases of acute pancreatitis.

PATHOLOGY The pathologist usually describes four types of acute pancreatitis, namely, edematous, hemorrhagic, acute pancreatic necrosis, and suppurative.

In edematous types of pancreatitis the inflammation is of long duration The pancreas is enlarged and hardened On section the inflammation is the most manifest in the interstitial tissues This is the usual form of pancreatitis which accompanies cholecystic disease A severer form of inflammation occurs when there is some obstruction of the pancreatic ducts In these inflammations, if some of the smaller ducts rupture, there is necrosis in surrounding tissues Necrosis of the pancreas follows the escape of activated pancreatic enzymes Activated pancreatic enzymes will cause an acute pancreatic necrosis in the absence of rupture of the pancreatic ducts. If there is an escape of infected pancreatic juice, *hemorrhage* may occur, to be followed by suppuration *Suppuration,* however, can occur in the absence of hemorrhage and hemorrhage can occur without suppuration In severe infections and in suppurative pancreatitis, pancreatic abscess may be present

The term fat necrosis is applied to the white opaque areas commonly seen on the surface of the pancreas, the mesentery, omentum, and parietal and visceral peritoneum. In severe pancreatitis the pancreas is large, soft and friable, and dark Hemorrhage or hemorrhagic phenomena may be either present or absent

SYMPTOMS AND FORMS OF ACUTE PANCREATITIS Acute pancreatitis occurs in persons in all decades of life The usual form, the *edematous pancreatitis* occurs most commonly in middle-aged women who have gallstones More than one half these patients are less than 50 years of age This form of the disease is benign, and usually is discovered by the surgeon at the time of surgical operations for gallstones

These patients give histories characteristic of the cholecystic disease which they

juice ensue. The localized diseases of the pancreas which may become diffuse pancreatic disease are the commoner causes of pancreatic insufficiency.

Localized Diseases of the Pancreas. The localized diseases of the pancreas which may be manifested as such or which may extend to cause aberration in its exocrine or endocrine functions are: the prenatal influences, those termed acute and chronic pancreatitis, the specific infections and those of less well-described etiologies.

Diseases of the Pancreas Due to Prenatal Influences. In embryos 3 to 4 mm in length there are two outpocketings from the primitive gut One of these, the dorsal pancreas, is cephalad of the level of the hepatic diverticulum. The other, the ventral pancreas, appears ventrally between the gut and the hepatic diverticulum. Unequal growth of the gut shifts the bile duct dorsad and brings the ventral pancreas into the dorsal mesentery. During the seventh week the dorsal pancreas and the ventral pancreas come together The short ventral duct fuses with the dorsal, and thereafter the long distal duct of the dorsal pancreas plus the entire ventral duct serves as the chief drainage for the external secretion The common outlet for the bile into the duodenum and the pancreatic ducts is but a retention of these primitive relations The proximal segments of the dorsal duct serve as the accessory pancreatic duct.

Accessory Pancreas. The commonest of all the *pancreatic anomalies* due to prenatal influences is *accessory pancreas* Many of the pancreatic rests in the abdomen or in the walls of the adult intestines are associated with the omentum, spleen and stomach. These widely distributed accessory pancreases are but displaced parts of the original primordia An accessory pancreas situated in the stomach or the duodenum may cause symptoms suggestive of gastritis, peptic ulcer, cholecystitis, or pyloric obstruction

Heterotopic pancreatic tissue situated in duodenal diverticula either in the pouch itself or in the duodenum adjacent to a diverticulum may produce intestinal obstruction. These aberrant bits of tissue in the submucosa along the digestive tube may originate intestinal obstruction, ulceration and hemorrhages

The pancreatic anomalies, aside from accessory pancreas, are annular pancreas, pancreatic ducts arising directly from the duodenum, absence of that part of the gland which arises from the dorsal primordium, failure of union between the dorsal and the ventral pancreas, and completely independent ducts.

Annular Pancreas Annular pancreas is characterized by a band or ring of pancreatic tissue which envelops the second portion of the duodenum, the bile duct and the portal vein

In an infant roentgenographic evidence of partial obstruction of the second *portion of the duodenum in the presence of jaundice is suggestive* of annular pancreas On rare occasions annular pancreas may be present without symptoms until adulthood and then be the cause of intestinal obstruction. Annular pancreas causing constriction and obstruction of the duodenum requires surgical treatment

Cystic Fibrosis of the Pancreas. Cystic fibrosis of the pancreas may occur among siblings, twins and more distant relatives. It is a recessive hereditary trait The lesions in the fetal pancreas appear in late intrauterine life and seem to result from an abnormality of the acinar secretion in the pancreas However, comparable disturbances are present in the liver, gallbladder, intestine, lungs, and possibly in the salivary glands. Intestinal obstruction and failure of pancreatic function is often associated with pancreatic fibrosis and secondary changes in the meconium. This intestinal obstruction may be complicated by volvulus or congenital peritoneal adhesions. There is evidence that the pulmonary lesion begins after birth and is primarily the result of *nutritional deficiency.*

Pathologically cystic fibrosis of the pancreas is characterized by obstruction of the ducts of the pancreas, the salivary glands and the trachea and bronchi, with resulting secondary changes

Cystic fibrosis of the pancreas is manifested by the presence of steatorrhea, dwarfism and chronic respiratory infections

glucose formed by the action of 100 ml of serum on starch) is normally 70 to 200 mg, but is increased in 8 of every 10 who have acute hemorrhagic pancreatitis. The intensity of the serum amylase values bears no relation to the severity of the disease. It is related to the acuteness or intensity of the disease, being higher during and immediately following the damage. The serum lipase also is increased.

The urine may contain albumin. Glycosuria, indicating transient as well as permanent diabetes, occurs in fewer than 1 of every 10 patients. When present it indicates severe damage of the pancreas and is most commonly observed in those who have suppurative lesions All patients with glycosuria have an associated hyperglycemia

Roentgenologic studies (scout (preliminary survey) films or simple roentgenograms of the abdomen) may reveal gallstones, gas in the small intestines, or nothing at all

In some instances there may be a similarity between the clinical syndromes of coronary thrombosis and acute pancreatic necrosis. In these, electrocardiography and serum enzyme determinations are required.

The mortality rate from pancreatic necrosis is around 10 per cent Some surgeons think that mortality rates may be decreased if operation is not performed immediately

One of every 10 who survive an attack of acute pancreatitis becomes diabetic. An even greater number are left with minor disturbances of carbohydrate metabolism An undetermined number of patients who survive an attack of severe acute pancreatitis have sufficient pancreatic atrophy and fibrosis to account for the presence of pancreatogenic steatorrhea

The mobilization of calcium in the regions of fat necrosis is said to be associated with a decrease in the concentration of serum calcium

Acute Pancreatic Necrosis. Acute pancreatic necrosis occurs most frequently in obese men between the ages of 30 and 60 years Cholelithiasis is present in about one half of these patients A history of addiction to alcohol is common The onset frequently follows a heavy meal and an alcoholic debauch

[illegible]

rhage

After an attack of acute pancreatitis diffuse suppurative inflammation or a pancreatic abscess may develop In other instances the inflammation is suppurative from the beginning These beginnings of suppuration of the pancreas are lymph-borne or hematogenous infections, extensions of infection from an adjacent organ.

The symptoms of suppurative disease of the pancreas are less intense than those of acute pancreatic necrosis There is a daily intermittent type of fever, and often there are chills and pain in the left upper part of the abdomen extending around to the left scapular region There may be symptoms of subdiaphragmatic abscess on the left side from rupture of a pancreatic abscess. Pus may pass down toward the left side of the pelvis or it may rupture into the lesser peritoneal sac or into the general peritoneal cavity Generalized peritonitis eventually may ensue.

On examination there is tenderness in the left upper portion of the abdomen. Rarely a mass may be palpated

Diagnosis often is not possible. Tests of serum enzyme are of no value diagnostically unless the enzyme content is decreased below normal limits. If suppurative inflammation of the pancreas is suspected, operation should not be delayed

Pseudocysts. Pseudocysts of the pancreas may follow an attack of hemorrhagic necrosis of the pancreas or suppuration of the pancreas

Diagnosis of Acute Pancreatitis. Often a presumptive diagnosis can be made

usually have In the more severe and acute forms of the disease the symptoms are the same as those of *acute pancreatic necrosis but less severe.*

On examination there are tenderness and muscle guarding in the epigastrium and left hypochondriac region often extending straight through to the back.

In the early diagnosis determination of *concentration of serum amylase is of no* assistance. The increase in serum amylase in acute transient pancreatitis is of brief duration. If the serum amylase is increased and drops suddenly to normal in conjunction with clinical improvement, edema of the pancreas is more likely the diagnosis than necrosis of the pancreas. Disturbances in carbohydrate metabolism are less common in acute edematous pancreatitis than *in acute hemorrhagic* pancreatitis There may be transient glycosuria, hyperglycemia or hypoglycemia.

Hemorrhagic Pancreatitis (With Hemorrhage and Necrosis). Hemorrhagic pancreatitis (with hemorrhage and necrosis) occurs most commonly in men, who may or may not have gallstone disease More than one half of these patients are more than 70 years of age Alcoholic debauches often precede this form of pancreatitis

There is an abrupt onset of agonizing pain in the epigastrium, often referred around to the back and to the loins The reference of severe pain to the left side of the epigastrium and around or through to the left subscapular region in an obese middle-aged man or woman is very suggestive of acute pancreatitis In some instances signs and symptoms of *pancreatic necrosis cannot be distinguished* from those of biliary colic or perforated peptic ulcer

The pain of acute pancreatitis is severe and steady It rarely is colicky or intermittent like the pains of intestinal obstruction. In more than half the patients the pain originates in the epigastrium In the rest the pain is generalized throughout the abdomen and flanks or occasionally in the chest and shoulders

Vomiting appears promptly after the onset of pain and tends to recur despite an empty stomach A few patients will have diarrhea The occurrence of gross melena is not due to pancreatitis.

On examination the pulse rate is accelerated, the blood pressure may fall, and collapse may ensue The skin is cold and clammy and there *may be cyanosis. In* some of those who have an acute hemorrhagic pancreatitis there appear spots of cyanotic staining and patches of slate blue color over the abdomen, with petechial patches *on the buttocks and a brownish discoloration just below* the ribs posteriorly. These spots have been thought to be pathognomonic of acute pancreatitis Davis called *attention to a mottling of the skin of the limbs*

The epigastrium may appear distended and the lower part of the abdomen flat by contrast Palpation of the abdomen elicits tenderness most marked above the umbilicus and often to the left of the midline. In severe pancreatitis muscle guarding is present, and often there is rigidity above the umbilicus. On auscultation it may be noted that intestinal peristalsis is decreased or temporarily *absent because* of intestinal ileus, which is so frequently present

An abdominal mass, usually firm, fixed and tender, is palpated sometime in the *course of the disease in one third of the patients* Among the patients who have interstitial pancreatitis a mass appears less frequently, but when present it usually is detected in the right upper quadrant About four fifths of patients with suppurative or cystic pancreatitis have abdominal masses which lie predominantly within the left upper quadrant About one third of the hemorrhagic-necrotic group *will have* abdominal masses situated on the right side of the abdomen Cullen's sign, a faint periumbilical ecchymosis, is rarely present

Leukocytosis is common but not invariably present *When it is* present, leukocytes range from 10,000 to 20,000 or more per cubic millimeter of blood

The concentration of serum amylase (results are expressed in milligrams of

The incidence of chronic pancreatitis is greatest in men who are between the ages of 30 and 50 years The disease also occurs in women

Chronic pancreatitis occurs both in a mild and in a severe form The disease is usually not suspected until it is found by the surgeon at the time of operation for disease of the biliary tract. The head of the pancreas is hard, somewhat nodular and usually enlarged so that the surgeon may suspect the presence of malignancy. Walters has expressed the belief that in these cases of suspected malignancy if cholecystenterostomy or cholecystgastrostomy results in a permanent cure, a diagnosis of chronic pancreatitis is justified five years after the operation

In the severe form of the disease there is a progressive and painless obstructive jaundice A change in the character of the stools is often the first symptom. The stools are soft and there are several motions a day. Once symptoms are present, they are the same as those observed in all of the diseases associated with steatorrhea (see Sprue, Chapter 22). Loss of body weight is progressive.

The physical examination is important because of the absence of evidence of disease except for that referable to the jaundice and the gallbladder. A transient glycosuria in which a tolerance test reveals a true diabetic curve may be present The gallbladder may be palpable, and there may be an absence of bile from the intestine on duodenal drainage If these findings are present in a person more than 45 years of age, carcinoma at the head of the pancreas should be first considered Carcinoma at the head of the pancreas cannot be excluded except by surgical exploration.

In those who have mild diabetes or steatorrhea the diagnosis of chronic pancreatitis may be suspected Irrespective of the manifestations the diagnosis is usually made at the time of surgical operation for disease of the biliary tract

Chronic Relapsing Pancreatitis. Chronic relapsing pancreatitis, characterized by recurring attacks of pain in the upper part of the abdomen, sometimes associated with disturbances in function of acinar and islet cells of the pancreas, is accompanied by steatorrhea, diabetes and calcification The disturbances in function are transient and mild at first, but they later may become permanent Comfort has expressed the belief that this disease is common.

The causes are not discoverable In some instances a long history of alcoholism may precede or attend the clinical onset Alcoholic and dietary indiscretions appear to precipitate acute attacks The disease makes its first appearance at ages from 10 to 66 years, with the mean at 38 years Unlike cholecystic disease, it is commoner in men than in women It is without predilection for the obese

The pathologic changes in the pancreas are determined by examination at operation, by microscopic study of surgical specimens, and by examination at necropsy They vary from edema, inflammation, hemorrhagic necrosis and abscess in the acute phase to atrophy, fibrosis, cysts, calcification and stones The pathologic changes tend to persist and progress in the intervals between recurrent clinical manifestations. The essential pathologic process may be either repeated attacks of acute interstitial pancreatitis, or repeated sublethal attacks of so-called acute hemorrhagic pancreatitis, or a combination of the two The cysts are pseudocysts and are regarded as encapsulated regions of hemorrhagic necrosis Stones may cause the pancreatitis in some cases, but the sequence of events is believed to be more commonly the reverse

SYMPTOMS Often there are chills, moderate fever, diarrhea, nausea, emesis, jaundice and constipation The attacks of pain are characteristically severe, steady and prolonged The pain most often gradually increases in severity, reaches a plateau, and then gradually declines Such a cycle may require from 2 to 35 days for completion The intervals between attacks vary from a few hours to years The seizure of pain requires repeated administration of opiates, which do not terminate the attack.

The painful seizure is the most violent manifestation of the disease which may have occurred recently or over a period of years The pain may be cramping, stab-

on the basis of the history and the physical examination. The diagnosis of acute pancreatitis is more certain if there is an increase of serum amylase and often of serum lipase

The presence of glycosuria and hyperglycemia adds further support to the diagnosis. A progressively increasing hyperglycemia is a bad prognostic omen.

Tests of the Exocrine Pancreatic Functions. The tests of pancreatic function are most profitably employed during or immediately after an attack of acute pancreatitis of any form.

The diseases of the pancreas affecting its external secretion, or secondarily the body as a whole, other than those due to insulin deficiency are not easy to diagnose, and for this reason a number of pancreatic functional tests have been devised.

Evidences of failure of pancreatic function may be detected by the presence of undigested meat fibers, increased amount of fat, and an increase (more than 25 per cent) of nitrogen in the feces. The urine may reveal evidences of disturbances of enzyme excretions and the presence of sugar In the acute pancreatic diseases there may be an increase in the concentration of sugar (hyperglycemia), glycosuria, and diminished sugar tolerance and an increase of serum and urine enzymes

Diseases of the pancreas for which functional testing is performed are either inflammatory or neoplastic, and the functional change produced is either pancreatic insufficiency or an obstructive phenomenon. Insufficiency is usually the result of an advanced diffuse lesion, the obstructive mechanism may result from an acute inflammatory process with minimal fibrotic change or from a neoplasm localized in the head of the pancreas Therefore patients who have mild inflammatory disease and whose pancreatic function is not tested shortly after an attack and those who have only moderate chronic functional change may show normal response In advanced pancreatic insufficiency both the duodenal and the serum enzymes will be diminished; in the obstructive processes duodenal enzymes are diminished, but serum enzymes are elevated.

Amylase By far the most significant test for acute pancreatitis is that for amylase and lipase in the urine and serum

Elevation of amylase (normal value, 70 to 200 units) in the serum in acute inflammation of the pancreas and salivary glands is thought to be due to the swollen tissue obstructing the ductal system sufficiently to increase the rate of reabsorption of ferment. In advanced renal disease retention may cause an elevation of amylase in the blood An elevated serum amylase is considered conclusive evidence of pancreatic edema or inflammation The determination of urine amylase is less reliable than that of serum amylase. The amylase is expressed in milligrams of glucose formed by the action of 100 ml. of serum on starch.

Usually in chronic recurrent pancreatitis the level of serum amylase is significantly elevated only during an exacerbation, but in some instances it may remain high during remissions. Extremely low levels may be recorded in far advanced pancreatic disease. An elevated serum amylase occurs in about a third of the patients who have carcinoma of the head of the pancreas and in the majority of those who have ampullary cancer.

Lipase Normal serum lipase expressed in terms of N/20 sodium hydroxide is 1 ml or less. In acute pancreatitis, in carcinoma of the pancreas, in some patients who have duodenal ulcers, and in cirrhosis of the liver, intestinal obstruction, mumps, and chronic alcoholism, increased values may be obtained.

Chronic Pancreatitis. There are two forms of this condition: one designated simply as chronic pancreatitis, the other known as chronic relapsing pancreatitis

Chronic pancreatitis is the commoner form. It often accompanies cholelithiasis, gallbladder disease, duodenal ulcer and, rarely, obstruction to the pancreatic duct by pancreatic or biliary calculi or new growths Judd and associates found pancreatitis at operation in 26 8 per cent of patients who had disease of the gallbladder or bile ducts. Primary disease of the pancreas, such as acute pancreatitis and pancreatic lithiasis, may be followed by chronic fibrosis of the gland. A few patients who have achlorhydria, gastroduodenitis and cirrhosis of the liver may show evidence of chronic pancreatitis. Necropsy on bodies of chronic alcoholics often discloses some degree of fibrosis of the pancreas.

Syphilis of the Pancreas. Syphilis of the pancreas is exceedingly rare except in congenital syphilis

The coexistence of syphilis and diabetes mellitus is not uncommon. However, diabetes mellitus if of syphilitic origin appears synchronously with the manifestations of syphilis and treatment will cause simultaneous disappearance of both syphilitic and diabetic symptoms. Moore has seen but one instance of diabetes due to syphilis.

The diagnosis of syphilis of the pancreas in the majority of instances is made on the basis of studies of material obtained at necropsy

Pancreatic Lithiasis. W. J Mayo expressed the belief, as have many others, that infection in the pancreas and perhaps stones are produced by disease of the biliary tract Like many of the other diseases of the pancreas, pancreatic lithiasis occurs predominantly in men, whereas gallstone disease occurs most commonly in women. The preponderance of pancreatic stones in men may be associated with chronic low-grade alcoholism The mechanism of formation of pancreatic calculi and the time required in the process are not known

As W J. Mayo pointed out, two types of calcium deposits occur within the pancreas, actual calculi lying within the ducts, and calcification within the parenchyma of the gland

The presence of calculi in the main pancreatic duct may produce incomplete obstruction. The secondary changes are not marked though the ducts become dilated and the glandular tissue gradually atrophies and disappears Inflammatory reaction in the parenchyma, secondary to obstruction, may be more acute than in incomplete obstruction of the ducts, and in some instances actually may lead to acute or subacute pancreatic necrosis, abscess and cyst formation Obstruction of the common bile duct and jaundice may occur. Changes in the liver develop in some advanced instances. Cirrhosis of the liver has been observed in association with pancreatic lithiasis, and tuberculosis has been reported in a few cases

Symptoms Pancreatic lithiasis may be without symptoms. If there be a symptom, it is a severe colicky pain simulating that of biliary colic. The pain begins in the epigastrium, passes along the left costal margin, extends to the low thoracic region of the back and to the left scapula In other instances the pain begins slowly, shortly after a meal, and terminates in severe colic associated with profuse perspiration In some cases the ingestion of alcohol seems to have brought on the pain.

Nausea and vomiting may occur in association with the attacks of colic or independently of them Disturbances of intestinal function similar to those of the irritable colon are frequent

When the lithiasis has been of long duration, diabetes mellitus of varying severity is associated in about one third of the cases.

Examination Tenderness with or without muscle guarding in the epigastrium may be present during an attack of colic There may be jaundice and hepatic enlargement, and both steatorrhea and creatorrhea A glucose tolerance test is performed if minimal abnormality of carbohydrate function is present In other cases the disturbance in carbohydrate metabolism is evident from the glycosuria and hyperglycemia

Pancreatic lithiasis associated with pronounced destruction of the pancreatic parenchyma may cause decrease or complete absence of pancreatic enzymes in the duodenum (Snell and Comfort)

Diagnosis The roentgenogram is the only means of establishing the diagnosis of pancreatic stones Treatment is not indicated if the diagnosis is based on the accidental demonstration of stones by roentgenographic examination of a patient who does not present symptoms.

Surgical intervention is usually advisable for patients who suffer from severe attacks of colic, particularly if intermittent obstruction to the pancreatic duct or acute pancreatitis is thought to accompany the attacks of pain

bing, colicky, steady, bright, dull and aching, constant or excruciating. The painful seizures vary considerably not only among patients but also in the individual patient. The tendency toward more frequent attacks with the lapse of time is a common feature of relapsing pancreatitis.

The primary or initial site of pain is in the epigastrium or over the upper part of the abdomen, the lower part of the abdomen, or in the lower thoracic and upper lumbar portions of the back. The pain may extend to the left shoulder.

Painful seizures last from a few hours to 3 weeks. There may be associated: dysphagia, nausea, vomiting, constipation, borborygmi, diarrhea, abdominal distention and abdominal soreness Chills and fever are common. During the acute attacks of pain symptoms of shock may occur if there has been hematemesis Pruritus often accompanies the jaundice

The course of the disease is characterized by recurring acute exacerbations separated by short or long intervals of relative clinical quiescence Diabetes and steatorrhea may be caused by either mild or severe attacks of pancreatitis In other instances sequelae develop as the result of pressure of the enlarged pancreas, from inflammation, abscess or cyst

EXAMINATION On examination evidence of loss of weight, fever, jaundice, shock, tenderness and muscle spasm, epigastric mass, hepatomegaly and splenomegaly may be found Some of the findings persist in the intervals between seizures Laboratory examinations reveal slight anemia, albuminuria, glycosuria, increased concentrations of blood urea, hyperglycemia and abnormal glucose tolerance Elevation of the concentration of serum bilirubin is common The values for serum amylase and lipase may be increased during the painful seizures, but they quickly subside, and as the disease advances, these values may be reduced below normal An increased amount of total fats in the feces may occasionally be present

DIAGNOSIS The diagnosis of chronic relapsing pancreatitis often is made difficult by the presence of associated disease of the biliary tract. Roentgenologic findings and experience in order to be mindful of this disease are helpful The diagnosis may be established by the history and by results of physical examination alone in some instances. Tests of pancreatic function and roentgenologic demonstration of calcification may prove the existence of disease of the pancreas and aid in the diagnosis After pancreatitis is established, its primary nature in the pancreas is suspected by the exclusion of diseases of the liver and biliary tract The diagnosis is more easily made during acute attacks than during remissions

In the differential diagnosis disease of the biliary tract, especially biliary colic, hydronephrosis, subacutely perforated duodenal ulcer, intermittent intestinal obstruction and heart disease can be excluded in most instances by the history and by laboratory tests Carcinoma of the pancreas or of the ampulla of Vater may cause pancreatitis which at first resembles primary chronic pancreatitis, but carcinoma is progressive Nontropical sprue is excluded, especially in the presence of steatorrhea

Tuberculosis of the Pancreas. Tuberculosis of the pancreas is exceedingly uncommon and rarely, if ever, primary The infection may reach the pancreas by the blood stream, through the lymphatics, by way of the pancreatic duct, or by extension from adjacent viscera

The symptoms occur in the late stages of pulmonary tuberculosis and are primarily those of pancreatic insufficiency and epigastric pain of varying intensity. Emaciation is often extreme. The glucose metabolism is disturbed and melanoderma is frequent The melanoderma may resemble the pigmentation seen in Addison's disease.

The clinical diagnosis is usually not made, but pancreatic tuberculosis should be suspected in patients suffering from pulmonary tuberculosis who have pigmentation of the skin, rapid loss of weight, steatorrhea, diabetes and pronounced pain in the upper part of the abdomen.

Diabetes Mellitus (Hypoinsulinism). The term diabetes mellitus designates a disturbance in carbohydrate metabolism in which there are hyperglycemia and glycosuria which presumably are due to pancreatic deficiency However, hyperglycemia and glycosuria do occur in disorders in which there is no primary pancreatic deficiency. These disorders are described under the heading melituria (p. 1063)

The incidence of diabetes, and thus its importance in the production of disabilities, has been emphasized by the results of the survey of the population of Oxford, Massachusetts, by members of the United States Public Health Service Among 3,500 persons there were 70 cases of diabetes However, there are no data which afford even reasonable estimates of the number of diabetic persons in these United States. Attempts to estimate the number of other persons who are susceptible are even more dubious

Diabetes mellitus is often hereditary and familial. The tendency to develop diabetes mellitus is transmitted as a mendelian recessive character In familial incidence of diabetes mellitus there is a tendency for the disease to appear at an earlier age in successive generations

Obesity is present in about three fourths of adult diabetic patients but its relation to the etiology of diabetes is not clear There is no good evidence to indicate that increased consumption of sugar is responsible for the development of the disease though excessive consumption of sugar is often practiced by the obese who are more likely than others to have diabetes

In practice it is observed that any disease which may destroy or reduce the amount of pancreatic tissue sufficiently may be associated with the onset of diabetes mellitus An example of such a disease is hemochromatosis

Other glands of the endocrine system affect carbohydrate metabolism The anterior pituitary maintains an important relationship with the islet cells in the regulation of carbohydrate metabolism Patients who have hypopituitarism (Simmonds' disease) are very sensitive to insulin whereas those who have hyperpituitarism (acromegalics) are insulin-resistant It seems that a small number of persons have diabetes due to excessive amounts of an anterior pituitary hormone In some diabetics who have an insulin-resistant form of the disease, the resistance has been attributed to anterior pituitary hormones

In some diabetics the sex hormones seem to bear etiologic importance. The possible etiologic importance of the sex hormones is suggested by the increased incidence of the disease at puberty (both sexes) and at the menopause Diabetes commencing at the time of the menopause may be improved by the administration of estrogen

Infertility in diabetic women may be remedied by proper control of diabetes Abortion and overdevelopment of the fetus, however, are of frequent occurrence The sugar tolerance of the diabetic woman may be found decreased during the early part of pregnancy During the last trimester of pregnancy the diabetes may become ameliorated.

It seems likely that the glycogenic adrenal steroids are in some way important in the genesis of diabetes mellitus

Thyrotoxicosis or hyperthyroidism increases the severity of diabetes and renders the control of the disease by insulin more difficult However, the disease is not caused by the thyrotoxicosis The relationship of thyrotoxicosis is likely due to the increased food consumption, the increased general rate of metabolism and the increased secretion of adrenal steroids

Infections do not cause diabetes but they intensify the diabetic state probably by the same mechanism whereby the sugar tolerance in nondiabetic patients is decreased during acute infectious processes This intensification of a disease by infection and the greater liability to infection is also observed in the endocrine deficiencies, which may affect the course of diabetes such as Simmonds' disease, Addison's disease, and myxedema. It seems that tertiary syphilis may be a precipitating factor in the onset of symptoms in potential diabetics and in the early appearance of gangrene in mild diabetics

Calcification of the Pancreas. Calcified deposits in the parenchyma of the pancreas are occasionally found in association with pancreatic lithiasis The average age of patients discovered to have pancreatic calcification is 40 years, but the condition has been found in children. The symptoms of diffuse calcification cannot be stated since lithiasis accompanies the parenchymal calcification The clinical diagnosis can be made only on the basis of roentgenologic examination.

The treatment is surgical if the presence of calculi can be proved and if colics occur.

Pancreatic Fistula. A fistulous tract leading from the pancreas to the abdominal wall may drain all or part of the pancreatic juice externally. Drainage of all of the secretion to the exterior gives rise to severe disturbances of nutrition and metabolism Drainage of a part of the secretion to the exterior does not cause nutritional defects unless the loss of pancreatic juice is excessive.

The commonest cause of pancreatic fistulas is drainage of pancreatic cysts by the surgical procedure of marsupialization A few fistulas are caused by penetrating wounds.

In excessive loss of pancreatic juice an acidosis may ensue. This may be compensated for to some extent if there is a loss of [illegible] chloric acid One of the earliest deviations is t [illegible] proteins are not disturbed except in cases of [illegible] from fluid lost by fistula and vomiting produces hyperazotemia The presence of dehydration, acidosis, hypochloremia and azotemia accounts for loss of weight, extreme asthenia, prostration, anorexia, nausea, and vomiting and oliguria Anemia is common.

ENDOCRINE DISORDERS OF THE PANCREAS

Interspersed between the system of ducts lined by alveolar cells which produce the exocrine secretion or the pancreatic juice, throughout the parenchyma of the pancreas are *islets of epithelial cells which elaborate the internal secretion,* insulin

INSULIN The international unit of insulin is the activity contained in 0 04082 mg of the third international standard preparation (1952)

Regular and Crystalline Zinc Insulin There are no significant differences in the action of *highly purified amorphous and crystalline preparations of* insulin, they are interchangeable when rapid action is desired The insulin prepared from zinc-insulin crystals has a potency of from 25 to 26 units per milligram of solid.

The peak effect of single doses of protamine zinc insulin can be *demonstrated in patients who are fed at a constant rate but is not apparent in* those receiving reasonably large doses regularly every 24 hours Once overlapping effects have been established, the active insulin is released at a more or less constant rate

A mixture of regular insulin and protamine zinc insulin is capable of combining rapid and prolonged effects By varying the proportions of the two, it is possible to fit the individual requirement

The reactions to protamine zinc insulin are similar to those encountered after the use of unmodified insulin Their onset, however, is more insidious, and they occur many hours after the injection, that is, late in the evening or in the early morning Headache, nausea and vomiting may occur owing to a hypoglycemic reaction 12 to 24 hours after the injection of the protamine zinc insulin.

Insulin ameliorates the symptoms of diabetes, but the nature of the underlying disturbance and the mechanism by which insulin produces its effects are still unknown

Irrespective of the physiologic and chemical details of the action of *insulin, it may* be said that in the normal person it lowers the levels of blood sugar. In either the normal person or the diabetic patient excessive doses induce hypoglycemia

The endocrine diseases of the pancreas are characterized by either a deficit or [illegible] the main [illegible] is [illegible] ia.

manifested by hyperglycemia and hyperinsulinism is manife[illegible]

Diabetes Mellitus (Hypoinsulinism). The term diabetes mellitus designates a disturbance in carbohydrate metabolism in which there are hyperglycemia and glycosuria which presumably are due to pancreatic deficiency. However, hyperglycemia and glycosuria do occur in disorders in which there is no primary pancreatic deficiency These disorders are described under the heading melituria (p. 1063)

The incidence of diabetes, and thus its importance in the production of disabilities, has been emphasized by the results of the survey of the population of Oxford, Massachusetts, by members of the United States Public Health Service Among 3,500 persons there were 70 cases of diabetes However, there are no data which afford even reasonable estimates of the number of diabetic persons in these United States. Attempts to estimate the number of other persons who are susceptible are even more dubious

Diabetes mellitus is often hereditary and familial The tendency to develop diabetes mellitus is transmitted as a mendelian recessive character In familial incidence of diabetes mellitus there is a tendency for the disease to appear at an earlier age in successive generations.

Obesity is present in about three fourths of adult diabetic patients but its relation to the etiology of diabetes is not clear. There is no good evidence to indicate that increased consumption of sugar is responsible for the development of the disease though excessive consumption of sugar is often practiced by the obese who are more likely than others to have diabetes

In practice it is observed that any disease which may destroy or reduce the amount of pancreatic tissue sufficiently may be associated with the onset of diabetes mellitus An example of such a disease is hemochromatosis.

Other glands of the endocrine system affect carbohydrate metabolism The anterior pituitary maintains an important relationship with the islet cells in the regulation of carbohydrate metabolism Patients who have hypopituitarism (Simmonds' disease) are very sensitive to insulin whereas those who have hyperpituitarism (acromegalics) are insulin-resistant. It seems that a small number of persons have diabetes due to excessive amounts of an anterior pituitary hormone In some diabetics who have an insulin-resistant form of the disease, the resistance has been attributed to anterior pituitary hormones

In some diabetics the sex hormones seem to bear etiologic importance The possible etiologic importance of the sex hormones is suggested by the increased incidence of the disease at puberty (both sexes) and at the menopause Diabetes commencing at the time of the menopause may be improved by the administration of estrogen.

Infertility in diabetic women may be remedied by proper control of diabetes. Abortion and overdevelopment of the fetus, however, are of frequent occurrence The sugar tolerance of the diabetic woman may be found decreased during the early part of pregnancy During the last trimester of pregnancy the diabetes may become ameliorated

It seems likely that the glycogenic adrenal steroids are in some way important in the genesis of diabetes mellitus

Thyrotoxicosis or hyperthyroidism increases the severity of diabetes and renders the control of the disease by insulin more difficult However, the disease is not caused by the thyrotoxicosis The relationship of thyrotoxicosis is likely due to the increased food consumption, the increased general rate of metabolism and the increased secretion of adrenal steroids.

Infections do not cause diabetes but they intensify the diabetic state probably by the same mechanism whereby the sugar tolerance in nondiabetic patients is decreased during acute infectious processes This intensification of a disease by infection and the greater liability to infection is also observed in the endocrine deficiencies, which may affect the course of diabetes such as Simmonds' disease, Addison's disease, and myxedema It seems that tertiary syphilis may be a precipitating factor in the onset of symptoms in potential diabetics and in the early appearance of gangrene in mild diabetics.

Calcification of the Pancreas. Calcified deposits in the parenchyma of the pancreas are occasionally found in association with pancreatic lithiasis. The average age of patients discovered to have pancreatic calcification is 40 years, but the condition has been found in children. The symptoms of diffuse calcification cannot be stated since lithiasis accompanies the parenchymal calcification. The clinical diagnosis can be made only on the basis of roentgenologic examination.

The treatment is surgical if the presence of calculi can be proved and if colics occur.

Pancreatic Fistula. A fistulous tract leading from the pancreas to the abdominal wall may drain all or part of the pancreatic juice externally. Drainage of all of the secretion to the exterior gives rise to severe disturbances of nutrition and metabolism. Drainage of a part of the secretion to the exterior does not cause nutritional defects unless the loss of pancreatic juice is excessive.

The commonest cause of pancreatic fistulas is drainage of pancreatic cysts by the surgical procedure of marsupialization A few fistulas are caused by penetrating wounds

In excessive loss of pancreatic juice an acidosis may ensue. This may be compensated for to some extent if there is a loss of hydrogen ion by vomiting of hydrochloric acid One of the earliest deviations is that of hypochloremia The plasma proteins are not disturbed except in cases of long-standing fistulas Dehydration from fluid lost by fistula and vomiting produces hyperazotemia. The presence of dehydration, acidosis, hypochloremia and azotemia accounts for loss of weight, extreme asthenia, prostration, anorexia, nausea, and vomiting and oliguria Anemia is common

ENDOCRINE DISORDERS OF THE PANCREAS

Interspersed between the system of ducts lined by alveolar cells which produce the exocrine secretion or the pancreatic juice, throughout the parenchyma of the pancreas are islets of epithelial cells which elaborate the internal secretion, insulin

INSULIN. The international unit of insulin is the activity contained in 0 04082 mg of the third international standard preparation (1952).

Regular and Crystalline Zinc Insulin There are no significant differences in the action of highly purified amorphous and crystalline preparations of insulin, they are interchangeable when rapid action is desired The insulin prepared from zinc-insulin crystals has a potency of from 25 to 26 units per milligram of solid

The peak effect of single doses of protamine zinc insulin can be demonstrated in patients who are fed at a constant rate but is not apparent in those receiving reasonably large doses regularly every 24 hours Once overlapping effects have been established, the active insulin is released at a more or less constant rate

A mixture of regular insulin and protamine zinc insulin is capable of combining rapid and prolonged effects By varying the proportions of the two, it is possible to fit the individual requirement.

The reactions to protamine zinc insulin are similar to those encountered after the use of unmodified insulin Their onset, however, is more insidious, and they occur many hours after the injection, that is, late in the evening or in the early morning. Headache, nausea and vomiting may occur owing to a hypoglycemic reaction 12 to 24 hours after the injection of the protamine zinc insulin

Insulin ameliorates the symptoms of diabetes, but the nature of the underlying disturbance and the mechanism by which insulin produces its effects are still unknown

Irrespective of the physiologic and chemical details of the action of insulin, it may be said that in the normal person it lowers the levels of blood sugar In either the normal person or the diabetic patient excessive doses induce hypoglycemia

The endocrine diseases of the pancreas are characterized by either a deficit or an excess production of insulin. Since the amount of available insulin exerts the main controlling influence over the concentration of the blood glucose, hypoinsulinism is manifested by hyperglycemia and hyperinsulinism is manifested by hypoglycemia

diabetes The diabetic patient who has one of these diseases may complain only of symptoms referable to it

Diffuse aches and pains, with or without evidence of peripheral nerve involvement and weakened vesical control and attacks of nocturnal polyuria and diarrhea may occur during the course of diabetes mellitus. In children enuresis is often the first symptom to attract attention. Abdominal pain beginning after the onset of the digestive disturbances is often an indication of impending coma. Anorexia is more commonly observed in children than is an increased appetite.

Ocular discomforts may be the subject of the complaint for which the patient seeks aid from the ophthalmologist In many cases the finding of early diabetic retinitis aids in the diagnosis

EXAMINATION. On examination most patients who have severe uncontrolled diabetes appear tired and have evidence of recent loss of weight and dehydration The skin may have lost its elasticity, its turgor and subcutaneous fat and may appear dry Examination of the skin of the soles and palms of children may reveal xanthosis.

The eruptive xanthomas secondary to the hypercholesteremia and lipemia of uncontrolled diabetes come and go with the lipemia Eruptive xanthoma occurs in any xanthomatosis in which there is hyperlipemia Furunculosis and pyogenic infections are common findings if the diabetes is not under adequate control.

The diabetic patient is more susceptible to infections than are normal persons For example, even with the use of insulin, findings suggestive of tuberculosis are about three times as common among diabetic persons as among the general population Findings indicative of tuberculosis in the diabetic patient tend to appear suddenly and to progress swiftly There is often a rapid loss of weight

Enlargement of the liver with infiltration with fat is a frequent finding in chronic diabetes, particularly in children It is usually an evidence of poor control of the diabetes.

The incidental finding of gallstones is higher among diabetic patients than among persons in normal health

The presence of cardiovascular disease is a frequent finding on examination of the diabetic patient at a much younger age than in normal persons The high incidence of arteriosclerosis in diabetes may be accompanied by other degenerative changes in the blood vessels in consequence of an abnormal metabolism.

Gangrene may be present in the toes, less frequently in the fingers Commonly the gangrene of the diabetic patient involves the whole foot The arteries of the leg will be found badly sclerosed up to the knee with decreased or impalpable pulses

Hypertension is an important and a frequent concomitant of arteriosclerosis in diabetes Hypertension and arteriosclerosis are both responsible for the observed myocardial changes Coronary heart disease among nondiabetic patients is found several times more frequently in men than in women However, coronary heart disease is present more frequently in diabetic women than in nondiabetic women

The peripheral nerves of the lower extremities are found to be affected more severely than those of the upper extremities, the peroneal nerve being more vulnerable than the tibial, the ulnar than the radial or the median Diabetic neuritis is characterized by weakness and paresthesias. The patient walks with a broad base, with shuffling gait, there is swaying in the Romberg position There may be slight ataxia Muscular power is impaired The tendon reflexes may be absent There may be present impairment of the sense of pain, of temperature, of vibration and of position, and hypalgesia over the feet and ankles.

The commonest ocular findings in diabetes are irregularities of the posterior surface of the cornea, retinal hemorrhages, exudates in the retina, and diabetic retinitis and catarac[illegible]

effects of the lack [illegible]

The specific gr[illegible]

In some cases the pathologic changes suffice to account for the occurrence of diabetes; in others they do not account satisfactorily for the dysfunction of the islet tissue When pathologic changes are present these are: (1) hyalinization of the islet cells present in about one third of those more than 40 years of age and (2) fibrosis observed in one fourth of the elderly patients. The islet cells in the young diabetic generally appear to be within the limits of normal.

Changes in other endocrine organs may be present in the diabetic. A decrease in the number and size of the eosinophilic cells of the pituitary gland may be present but this finding is not constant At necropsy degenerative changes in the anterior lobe (resulting from hemorrhage) have been observed in cases in which spontaneous amelioration of the diabetic symptoms occurred during life presumably as a result of the pituitary infarction

Arteriosclerosis is found at necropsy in all cases in which there had been diabetes for 5 years or more. Infarcts of the heart, coronary sclerosis, and arteriosclerosis of the aorta are present in a large proportion of the cases Infiltration of glycogen in the kidneys, hepatic cells, and cardiac muscle, and the deposition of lipids in the reticulo-endothelial tissues may be present

The *Kimmelstiel-Wilson syndrome* occurs in mild hypertensive diabetics of middle age This syndrome is characterized by widespread edema, albuminuria, hypertension and failure of renal functional activity There is present a peripheral neuropathy with locomotor sensory disturbances which simulate tabes dorsalis of syphilis There is present a retinitis which combines the characteristics of the diabetic and the advanced glomerulonephritic retinopathies. Congestive heart failure, hypoproteinemia, and hyperazotemia ensue.

In summary, despite the fact that the islet cells in the diabetic pancreas often show little or no detectable histologic changes it would seem that true diabetes mellitus in all cases is due to disease of the islet cells, as a result of which they no longer elaborate a requisite amount of insulin.

SYMPTOMS. In 1 of every 5 who have diabetes it becomes manifest in the first decade of life. In approximately half of all who have the disease the onset occurs between the ages of 40 and 60 years. There is a declining susceptibility thereafter While diabetes affects all races, the Irish and the Hebrews are said to be particularly susceptible to the disease

The symptoms of diabetes may commence during an acute pancreatitis in those who survive the attack Early diabetes may be asymptomatic, the disease being discovered in the course of a routine examination of urine or blood Patients who have well developed diabetes complain of weakness and fatigue, loss of weight, polyphagia, polydipsia and polyuria (the cardinal symptoms)

In elderly patients who have a mild form of diabetes, polyphagia may precede glycosuria by years Polydipsia and polyuria are associated with hyperglycemia and glycosuria. Also polydipsia may be secondary to excessive loss of extracellular fluid or be accentuated by a chronic nephritis

Generalized weakness and easy fatigability may be the only symptoms of the disease. Backache and impotency are frequent complaints and in some patients may constitute the initial symptom or chief concern Polyuria and particularly nocturia may accentuate fatigue by interrupting sleep

Most patients are aware of appreciable loss of weight by the time the diagnosis is established Loss of weight is due to loss of glucose and ketone bodies in the urine, to loss of fluid and mineral resulting in dehydration, and to the increased metabolic rate. In most patients loss of body weight is indicative of the severity of the disease

Infections of the skin, such as furuncles and carbuncles, are frequent complaints Pruritus vulvae occurs in diabetes, but this condition is generally not due to diabetes Infections in the urinary tract are common in diabetes, particularly in association with the glycosuria of uncontrolled diabetes There is a relatively high incidence of pulmonary tuberculosis, cholecystitis and cholelithiasis among patients who have

excess of the capacity to utilize them, and acidosis ensues The serum bicarbonate concentration decreases as base combines with the acid metabolites, and sodium and potassium are excreted in the urine combined with the acid end products Progressive acidosis and dehydration further impair the utilization of insulin and hence aggravate the deficiency

The symptoms of an acidosis consist of progressive weakness, with malaise, headache, and thirst On examination the mucous membranes are dry, the eyes are sunken, the eyeballs decreased in size and soft, and the breath has a sweet odor. Often abdominal pain and muscular cramps due to sodium deficiency may be present As the acidosis progresses, hyperpnea and the Kussmaul type of respiration appear The loss of sodium results in severe dehydration with hemoconcentration As the acidosis and dehydration increase, the pulse becomes rapid and feeble, the temperature subnormal and the blood pressure falls At this point peripheral circulatory collapse and shock quickly ensue At this time leukocytosis is usually present

Acetone is the first of the ketone bodies to appear in the urine, and then acetoacetic acid and beta-hydroxybutyric acid follow In those who have renal impairment, large quantities of acid metabolites may accumulate in the serum, causing a marked reduction in the concentration of the serum bicarbonate without the appearance in the urine of appreciable quantities of acid metabolites

A carbon dioxide-combining power of serum of less than 10 mEq. per liter indicates the presence of severe acidosis, with coma A carbon dioxide-combining power of serum between 10 and 20 mEq. per liter accompanies moderate acidosis

Arteriosclerosis and Atherosclerosis Diabetes mellitus is often associated with excessive arteriosclerosis Arteriosclerosis develops in young diabetic adults who have an inadequately controlled diabetes In addition to the deficiency of the hormone insulin, there is a dietary or nutritional factor, related to fat metabolism, which contributes to the development of arteriosclerosis in these young patients

Postmortem examinations have provided evidence that in young persons who have had diabetes of more than 10 years' duration the lesions of the arteries are of the three common types, namely, calcification and sclerosis of the tunica media of the Monckeberg type, intimal atheromatosis involving the aorta as well as the coronary arteries, and arteriolar sclerosis evident especially in the renal and retinal vessels Roentgenologic examination of the legs of youthful patients who have diabetes often reveals arteriosclerosis

On general physical examination if a youth is found to have arteriosclerosis he [illegible] examined for evidence of diabetes mellitus Often [illegible]
[illegible]
[illegible] About one fourth of all deaths in diabetes not occurring in coma are due to heart disease which is terminated by coronary thrombosis

Gangrene beginning in the toes, or less frequently in the fingers, is a common complication of diabetes mellitus and arteriosclerosis Gangrene may be instituted by mild trauma such as trimming the toenail or by shaving off too closely a corn with a razor blade Infection follows immediately.

Endocrine Pancreatic Function and the Glucose Tolerance Tests. The fasting blood sugar concentration may be normal in the diabetic individual if there is only mild impairment of the functional activity of the islet cells of the pancreas.

When glucose is ingested, it is rapidly absorbed through the stomach and duodenum The blood glucose concentration rises immediately and reaches its maximal concentration, in the normal person, in about 1 hour and it returns to normal concentration in from 2 to 3 hours.

Glucose tolerance tests consist in measuring the blood sugar level at stated intervals following oral or intravenous administration of a standard dose of glucose.

sugar content despite the fact that the volume of urine is increased. The kidneys in diabetes are often affected. There is an albuminuria. As the renal functional activity decreases there is hyperazotemia and finally renal decompensation and failure

In diabetes the fasting blood sugar may be as low as 130 mg per 100 ml. but is more commonly about 150 mg. In severe diabetes the value for blood sugar may be more than 300 mg In diabetic coma values of 300 to 600 or more mg. per 100 ml are present in some cases. A fasting blood sugar of more than 120 mg. per 100 ml is usually due to diabetes mellitus. In diabetes, normal, low, or high cholesterol values are encountered

There is no correlation between the incidence of acidosis and coma and a high blood lipid value, nor is the degree of the cholesteremia dependent on the severity of the acidosis or on the height of the blood sugar values. In severe diabetes the blood may appear milky, owing to the lipemia, the fat content reaching high values in extreme cases as compared to 0 to 600 mg per 100 ml for the normal.

In mild or moderate degrees of diabetes the basal metabolism is normal. In those whose body weight is within the limits of normal and who have severe diabetes the metabolism frequently is elevated, whereas in patients on reduced fasting diets it usually is reduced below normal

Diagnosis The criteria required for the diagnosis of diabetes mellitus are glycosuria, fasting hyperglycemia (blood glucose concentration of more than 120 mg per 100 ml), and in mild diabetes a diabetic type of glucose tolerance curve

Complications The complications of diabetes may be manifested acutely or chronically In either case the patient may seek medical aid for the complication rather than the disease The acute complications of the disease are mainly ketosis and acidosis

Ketosis (Diabetic Acidosis and Coma). Formerly it was believed that formation of *ketone bodies* was an abnormal metabolic process due to incomplete combustion of fatty acids and that it was necessary to metabolize carbohydrates in order to utilize the ketone bodies completely

Ketone bodies and ketosuria are usually associated with the acidosis of diabetes mellitus Studies carried out by Waters, Fletcher and Mirsky, using a heart-lung preparation, when the amount of glucose and ketone bodies in the blood could be regulated at will, have shown that glucose is not necessary for the metabolism of ketone bodies The fact that insulin can reduce ketosis and still not increase the utilization of ketone bodies in extrahepatic tissue leaves only the possibility that insulin prevents the formation of increased amounts of ketone bodies by the liver

The concept has been brought forth that insulin may be either ketogenic or antiketogenic When insulin is given in such amounts that hypoglycemia results, there is a reduction of the glycogen stores in the liver, since there is a tendency to maintain the glucose level of the blood Concurrent with the low hepatic glycogen there is an increased metabolism of fat by the liver and a resulting ketonemia and ketonuria On the other hand, if insulin is given in amounts sufficient to halt glycogenolysis, there will be an increased carbohydrate utilization by the liver and a resulting decrease in fat oxidation which will reduce the amount of ketone bodies produced. Thus, in man, ketonuria and aglucosuria may be present at the same time, it appears that ketonemia and ketonuria are normal physiologic responses to a lack of carbohydrate and an increased metabolism of fat in the liver

Diabetic acidosis and coma *are the result of accumulation of excess products of intermediary metabolism of protein and fat in conjunction with severe dehydration* and depletion of mineral Immediate causes of acidosis may be inadequate insulin dosage or added insulin requirement during infections, surgical procedures, trauma, vomiting and diarrhea, and thyrotoxicosis

When an inadequate insulin dosage has been administered in the presence of infection, intermediary metabolites of protein and fat combustion are formed in

excess of the capacity to utilize them, and acidosis ensues. The serum bicarbonate concentration decreases as base combines with the acid metabolites, and sodium and potassium are excreted in the urine combined with the acid end products. Progressive acidosis and dehydration further impair the utilization of insulin and hence aggravate the deficiency.

The symptoms of an acidosis consist of progressive weakness, with malaise, headache, and thirst On examination the mucous membranes are dry, the eyes are sunken, the eyeballs decreased in size and soft, and the breath has a sweet odor. Often abdominal pain and muscular cramps due to sodium deficiency may be present. As the acidosis progresses, hyperpnea and the Kussmaul type of respiration appear. The loss of sodium results in severe dehydration with hemoconcentration As the acidosis and dehydration increase, the pulse becomes rapid and feeble, the temperature subnormal and the blood pressure falls. At this point peripheral circulatory collapse and shock quickly ensue At this time leukocytosis is usually present.

Acetone is the first of the ketone bodies to appear in the urine, and then acetoacetic acid and beta-hydroxybutyric acid follow. In those who have renal impairment, large quantities of acid metabolites may accumulate in the serum, causing a marked reduction in the concentration of the serum bicarbonate without the appearance in the urine of appreciable quantities of acid metabolites

A carbon dioxide-combining power of serum of less than 10 mEq. per liter indicates the presence of severe acidosis, with coma A carbon dioxide-combining power of serum between 10 and 20 mEq per liter accompanies moderate acidosis.

Arteriosclerosis and Atherosclerosis Diabetes mellitus is often associated with excessive arteriosclerosis Arteriosclerosis develops in young diabetic adults who have an inadequately controlled diabetes In addition to the deficiency of the hormone insulin, there is a dietary or nutritional factor, related to fat metabolism, which contributes to the development of arteriosclerosis in these young patients.

Postmortem examinations have provided evidence that in young persons who have had diabetes of more than 10 years' duration the lesions of the arteries are of the three common types, namely, calcification and sclerosis of the tunica media of the Monckeberg type, intimal atheromatosis involving the aorta as well as the coronary arteries, and arteriolar sclerosis evident especially in the renal and retinal vessels Roentgenologic examination of the legs of youthful patients who have diabetes often reveals arteriosclerosis

On general physical examination if a youth is found to have arteriosclerosis he is examined for evidence of diabetes mellitus Often the ophthalmologists may be

which is terminated by coronary thrombosis

Gangrene beginning in the toes, or less frequently in the fingers, is a common complication of diabetes mellitus and arteriosclerosis Gangrene may be instituted by mild trauma such as trimming the toenail or by shaving off too closely a corn with a razor blade Infection follows immediately

Endocrine Pancreatic Function and the Glucose Tolerance Tests. The fasting blood sugar concentration may be normal in the diabetic individual if there is only mild impairment of the functional activity of the islet cells of the pancreas.

When glucose is ingested, it is rapidly absorbed through the stomach and duodenum The blood glucose concentration rises immediately and reaches its maximal concentration, in the normal person, in about 1 hour and it returns to normal concentration in from 2 to 3 hours

Glucose tolerance tests consist in measuring the blood sugar level at stated intervals following oral or intravenous administration of a standard dose of glucose.

Concomitant specimens of urine should be analyzed for sugar. Glucose tolerance tests may be carried out by a variety of means. It is advisable to become familiar with one type of test in order to give confidence in the interpretation of results and the factors which tend to modify it

The glucose tolerance test expresses the total disturbances in carbohydrate metabolism without revealing whether the disturbance is due to a failure in hepatic or tissue glycogenesis, inability to maintain a normal blood sugar by glycogen or protein metabolism or an inability of the tissues to utilize glucose.

The glucose tolerance tests commonly used are: (1) the carbohydrate test meal, (2) the standard 1-dose, 3-hour test, (3) the Exton-Rose 2-dose, 1-hour test and (4) the intravenous test.

The carbohydrate test meal is less commonly used

The standard 1-dose, 3-hour test is often modified to extend over only 2 hours. The test is considered negative for diabetes if the blood sugar concentration after the ingestion of glucose returns to normal within 2 hours Under these circumstances the actual height reached by the blood sugar is unimportant. The height of the blood sugar in diabetes usually exceeds 180 mg. of glucose per 100 ml of blood during the test The blood glucose in diabetes remains elevated above normal for more than 2 hours

The urine may contain glucose even though the blood glucose has not exceeded 170 mg. per 100 ml at any time during the test and still the patient not have diabetes In diabetes there is glucose in at least two of the urine specimens

In the Exton-Rose test the blood glucose level in the diabetic patient increases more than 25 mg per 100 ml of blood during the second hour and the blood glucose concentration is more than 160 mg. per 100 ml at the end of the second hour The urine of a diabetic patient usually contains sugar

After 0 5 gm of glucose per kilogram of body weight administered intravenously in a 20 per cent solution to a diabetic patient the blood sugar concentration remains above normal for more than one and one half hours.

The errors of interpretation of any of the glucose tolerance tests are many and variable These may be enumerated as: (1) Failure to perform test on a *fasting* individual. In such an instance there is a glucose concentration which exceeds the upper limits of normal of 120 mg per 100 ml (2) A restriction of carbohydrates in the diet prior to the test dose of carbohydrates will produce an abnormally high hyperglycemia and a glycosuria in a normal individual On the contrary a diet high in carbohydrates prior to the test dose of carbohydrate will decrease the degree and the prolongation of the hyperglycemia F [illegible]
a more marked hyperglycemia when the [illegible]
rich in carbohydrate If there is any dou [illegible]
taining 80 gm of protein and 300 gm of carbohydrate for 3 or 4 days prior to the test (3) When there is a question of the factor [illegible] there is in some the test may be diagnostically helpful in a negative [illegible] the usual hyperglycemia after the test dose of carb [illegible] tion is being tested when there is a suspected failure of intestinal absorption the *intravenous test should be administered* (4) *Endocrine dys*functions other than that of pancreatic failure may cause aberrations in response to the test doses of carbohydrate For example, hyperpituitarism gives a response like that of diabetes, while [illegible] of an increased glucose toler- [illegible] est should be avoided Exer- [illegible] emia is not necessarily due to [illegible] ive glycogenesis in the liver and tissues or a protein disturbance when the glycogen reserve is decreased.

Hypoglycemia in the Infant. The diabetic mother may pass on to her *child* an innate susceptibility to diabetes In addition to this the newborn of the diabetic mother may suffer from attacks of hypoglycemia and require early and frequent feedings or the injection of glucose The weight of the infant, unless the child is excessively small,

does not influence the mortality rate, which is about four times as great among infants of diabetic mothers as among those of nondiabetic mothers

Postoperative Convalescence. Postoperatively the diabetic patient is exposed to the risk of acidosis, necrosis of tissue, hypoglycemia due to overdosage with insulin, and the complications of arteriosclerosis. It is advisable to administer about two thirds of the usual dose of protamine-zinc insulin on the morning of the operation. After operation, crystalline or regular insulin is given every 4 to 6 hours in doses determined by the findings in the urine or preferably by the blood-glucose levels Lesions requiring surgical intervention, as well as the operation itself, increase the patient's insulin requirement.

The principal cause of death in operations on diabetic patients is arteriosclerotic heart disease

Nonpancreatic Melituria and Other Reducing Substances in the Urine. Following the ingestion of a meal there occurs in the urine of normal persons an increase in reducing substances. This *glycuresis* is due to the excretion of small quantities of glucose and unassimilable carbohydrate with its decomposition products

Following the ingestion of abnormally large quantities of cane sugar, glucose or starch, a certain proportion of normal persons show an appreciable glycosuria which is of no clinical significance This form of glycosuria is termed *alimentary glycosuria*

Transient glycosuria may occur in thyrotoxicosis as well as marked anxiety states and after the intravenous administration of glucose

Glucose is found in the urine of 10 to 20 per cent of pregnant women Since diabetes mellitus may first manifest itself during pregnancy, it is essential to check the fasting level of blood sugar in every case of pregnancy glycosuria and to follow the course of the glycosuria after gestation

Glycosuria occurs frequently in patients who have acute nephritis, nephrosis, and nephrosclerosis In the late stages of diabetes and nephrosclerosis, relatively high values for blood sugar may appear

During lactation the urine may contain appreciable quantities of *lactose*. *Galactose* may be present in the urine after the ingestion of galactose Occasionally it is observed in nursing babies who have gastrointestinal dysfunction

Fructosuria is most likely to be detected following the ingestion of large quantities of this sugar, particularly in the presence of hepatic insufficiency Essential fructosuria is a rare inborn error of metabolism associated with constant levulosuria and without apparent disturbance in the metabolism of other carbohydrates Fructose may appear in the urine in conjunction with glucose in diabetes mellitus.

Pentosuria most commonly occurs as a transient melituria following the ingestion of large quantities of plums, prunes, cherries and grapes In rare instances essential pentosuria occurs as an inborn error of metabolism which appears to be hereditary in nature It is of no significance

The diagnosis of the type of melituria, that is, the specific sugar which is being excreted, requires the use of complex and expensive laboratory procedures. In the presence of a normal blood sugar concentration with history suggestive of some one of the foregoing conditions having been extant, melituria due to a sugar other than glucose can be fairly safely diagnosed provided undue retention of the urine in the bladder is excluded and insulin had not been administered prior to the urine test.

Renal Disease and Glycosuria. In contrast to the innocent renal glycosuria there are glycosurias due to renal disease In various types of renal disease the tubular capacity to reabsorb glucose may be lowered as it is in benign renal glycosuria Usually, however, glomerular filtration is decreased proportionately, and hence there is no glycosuria If the tubules are principally affected, glycosuria will appear The elderly diabetic patient will manifest a lesser degree of glycosuria at a given blood sugar concentration than the younger patient This is because of the

greater frequency of nephrosclerosis in the aged. *Renal factors* must thus be tak into account in evaluating the significance of glycosuria in a given patient

Renal Diabetes (Diabetes Innocens). The renal threshold for glucose in th normal individual varies from 150 to 180 mg. per 100 ml. of blood. The averag value is 160 mg per 100 ml. of blood. In diabetes mellitus the threshold may b raised and may reach 200 or more mg per 100 ml. of blood. In renal glycosur glucose may appear in the urine in the presence of a blood glucose concentratio which is within the range of the normal.

Glycosuria occurring when the blood glucose is within the range of the norm has been termed renal diabetes, diabetes innocens, or benign diabetes, in which th level of blood sugar is normal in the fasting patient In some patients the value fo blood sugar rises above the renal threshold for glucose but the glucose is quickl excreted in the urine while in others the glucose is excreted immediately even a normal blood glucose concentrations.

Renal glycosuria generally is regarded as a rare disorder Among young adul examined for induction into the army, however, Blotner and Hyde found 33 in stances of renal glycosuria among 367 who had glycosuria, an incidence of 9 pe cent

Renal glycosuria may occur at any age There is a high incidence of diabetes i the families of patients manifesting renal glycosuria, but no case in which this benig condition progressed to diabetes has been reported

The glucose tolerance curve permits the differentiation of glycosuria of rena origin from that of diabetes. In renal glycosuria the glucose tolerance curve i normal.

The glycosuria following the intravenous administration of glycose is not be to considered either a renal glycosuria or diabetes mellitus. It is due to the norma renal threshold for glucose having been exceeded as the result of the administration of glucose

The prognosis of renal glycosuria is good, with normal life expectancy The amount of sugar lost in the urine is relatively slight and hence does not induce any evidence of malnutrition.

Reducing Substances in the Urine. The copper-bearing solutions used in the analysis of urine for sugars may be reduced by substances in the urine other than sugars Among the many substances which may cause this false positive reaction on analysis of the urine may be mentioned, excessive amounts of uric acid, nucleoprotein and conjugate glycuronates which may be formed after the administration of camphor, chloral hydrate, salicylates, pyramidon (aminopyrine) and sometimes morphine Reducing substances may appear in the urine after the ingestion of various poisons and particularly in poisoning by the phenols The administration of chloroform may produce reducing substances in the urine.

In practice, reducing substances in large quantities in the urine of a patient not receiving medication and who has not been poisoned may be considered to be sugar Every patient who has a melituria is to be considered a diabetic until proved not to have diabetes

Hyperinsulinism. Hyperinsulinism implies an excessive secretion of insulin by the pancreas resulting in hypoglycemia The common example of hyperinsulinism

ensuing

ac-

see

).

with symptoms of varying intensity. There are feelings of hunger, apathy or confusion The patient may be irritable and hysterical and quickly lapse into unconsciousness

... is seen in the early stages of the reaction he appears pale and weak

with moist skin and trembling muscles The pulse is full and rapid and the blood pressure is often increased There is a hypoglycemia. The response to the administration of glucose is rapid.

Insulin shock, when unconsciousness is present, is differentiated clinically from diabetic coma by the moist, pale skin, normal consistency of the eyeballs by touch, muscle tremors, normal respirations, full pulse and hypoglycemia The most important diagnostic procedure may be a search of the personal effects of the patient for *a card indicating that the patient is a diabetic*

Analysis of the urine may not be helpful for the urine may or may not contain glucose.

Spontaneous Hypoglycemia (*Hyperinsulinism*) Spontaneous hypoglycemia occurs in association with islet cell adenomas, adenocarcinomas and in functional or organic disease which may be caused by disturbances in the adrenal glands, liver, pituitary, thyroid, thymus, muscular system or nervous system, as well as by exercise, undernutrition, lactation and other conditions in addition to altered production of insulin.

Hypoglycemia-like symptoms associated with neurosis occur relatively frequently In these neurotic patients there is the emotional instability and a psychoneurosis. The fasting blood sugar concentration is within normal limits. The attacks, which occur usually before meals, can be relieved by remedies which have no pharmacologic potency. The neurotic patient does not have attacks during the night unless the patient knows that such are supposed to occur

Adenomas of the islet cells (islets of Langerhans) are rare. There are only a few proved cases of these tumors Even if these tumors are present, it is averred that only 2 of every 10 persons who have nesidioblastomas (islet cell tumors) have symptoms When present, these tumors are numerous and widely dispersed through the pancreas The mass of islet cell adenomas in an affected pancreas may exceed the mass of islet cells in the normal pancreas Likewise the insulin concentration in these abnormal cells is from 4 to 40 times the amount of insulin per unit of weight of normal pancreatic tissue Adenomas have no sex or age preferences The malignant islet adenomas lack encapsulation and have microscopic evidence of invasion, the presence of tumor cells in the blood vessels, and metastasis

Malignant insulinomas often occur in persons from 15 to 20 years of age The associated hypoglycemia tends to be severe and difficult of management The attacks occur frequently, can be precipitated easily by withholding food, and tend to increase in intensity.

The malignant character of the islet cell tumors which have been diagnosed as malignant on the basis of their histologic appearance is not always borne out by the duration of the life of the patient. In a few instances these patients have lived for 10 years after removal of a large part of the pancreas without recurrence of symptoms

In those who have adenomas or adenocarcinomas of the islet cells of the pancreas there are pathologic changes in the brain consisting of capillary dilatation, scattered small hemorrhages, perivascular infiltration of lymphocytes, atrophy of the cortex with degeneration of the ganglion cells, and swelling of the glia and axis cylinders

SYMPTOMS Tumors of the islets of Langerhans may exist without any clinical indication that they are present When these islet cell adenomas make their presence known, there are hyperinsulinism and a characteristic syndrome of hypoglycemia, very much the same as that produced by an overdose of insulin or the reaction from epinephrine

Characteristically the attacks appear in the early morning hours before breakfast, or during the day, after some undue physical exertion, or after postponement of a meal The patient volunteers the information that eating prevents the attacks and affords immediate relief from symptoms The spontaneous hypoglycemic syndrome begins with an acute attack of exhaustion and fatigue which may increase rapidly in severity until there is loss of consciousness, or until there are convulsions, or both

greater frequency of nephrosclerosis in the aged. Renal factors must thus be taken into account in evaluating the significance of glycosuria in a given patient.

Renal Diabetes (Diabetes Innocens). The renal threshold for glucose in the normal individual varies from 150 to 180 mg. per 100 ml. of blood. The average value is 160 mg. per 100 ml. of blood. In diabetes mellitus the threshold may be raised and may reach 200 or more mg. per 100 ml. of blood. In renal glycosuria glucose may appear in the urine in the presence of a blood glucose concentration which is within the range of the normal

Glycosuria occurring when the blood glucose is within the range of the normal has been termed renal diabetes, diabetes innocens, or benign diabetes, in which the level of blood sugar is normal in the fasting patient. In some patients the value for blood sugar rises above the renal threshold for glucose but the glucose is quickly excreted in the urine while in others the glucose is excreted immediately even at normal blood glucose concentrations.

Renal glycosuria generally is regarded as a rare disorder Among young adults examined for induction into the army, however, Blotner and Hyde found 33 instances of renal glycosuria among 367 who had glycosuria, an incidence of 9 per cent.

Renal glycosuria may occur at any age. There is a high incidence of diabetes in the families of patients manifesting renal glycosuria, but no case in which this benign condition progressed to diabetes has been reported.

The glucose tolerance curve permits the differentiation of glycosuria of renal origin from that of diabetes. In renal glycosuria the glucose tolerance curve is normal.

The glycosuria following the intravenous administration of glycose is not be to considered either a renal glycosuria or diabetes mellitus. It is due to the normal renal threshold for glucose having been exceeded as the result of the administration of glucose

The prognosis of renal glycosuria is good, with normal life expectancy The amount of sugar lost in the urine is relatively slight and hence does not induce any evidence of malnutrition.

Reducing Substances in the Urine. The copper-bearing solutions used in the analysis of urine for sugars may be reduced by substances in the urine other than sugars Among the many substances which may cause this false positive reaction on analysis of the urine may be mentioned, excessive amounts of uric acid, nucleoprotein and conjugate glycuronates which may be formed after the administration of camphor, chloral hydrate, salicylates, pyramidon (aminopyrine) and sometimes morphine. Reducing substances may appear in the urine after the ingestion of various poisons and particularly in poisoning by the phenols. The administration of chloroform may produce reducing substances in the urine

In practice, reducing substances in large quantities in the urine of a patient not receiving medication and who has not been poisoned may be considered to be sugar. Every patient who has a melituria is to be considered a diabetic until proved not to have diabetes.

Hyperinsulinism. Hyperinsulinism implies an excessive secretion of insulin by

If the patient is seen in the early stages of the reaction he appears pale and w[illegible]

Unless there are special symptoms, such as those occurring in some instances of islet cell adenomas, the clinician is often unaware of the presence of these benign pancreatic tumors until the symptoms from pressure arise or he finds a tumor on physical examination.

Benign Tumors. Benign tumors of the pancreas usually are discovered at necropsy without having produced any known symptoms. These tumors are adenomas (islet cell), fibroadenomas, fibromas, lipomas, myxomas, chondromas, and benign cysts.

The cystic tumors of the pancreas comprise a group of uncertain genealogy as to whether they arose as cysts or whether they are true tumors with secondary cystic degeneration

Pancreatic cysts may present themselves as symptomless tumors in the mid or left epigastric regions or as tumors in this situation producing pressure symptoms These cysts are important sources for pancreatic fistulas after they have been marsupialized by the surgeon.

The *large cystic tumors* which compress adjacent structures will eventuate in death unless they are removed There is always the possibility, too, that malignant change may occur or has occurred Any tumor of the pancreas is suspected as being malignant until definite information to the contrary is available

Benign pancreatic cysts often develop after trauma, obstruction of pancreatic ducts, or pancreatitis Pratt estimated that precedent trauma is the basic etiologic agent in one third of all pseudocysts. Obstruction of the pancreatic ducts by calculi, gallstones, swollen lymph nodes and *Ascaris lumbricoides* may be a causative factor.

An acute pancreatitis in association with hemorrhage and necrosis is believed to be the basic factor in the production of many pseudocysts and degeneration cysts, or hemorrhagic cysts In 47 cases of pancreatic cyst, Judd was able to identify an associated pancreatitis in 4 Pancreatitis with contraction of fibrous tissue may be capable of producing obstruction of ducts and thus causing the ensuing dilatation—a mechanism operative in cystic fibrosis of the pancreas present at birth

The factor of cholecystitis in the production of cysts is, like many of the other supposed etiologic factors, difficult to elaborate Judd, Mattson and Mahorner found that only 16 of 47 of their patients gave any evidence of cholecystitis and that 13 of these 16 had only gallstones

The proliferative cysts are adenomatous tumors which have an inherent tendency to form a cyst or which for some reason undergo degeneration and liquefaction

Congenital cysts of the pancreas may be present in association with polycystic disease of the kidneys and liver In rare instances an isolated dermoid cyst may be found

Pathologists classify pancreatic cysts as (1) proliferative cysts (cystadenomas), (2) retention cysts, (3) cystic fibrosis of the pancreas, (4) congenital cysts, (5) degeneration cysts and (6) parasitic cysts and pseudocysts.

Cysts in the pancreas vary in size and number They have smooth surfaces and seem, at times, to be easily ruptured Their contents are as variable as the origins of cysts themselves Pancreatic cysts often remain symptomless for a long time before the patient seeks help Some of the patients reported by Judd had had pancreatic cysts more than 20 years

The symptoms may commence with an awareness of slight discomfort and fullness in the upper part of the abdomen for a long time before there is pain. Nausea, vomiting, and constipation develop, and loss of weight ensues The patient is aware that the pain increases in severity as the girth of the abdomen increases.

As the cyst enlarges there may develop jaundice, ascites, edema of the lower extremities, and intestinal or ureteral obstruction Dyspnea may be present when the cyst is large Destruction and compression of the surrounding pancreatic tissue may

The many symptoms may be enumerated as sweating, flushing, pallor, chilliness. trembling, dizziness, weakness, and palpitation of the heart. During the attack often there are hunger, nausea and epigastric pain The abdominal pain may mimic, and is occasionally thought to be, the pain of peptic ulcer.

In some the central nervous system is profoundly affected. The manifestations are headache, restlessness, dysarthria, diplopia, tonic or clonic muscle spasms, convulsions, hyperreflexia, bilateral plantar extension, and, in extreme instances, coma and death The psychiatric components may comprise emotional instability, fear, disorientation, irritability, automatic behavior, negativism, delirium, mania, amnesia and stupor or unconsciousness. Severe attacks of disturbance of the central nervous system may leave residual headache and spasticity; occasionally palsy or an abnormal mental state will persist for a period after subsidence of an attack Generally the changes due to the nervous system are reversible on treatment.

Examination Physical examination, except during the attack, reveals no abnormality referable to hyperinsulinism During an attack the concentration of blood sugar is usually less than 50 mg per 100 ml and frequently is less than 30 mg (Wilder) The value for fasting blood sugar in these patients often is normal but tends to be decreased

The application of the usual tests of hepatic function will serve to aid in the recognition of most cases with hypoglycemia secondary to hepatic derangement. The glucose tolerance curve in hepatic disease is of the high plateau type, similar to that seen in diabetes mellitus Roentgenologic examination may reveal a duodenal ulcer when symptoms are suspected as being related to this disease

The glucose tolerance test in the diagnosis of organic hyperinsulinism reveals variable results and its value is doubtful The value for fasting blood sugar gives more information than that of glucose tolerance tests A glucose tolerance test may show a subnormal fasting blood sugar. The blood sugar concentration rarely exceeds *120 mg per 100 ml during the test The blood sugar returns to subnormal* values within two hours, and its maintenance at low levels, usually throughout 3 to 6 hours after the test, is often observed The detection of an accelerated rate of removal of *glucose from the blood stream is diagnostically important In an adverse way the* glucose tolerance test may be of diagnostic importance, for in an hour or two after [illegible] occur

[illegible] *y the presence of a* blood sugar concentration of less than [illegible] mg per 100 ml of blood, or less than 40 mg per 100 ml. following restriction of carbohydrates or fasting plus exercise or during a spontaneous attack of hypoglycemia The *symptoms of hypoglycemia* are relieved by sugar, preferably given intravenously, and without the patient's knowledge of what is injected. In hyperinsulinism the glucose tolerance curve rises from hypoglycemic concentrations (60 mg per 100 ml of blood or less) to attain a concentration not in excess of 120 mg per 100 ml, falls again to subnormal levels within 2 hours and maintains the subnormal levels for from 3 to 6 hours. Hyperinsulinism is characterized by a progressive course, the attacks becoming more frequent and severe.

The preferred treatment is surgical removal Even in the presence of metastasis this may be required if for no other reason than for temporary *alleviation of the* hypoglycemia In some patients, however, the metastatic cells independently elaborate insulin, and the attacks of hypoglycemia will continue unabated even though the primary focus has been removed

TUMORS OF THE PANCREAS

There are benign tumors and primary and secondary malignant tumors of the pancreas, as well as a middle group of tumors of questionable genealogy and potentialities.

In an occasional case there will be minimal or no local symptoms of carcinoma of the pancreas. Recurring venous thrombi in various parts of the body begin to take place and their discovery initiates search for a primary malignant lesion which may be found in the pancreas

Examination. The liver is usually palpable Some enlargement of the liver is due to engorgement, and often hepatic metastasis is present. A distended gallbladder can be palpated clinically in about one half of these patients and the enlarged liver has no implications in regard to the presence or absence of jaundice The pancreas is relatively inaccessible to palpation A pancreatic mass is not commonly palpated. Splenic enlargement is rarely present

Ascites may develop as a result of (1) metastasis to the peritoneum or liver, and (2) thrombosis of the portal vein or (3) compression of the portal vein by lymph nodes or by malignant tissue

The disturbance of carbohydrate metabolism if present is manifested by glycosuria or hyperglycemia or by an impaired glucose tolerance, which is present in 4 of every 10 cases of primary pancreatic carcinoma. A combination of glycosuria, hyperglycemia and an impaired glucose tolerance may be demonstrated in 1 of every 3 cases.

The traditionally large, bulky, fermenting, fatty or greasy stools are seldom observed

Comfort and Osterberg employed determinations of both serum amylase and lipase. In their experience the serum lipase concentration was elevated in 40 per cent, while the serum amylase concentration was elevated in only 8 per cent of cases of carcinoma of the pancreas

Pancreatic secretion obtained with the use of a double-lumen gastroduodenal tube after the administration of secretin, mecholyl, or insulin will demonstrate some impairment in pancreatic secretory function There are diminished concentration of one or more of the enzymes, and reduction in total volume of secretion and lessened concentration of bicarbonate

In jaundiced patients the serum bilirubin concentration may have some value *in the differential diagnosis of pancreatic carcinoma and choledocholithiasis* In carcinoma the concentration is usually consistently greater, whereas in choledocholithiasis the concentration of bilirubin in the blood frequently fluctuates widely during a brief period of observation

Diagnosis A definite diagnosis can only be established by biopsy at the time of exploratory operation if the surgeon wishes to obtain the tissue, or by necropsy The roentgenologic examination of carcinoma of the pancreas yields indirect signs produced by the neoplasm on adjacent structures, particularly the duodenum

The diagnosis is often difficult and almost always is presumptive. It is particularly difficult when jaundice is not present or when either the body or the tail of the pancreas is predominantly involved The importance of demonstrating some impairment of carbohydrate metabolism and the value of roentgenograms and of determinations of concentration of pancreatic enzymes in the blood must be given due consideration When present, symptoms of painless jaundice, palpable distended gallbladder and fatty stools are significant

Carcinoma of the pancreas is a rapidly progressive disease. Death occurs on the average in 7 months after the first appearance of symptoms.

Sarcoma. Primary sarcomas of the pancreas are rare. These tumors commonly are solid Some are cystic The contents of the cysts are hemorrhagic and the walls are covered with bleeding nodular projections Apparently there is no predilection for any one part of the gland Local growth is rather rapid and the tumor may attain considerable size Metastatic extension, however, is not so widespread as in carcinoma The age incidence is similar to that of carcinoma and there is the same preponderance in males.

cause symptoms of pancreatic insufficiency consisting of large and bulky bowel motions which contain excess fat. In a few the symptoms of diabetes are present.

On examination there may be present an epigastric tumor, the size of which varies greatly; some tumors are so large as to occupy the greater part of the abdominal cavity. In 95 per cent of Judd, Mattson and Mahorner's patients the tumor was palpated above the umbilicus. Most cysts are spherical or dome-shaped with a smooth surface On palpation they are firm and resistant, but often fluctuation can be detected. As a rule, the mass does not move with respiration. On percussion the cyst will be flat with a zone of tympany intervening between it and the liver.

Roentgenologic examination, when due consideration is allowed for the history and the findings on physical examination, is frequently diagnostic However, a definite diagnosis can be made only on the basis of histologic study The diagnosis of pancreatic cysts is considered whenever there is present a tumor in the epigastric region of a middle-aged or an elderly patient, which has slowly enlarged and is not tender on palpation. Rarely are these tumors fluctuant to a detectable degree on palpation

The prognosis in most cases after surgical treatment of pancreatic cysts is good. If marsupialization is performed, a fistula may follow.

Malignant Tumors. *Carcinoma.* Of all the tumors of the pancreas, including benign and malignant growths, carcinoma is the commonest It is not a rare disease of middle-aged and aging individuals.

Most often the lesion is a scirrhous carcinoma, hard, nodular, and fixed on palpation, and of fibrous appearance when viewed grossly. These tumors are situated predominantly in the body and tail of the gland and tend to extend to massive involvement and to metastasize more widely than do the more rarely situated carcinomas of the head of the pancreas Carcinomas situated in the head of the pancreas often involve the lower end of the common duct, surrounding and compressing it, and invade the duodenum, the stomach and the colon.

The most frequent spread is to the liver through the portal vein From the liver the venous drainage may carry the cancer cells to the lungs and thence systemically to the adrenals, kidneys, spleen, bones and other structures including the brain. The posterior surface of the body of the pancreas lies directly over the celiac plexus and is immediately adjacent to the nerves entering and emerging from this plexus Severe abdominal pain may originate from extension along nerve sheaths.

SYMPTOMS Pancreatic carcinoma occurs most commonly in men in the sixth decade of life. It does occur in women and even in persons less than 20 years of age It has no racial preferences. Onset of symptoms of carcinoma of the pancreas may be ushered in by thrombophlebitis in a patient who has never had any venous trouble in the legs In most cases, however, the initial symptom is abdominal pain Commonly the disease commences with the so-called painless jaundice. However, patients who have so-called painless jaundice often suffer from varying degrees of pain.

Eusterman and Wilbur described the pain in their patients as follows of epigastric situation, extension around to the back, dull aching character, moderate severity, constant, steady progression, exaggeration at night and no relationship to normal events of the digestive cycle There is no constant type or location of pain which can be considered peculiar to pancreatic carcinoma The disease may begin with severe pain simulating that of acute cholecystitis or the pain of peptic ulcer The common complaints, such as loss of weight, anorexia, weakness, vomiting, diarrhea, and constipation are irregularly present

In some cases nausea and vomiting, suggestive of intestinal obstruction, are among the earliest manifestations of a primary pancreatic neoplasm In other cases local symptoms and signs are preceded by persistent diarrhea. Whenever a persistent diarrhea which cannot be accounted for afflicts a person of middle age, carcinoma of the pancreas should be suspected.

pause. A deficiency of the thyroid hormone tends to cause dysfunction of the reproductive system, inhibits estrus and counteracts the effects of estrone.

In the presence of thyroid deficiency there is an accumulation of water in the intracellular spaces. The administration of thyroid causes diuresis in the hypothyroid individual.

There is retention of calcium in hypothyroidism In hyperthyroidism, on the administration of thyroid there is an increased excretion of calcium and of phosphate without affecting the concentrations of the serum calcium and phosphorus However, in prolonged hyperthyroidism osteoporosis may be present

In the normal person administration of iodine stimulates the thyroid, whereas [illegible] paradoxical [illegible] the action [illegible] absence of nervous connections It has been assumed, however, that the apparent nervous control is mediated through the hypothalamic centers of the autonomic nervous system and thus in disease may affect the function of the gland

Diseases of the Thyroid Due to Congenital Malformations. The thyroid occasionally is involved in developmental defects The gland may be absent, as in sporadic cretinism. The thyroglossal tract, which normally is absorbed in early fetal life, may persist and give rise to thyroglossal cysts A high percentage of cures follows the radical excision (Sistrunk) of the entire thyroglossal tract (see Diseases of the Neck, Chapter 5)

Aberrant thyroid tissue may occur at the foramen cecum, where the thyroglossal duct normally ends, in interrupted masses along the original path of the duct, or in the thoracic cavity The last-named site must be kept in mind in cases of thyrotoxicosis in which there is no evidence of cervical enlargement Thyroid tissue may also be present in the ovary as the so-called ovarian struma Like the normally located gland, ectopic thyroidal tissue may give rise to hyperthyroidism

Cysts of the thyroid may be of congenital origin but they usually arise from hemorrhage into a follicle or from degenerative changes in an adenomatous nodule. *Hemorrhage* into a cyst, on the other hand, may result in thyroid apoplexy. In regions where nodular goiter is common, hemorrhages may occur early in life In older patients atherosclerotic changes may often be demonstrated in the arteries Rupture of these damaged thyroid vessels with resultant acute severe hemorrhage is uncommon but well recognized In their more severe form these hemorrhages are the principal cause of cyst formation The content of the larger cysts, and particularly of those developing within the mediastinum, is high in iron and low in iodine, indicating the hemorrhagic origin In hemorrhage into the thyroid gland there is a rapidly developing tumor, often there are fever and fast pulse if the hemorrhage be large In large hemorrhages pressure symptoms with resulting suffocation may develop and death ensue

Thyroiditis. Thyroiditis may occur as an acute, a subacute or a chronic infection occurring most commonly in middle aged women and rarely in men and children

Acute Thyroiditis. Inflammation of the thyroid gland is rare. When it does develop, it is usually during the course of acute infectious processes The gland becomes tender, enlarged, and may cause dyspnea and dysphagia. The inflammation usually subsides without suppuration or abscess formation

Subacute Thyroiditis. Subacute thyroiditis is a self-limited inflammation of the thyroid gland which may be initiated by a viral infection and prolonged by a granulomatous reaction to displaced or perverted colloid

In the past, subacute thyroiditis rarely was diagnosed, and therefore its true morbidity is not known In recent years it seems to have been diagnosed more frequently than formerly, but whether the greater number of diagnoses represents an

In general the symptoms are essentially those of carcinoma. Pain comprises the outstanding symptom, and jaundice is both a later appearing and less common manifestation. The tumor appears to be palpable oftener than is carcinoma. The other clinical, laboratory and roentgenologic features are no different from those observed in carcinoma and the course is as rapidly progressive

The diagnosis of sarcoma of the pancreas is made on the basis of biopsy or necropsy study. The prognosis is the same as that for carcinoma of the pancreas.

Malignant Cysts. *The relative incidence of malignant and benign pancreatic* cysts is about 1 malignant cyst for every 9 benign cysts True papillary cystadenocarcinoma is extremely rare in the pancreas Malignant cystic disease of the pancreas occurs equally in men and women in middle life The average age is 53 years.

If a pancreatic cyst displays a rapid increase in size or is unusually painful, *malignant change should be suspected*

On examination the most prominent finding is the presence of a large tumor. Within a short time re-examination reveals that the tumor is progressively increasing in size and is not tender. Loss of weight is an outstanding symptom.

The diagnosis is established by biopsy or necropsy studies The treatment is surgical Palliative marsupialization may be necessary when extirpation is impossible.

THE THYROID GLAND

The thyroid gland is a large, ductless organ in front of and on each side of the trachea *It is made up of two lateral lobes and an isthmus which unites the lobes below.* The gland is enclosed in a thin envelope of connective tissue, and is composed of a number of closed follicles, or alveoli, which usually are filled with colloid material, and are surrounded by a network of vessels which is supported by the interstitial connective tissue.

The average adult thyroid contains about 10 mg. of iodine. Iodine exists in the gland as inorganic iodide, 10 per cent, diiodotyrosine (precursor of thyroxin), 60 per cent: and thyroxin (the active principle of the gland) 30 per cent, which is elaborated by the thyroid directly into the blood

The secretion of thyroxin is regulated by the concentrations of thyroxin and iodides in the blood, by the thyrotropic hormone of the anterior pituitary gland and by the action of the sympathetic division of the autonomic nervous system

The selective absorption of iodides from the blood is well demonstrated by the administration of radioactive iodine (usually I^{131}) in a dose equivalent to the amount of iodide contained in a normal daily diet. The iodide is rapidly absorbed from the intestine and passes into the plasma, from which it is selectively taken up by the thyroid gland Often 20 per cent of the administered radioactive iodide will be in the thyroid at the end of 6 hours. A normal thyroid will collect 80 times more of the radioactive iodide than will other tissues of the body A hyperplastic gland may collect 2 to 4 times as much radioactive iodide as that collected by the normal gland There is a maximal point of absorption beyond which the thyroid will not absorb more iodide despite its concentration in the blood In myxedema the iodide uptake is negligible.

Thyroxin *objectively affects metabolism, circulation, muscles, reproductive organs,* and water metabolism and calcium exchange.

The administration of desiccated thyroid causes a *disturbance of the heat-regulating* center in the hypothalamus. The alimentary tolerance for glucose is diminished, as evidenced by the fact that glycosuria may follow the ingestion of a large dose of carbohydrate. Fat metabolism also is affected

The administration of thyroid extracts stimulates the circulation The increased circulatory rate is a reflex response to the increased metabolism. The cardiac output is increased with a generalized increase in the blood flow through the periphery.

Large doses of thyroid induce progressive muscular changes and, finally, muscular atrophy.

The size of the thyroid gland and its iodine metabolism increase at puberty, during menstruation and in pregnancy. The gland decreases in size after the meno-

ency of the thyroid hormone tends to cause dysfunction of the repro-
, inhibits estrus and counteracts the effects of estrone.

Thyroiditis. Subacute thyroiditis is a self-limited inflammation of
.and which may be initiated by a viral infection and prolonged by a
.s reaction to displaced or perverted colloid
st, subacute thyroiditis rarely was diagnosed, and therefore its true
ıot known In recent years it seems to have been diagnosed more fre-
formerly, but whether the greater number of diagnoses represents an

actual increase in the frequency of the disease, or whether it is due to better recognition, is not known.

It has been observed that subacute thyroiditis sometimes follows infections of the upper part of the respiratory tract, measles, malaria, and scarlet fever. The prolonged chronic inflammatory process observed in the thyroid gland may be the result of a foreign body reaction to colloid which escapes into tissue spaces when the cells lining the follicles are damaged by infection.

Subacute thyroiditis occurs most commonly in patients between 30 and 50 years of age. In Crile and Rumsey's series the mean age was 42 years. Only 5 of the 38 patients were men.

The inflammatory reaction usually involves the entire thyroid gland but may affect only a portion of a lobe The occurrence of subacute thyroiditis in an adenomatous or a previously abnormal gland is unusual.

There is moderate enlargement of the thyroid up to two or at most three times its normal size The capsule is thin and pale On cut section the involved region is seen to be abnormally white, avascular, and hard but pliable. Pathologically, subacute thyroiditis is differentiated from Riedel's struma by the fact that in the latter disease there is extensive involvement of all the surrounding structures In subacute thyroiditis the inflammatory process is limited to the thyroid gland

SYMPTOMS. The symptoms of subacute thyroiditis are variable, but Crile and Rumsey have separated the manifestations into two categories: (1) the acute fulminating type with fever, pain, exquisite thyroid tenderness and severe systemic symptoms, and (2) the chronic type, with little if any fever, slight pain, slight tenderness and insignificant systemic symptoms

Between these two extremes there are many forms which present all combinations and degrees of local and systemic reactions. Subacute thyroiditis is essentially a self-limited disease which eventually subsides without demonstrable damage to the thyroid

The symptoms commence with fatigue, weakness and lassitude. Temperatures often rising to 101 F (38.3 C), and occasionally to 104 F (40 C), accompany the acute phase, and a low-grade fever may be prolonged for weeks or even months Night sweats, chills, and loss of body weight may occur Patients may experience symptoms of pressure resembling globus hystericus, and may complain of unusual nervousness, tremor, weakness, excessive perspiration, heat intolerance and palpitation

During the acute phase of the disease a sore throat, pain on swallowing, and exquisite tenderness of the thyroid are experienced Pain usually extends behind the ear on the affected side and occasionally to the occiput, face or jaw Occasionally the pain may be so severe in the jaw or the throat that teeth may be pulled or tonsils removed in attempts to give relief

EXAMINATION. The thyroid gland is firm, tender, and usually diffusely enlarged to one and one-half or two times its normal size, but it is readily palpable because of its hardness In some the firmness and tenderness may appear as a localized process involving only the isthmus or part of a lobe On subsequent examinations [illegible]

ness at the onset

The pulse rate is uniformly elevated in the acute form of subacute thyroiditis but in the chronic type may be normal

The sedimentation rate of the blood is said to be extremely high. In subacute thyroiditis the thyroid takes up little or no radioactive iodine. Other laboratory tests are of little value The leukocyte count is not elevated The basal metabolic rate is not materially affected, but occasionally it will be increased In three fourths of the cases the basal metabolic rates are in the normal range of —10 to +10 per cent.

DIAGNOSIS. The diagnosis of subacute thyroiditis is predicated on the finding of a firm and tender thyroid gland during or subsequent to infections of the upper part of the respiratory tract, measles, malaria and scarlet fever. When the entire gland or one entire lobe is uniformly involved, the diagnosis usually is clear In the chronic phase, however, and especially when the thyroid is asymmetrically involved, it is difficult to establish the diagnosis unless there is a history of sore throat, persistent pain in the ear or jaw, or pain and tenderness over the thyroid gland at the onset of the disease. The presence of systemic symptoms further confirms the diagnosis.

Needle Biopsy. The diagnosis in questionable or obscure instances, according to Crile, may be greatly facilitated by biopsy Employment of the Vim-Silverman liver-biopsy needle has obviated the need for surgical exposure of the thyroid

Chronic Thyroiditis. Chronic thyroiditis is a rare condition occurring almost exclusively in middle-aged or elderly women.

Three types of chronic thyroiditis are recognized (1) In *Hashimoto's goiter* there is atrophy of the acini of the thyroid gland with replacement of the parenchymatous cells by a diffuse infiltration of lymphocytes This invasion of the thyroid by lymphocytes is only an exaggeration of what occasionally is seen in normal glands and commonly is found in exophthalmic and simple goiters The lymphocytes appear to fill regions in which degeneration or involution of the follicles occurs This form of thyroiditis responds well to irradiation (2) In *Riedel's goiter* there is replacement of the normal acinar tissue by dense fibrous connective tissue The gland becomes hard and may give symptoms due to pressure on the trachea and esophagus (3) In *struma fibrosa* there is fibrosis of the gland secondary to an acute or a chronic inflammatory process. The condition is characterized by the presence of pseudogiant cells giving the giant cell type of thyroiditis.

SYMPTOMS. Chronic thyroiditis generally follows a prolonged chronic course. It occurs in patients who give a history of chronic infection (for example, syphilis or respiratory disease). It is assumed that the thyroiditis is secondary to these infections or to vascular changes which induce nonspecific degenerative changes in the gland. The symptoms therefore are those of the original disease plus the effects of the enlarged, hardened gland pressing on the trachea.

Examination reveals the thyroid gland to be enlarged and hard, often it extends substernally.

The diagnosis of chronic thyroiditis is made on the basis of the foregoing description of the disease. Determination of the type of pathologic change requires microscopic study. In Hashimoto's disease the gland is symmetrically enlarged, but resilient. In Riedel's struma the normal shape of the gland is not retained, but its surface remains smooth, tender and not nodular This process tends to adhere to surrounding structures Riedel's struma may affect only part of a lobe Hashimoto's disease occurs almost entirely in women, Riedel's struma occurs also in men Either may occur at any age.

Goiter. Any enlargement of the thyroid gland is designated as a goiter. To differentiate the various types of goiter, the American Association for the Study of Goiter has adopted the following terminology and classification:

1 Nontoxic goiter
   a. diffuse (endemic and adolescent)
   b nodular (adenomatous and colloid)
2. Toxic goiter:
   a. diffuse (Graves' disease, primary hyperthyroidism)
   b. nodular (toxic adenoma, secondary hyperthyroidism)
3 Malignant goiter
4. Inflammatory disease (discussed earlier)

In diffuse nontoxic goiter there is a symmetric, soft enlargement which occurs most frequently at puberty, during pregnancy, or during other periods of stress.

The term toxic goiter implies that the thyroid makes available an excessive supply of utilizable thyroxin.

Nontoxic Goiters. *Simple or Endemic and Adolescent Goiter.* Simple goiter is a deficiency disease caused by a lack of a sufficient available supply or utilization of iodine There is enlargement of the thyroid without associated toxic manifestations.

This form of goiter is endemic and sporadic Endemic goiter occurs in well-defined geographic regions where iodine deficiency is prevalent. Inhabitants of mountainous regions are particularly likely to be goitrous. Thus in the Eastern United States the goiter belt extends along the Appalachian range, particularly along the eastern slopes of the Alleghenies. In the Ozark Mountains or Plateau (south central part) goiter is moderately endemic. On the West Coast goiter is encountered along the western slopes of the Rockies. In the north along the Great Lakes is a large endemic area for goiter.

In addition to the requirement of an optimal iodine concentration in the food and drink, a deficiency of vitamin A may induce goiter when the iodine intake is in the lower range of normality The goitrogenic effects of fats have also been demonstrated Poor sanitation, infections, avitaminosis, puberty and pregnancy increase the requirement for iodine and are conducive to the development of goiter.

During the early stages of the disease there is a diffuse enlargement of the gland, the follicles being distended with colloid (colloid goiter) As time passes, the simple goiter, either spontaneously or as the result of the administration of iodine, may be reduced to normal size or it may become atrophied In the atrophied gland the alveoli become distorted and compressed, and the epithelium remains high and irregularly arranged. In long-standing goiter the gland may become nodular. Most modules of the thyroid consist of follicles distended with colloid, others undergo cystic degeneration. Adenoma of the thyroid is commoner in nodular glands than in the normal, it may undergo malignant change and give rise to carcinoma

Girls and women are more prone to acquire the disease than are boys and men, and the goiter tends to become larger in females than in males The incidence in males reaches a maximum before the age of puberty, whereas in females maximal occurrence is present after puberty.

The goiter may become large without having attracted the attention of the patient Some patients may complain of symptoms that suggest pressure on the esophagus, trachea or recurrent laryngeal nerves.

On examination the thyroid gland is smooth, soft and enlarged throughout, the borders may be somewhat indistinct, there are no bruits or thrills. In boys in whom goiter develops before puberty the gland later may become smaller, but in girls such is not the rule In many the enlargement tends to fluctuate in size in proportion to various stresses, but slowly increases in size During pregnancy there is some enlargement of the thyroid gland With the approach of middle life the lesions often become nodular During the remainder of the patient's life the goiter tends to become larger and more nodular Thyrotoxic changes may occur. Malignant changes occur more frequently in association with nodules in the thyroid gland than in the diffusely enlarged gland Hemorrhage into a cyst may cause acute pain and swelling in the neck

The diagnosis is established by the presence of the enlarged thyroid gland In acute thyroiditis there is a history of recent onset of pain and swelling The mass is associated with tenderness, fever and leukocytosis The differentiation of diffuse endemic goiter present in a middle-aged person from carcinoma of the thyroid gland is impossible until histologic studies have been completed

Simple goiter, in its early stages, is readily curable by the administration of iodine.

Nodular (Adenomatous and Colloid) Goiter. The goiter of endemic and adolescent (simple goiter) origin is characterized in the early stages by a diffuse en-

largement of the thyroid gland. The follicles are distended with colloid—the colloid goiter. The gland apparently has undergone hyperplasia as a compensatory reaction to the lack of iodine

The hyperplastic thyroid gland of colloid goiter maintains a normal physiologic function despite its abnormal anatomic state. It may be looked on as a gland in the resting stage following active hyperplasia In some instances, however, the hyperplastic gland may undergo exhaustion atrophy, in which case the alveoli become distorted and compressed and the epithelium remains high and irregularly arranged With the advent of involution the accumulation of colloid in the involuted gland may also be termed colloid goiter. Hyperplasia and involution may be successively repeated

In long-standing goiter there is a tendency for the gland to become nodular This is explained by assuming that the stimulation of the gland is not always uniform, in which case a diffuse colloid goiter results If a localized region is stimulated, this tends to cause pressure atrophy of the surrounding cells and the formation of a fibrous capsule around it, thus giving rise to a nodule The disturbed activity of the cells also renders them more prone to undergo neoplastic change than normally functioning cells. Hence adenoma is much commoner in nodular thyroid glands than in normal thyroid glands The adenoma in turn may undergo malignant change and give rise to carcinoma. Most nodules of the thyroid consist of follicles distended with colloid (colloid nodules); others undergo cystic degeneration

Nodular goiter causes no symptoms unless it is very large or it is situated substernally Large substernal goiters are mediastinal tumors and they are thus manifested

On examination the nodules are palpated There may be one nodule or several nodules or, in some instances, one lobe or all of the lobes of the thyroid are involved

Diagnosis is established by palpation unless the adenoma is substernally situated and then it is diagnosed by roentgenologic examination

In the early stages of nodular goiter iodine may be therapeutically beneficial

ENDOCRINE DISORDERS OF THE THYROID

Hypothyroidism. A deficiency of the thyroid hormone is responsible for (1) cretinism when the deficiency occurs before birth or during infancy, (2) juvenile hypothyroidism when the deficiency is less profound and occurs during childhood, (3) hypothyroidism in the adult when the deficiency is partial and (4) myxedema when it is complete.

Cretinism. In regions in which goiter is endemic a condition characterized by dwarfism and imbecility is designated as cretinism. Two types of cretinism are de- [illegible] the endemic, [illegible] differences [illegible]

[illegible] the sporadic cretin there is failure of development of the thyroid In the cretin residing in an area of endemic goiter there may be a congenital absence of the thyroid gland, but usually there is degeneration of the thyroid in uterine life or in early infancy. The lack of iodine is the chief cause of cretinism, but a congenital absence of the thyroid or factors which cause destruction of the gland, such as infections or hereditary syphilis, may induce the disorder

Symptoms. The symptoms vary in accordance with the age at onset of the disease, the interval without therapy, and the severity of the disease. The brain of the cretin fails to develop properly and imbecility results. There are marked apathy, defective speech, a clumsy gait, incontinence and other evidence of maldevelopment of the neuromuscular system The cretin is a dull and placid idiot or imbecile Sitting,

walking and talking are considerably delayed. Often there are anorexia and constipation.

Examination The cretin is dwarfed owing to a delay in the appearance and lack of function of the ossification centers. The deficient growth of the sphenoid bone gives a characteristic depression at the root of the nose

The skin is thick, dry and cold; the hair is sparse or may *fall* out; the nails are thin and brittle, the teeth become carious early in life. The hands and feet are fat and the digits are short The lips are thick and dry The tongue is thick and protrudes through the open, gaping mouth, dribbling saliva. The cretin is very susceptible to infection and, like the mongolian idiot, may succumb easily to infection while young

Owing to hyaline degeneration, the muscles are flaccid The abdomen protrudes; umbilical hernias are frequent. There is a tendency toward adipose deposits about the hips and above the mons veneris Delayed dentition, pallor, and anemia and sexual infantilism are characteristic

Determinations of the basal metabolic rate are helpful, but not conveniently done because of the necessity of a special respiratory chamber A high serum cholesterol concentration and a low plasma protein-bound iodine are found Roentgenograms reveal delayed appearance of ossification centers.

Diagnosis The diagnosis of cretinism should be considered in any child showing delay in all phases of development Suggestive manifestations are delayed osseous development, mental retardation, bradycardia and hypothermia The various kinds of idiots and dwarfs are to be differentiated (see Dwarfishness, Chapter 16)

The mongolian idiot is more active than the cretin, has finer features, and has hypermobility of the joints The skin is warm and moist The wide spacing of the eyes in ocular hypertelorism may simulate cretinism because of dwarfism and mental deficiency. In mongolian idiots growth is not stunted and the basal metabolism is normal

The success of thyroid therapy in cretinism is dependent on the age at which it is begun, on the dosage and the duration of treatment, as well as on the severity of the disease It should be given a trial.

Juvenile Hypothyroidism. During childhood, in juvenile hypothyroidism, *thyroid insufficiency of a milder degree than that of the cretin is present*

There are many symptoms common to cretinism, juvenile myxedema, and adult myxedema. Prominent among these are stunting of growth, and mental retardation In juvenile hypothyroidism early development is normal, but later a great retardation ensues. *The genitalia are normal, but puberty is delayed*

Examination reveals the child to be small for its age The skin is dry and thick. The hair is dry, and the nails are brittle There is mental retardation

Examination in juvenile myxedema reveals a stunting of growth due to retardation in osseous development The retardation in osseous development with a resulting subnormal bone age, as determined by roentgenologic examination, is a characteristic feature of juvenile hypothyroidism There is usually present some abnormal ossification of the cartilages of the epiphyses and of the round bones (epiphyseal dysgenesis). The porous stippling of the cartilage observed in epiphyseal dysgenesis is not always present in hypothyroidism, and a similar appearance in the roentgenogram is observed in osteochondritis deformans and in chondrodystrophy The disturbance in ossification is particularly likely to affect the hip, and because of the similar appearance in the roentgenogram, may suggest osteochondritis deformans juvenilis (Legg-Perthes disease)

There are elevated cholesterol content of the blood, reduced basal metabolic rate, and subnormal rate of creatine excretion

The determinations of the basal metabolic rate and the rate of creatine excre-

tion are useful procedures in the diagnosis of hypothyroidism. The concentration of *cholesterol in the blood is frequently increased but may be within the normal limits.* However, as has been shown by Wilkins, the cholesterol level uniformly rises after the cessation of thyroid therapy.

Hypothyroidism in the Adult. In the adult, hypothyroidism when complete gives rise to a characteristic syndrome designated as myxedema The milder forms of hypothyroidism in the adult are difficult to recognize, for the early degrees of hypothyroidism give but few vague symptoms, which are suggestive of a psychoneurosis. The presence of a basal metabolic rate of −20 to −30 per cent is significant.

***Myxedema** (Gull's Disease)* Myxedema is a moderately rare disease It occurs 4 out of every 5 times in women

Of the causes of myxedema, the excessive administration of thyroid extracts and goitrogenic compounds, the use of radioiodine and roentgen rays, thyroidectomy, and thyroiditis are common. Spontaneous occurrences are observed

Marked atrophy of the thyroid gland occurs in Simmonds' disease because of hypothyrotropinism The majority of patients with thyroid atrophy, however, do not have panhypopituitarism. That the pituitary is not deficient in some instances is indicated by the presence of an excessive amount of thyrotropin in the blood and urine of some patients who have myxedema

The hypothyroidism found in patients who have undergone thyroidectomy or radioiodotherapeusis results from removal or injury of an excessive amount of thyroid tissue

The various goitrogenic agents produce myxedema either by preventing the gland from concentrating iodide or by interfering with the utilization of iodide in the synthesis of thyroxin, as exemplified by thiouracil. On withdrawal of ingestion of the antithyroid agent, the myxedema usually disappears

With extensive inflammatory changes in the thyroid, such as occur in severe forms of thyroiditis, so much of the acinar tissue may be destroyed that myxedema ensues.

In myxedema there is often an infiltration of the thyroid gland by connective tissue and lymphocytic cells which replace the glandular epithelium In primary myxedema there is no evidence of pituitary insufficiency Chronic thyroiditis and hyperthyroidism may *terminate in myxedema Otherwise the factors responsible for the condition are* obscure and usually unknown.

Myxedema commences insidiously The patient observes a thick dry skin and a puffed face, particularly the upper lids which seem heavy and enlarged There are complaints of inability of mental concentration, fatigue, slow and awkward movements, *drowsiness, muscular stiffness, falling hair and inability to get around quickly.* The patient is aware of but is not concerned about the lack of emotional response Myxedema is the only known disease in which otherwise normal young men and women will admit of decrease of libido and impotence without concern

Patients who have mild degrees of hypothyroidism may complain of a constant ache or pain in the chest which is aggravated by effort The anginal pain in myxedema is often secondary to the arteriosclerosis of the coronary vessels which is common among myxedematous patients beyond middle life. It is this form of angina that is relieved by thyroid therapy, angina due to intrinsic heart disease is aggravated by such therapy.

The tongue is thickened enough to interfere with the speech, which is slow, owing to difficulty in enunciation, and is bass and husky. The voice and speech of the myxedematous patient characteristically simulate the voice and speech of one who has acute alcoholic intoxication.

The face lacks expression when quiet, but this may not be apparent when the patient talks. The nose thickens and the cheeks are flabby. The fingers are short and stubby The teeth loosen and fall out Owing to puffy upper eyelids the palpebral fissures appear small Deafness may be found as a result of swelling of the larynx and tympanic membrane

walking and talking are considerably delayed. Often there are anorexia and constipation.

EXAMINATION The cretin is dwarfed owing to a delay in the appearance and lack of function of the ossification centers. The deficient growth of the sphenoid bone gives a characteristic depression at the root of the nose

The skin is thick, dry and cold; the hair is sparse or may fall out, the nails are thin and brittle, the teeth become carious early in life. The hands and feet are fat and the digits are short. The lips are thick and dry The tongue is thick and protrudes through the open, gaping mouth, dribbling saliva. Determinations of the basal metabolic rate are helpful, but not conveniently done because of the necessity of a special respiratory chamber A high serum cholesterol concentration and a low plasma protein-bound iodine are found. Roentgenograms reve[illegible]

DIAGNOSIS [illegible]
delay in all pha[illegible]
development, m[illegible]
of idiots and dwarfs are to be differentiated (see Dwarfishness, Chapter 16)

The mongolian idiot is more active than the cretin, has finer features, and has hypermobility of the joints The skin is warm and moist. The wide spacing of the eyes *in ocular hypertelorism may simulate cretinism* because of dwarfism and mental deficiency. In mongolian idiots growth is not stunted and the basal metabolism is normal

The success of thyroid therapy in cretinism is dependent on the age at which it is begun, on the dosage and the duration of treatment, as well as on the severity of the disease It should be given a trial

Juvenile Hypothyroidism. During childhood, in juvenile hypothyroidism, thyroid insufficiency of a milder degree than that of the cretin is present.

There are many symptoms common to cretinism, juvenile myxedema, and adult myxedema Prominent among these are stunting of growth, and mental retardation. In juvenile hypothyroidism early development is normal, but later a great retardation ensues The genitalia are normal, but puberty is delayed

Examination reveals the child to be small for its age. The skin is dry and thick. The hair is dry, and the nails are brittle. There is mental retardation

Examination in juvenile myxedema reveals a stunting of growth due to retardation in osseous development The retardation in osseous development with a resulting subnormal bone age, as determined by roentgenologic examination, is a charac*teristic feature of juvenile hypothyroidism. There is usually present some abnormal* ossification of the cartilages of the epiphyses and of the round bones (epiphyseal dysgenesis). The porous stippling of the cartilage observed in epiphyseal dysgenesis is not always present in hypothyroidism, and a similar appearance in the roentgeno*gram is* observed in osteochondritis deformans and in chondrodystrophy The disturbance in ossification is particularly likely to affect the hip, and because of the similar appearance in the roentgenogram, may suggest osteochondritis deformans juvenilis (Legg-Perthes disease)

There are elevated cholesterol content of the blood, reduced basal metabolic rate, and subnormal rate of creatine excretion.

The determinations of the basal metabolic rate and the rate of creatine excre-

adenoma, or adenomas, which give rise to the observed symptoms. In diffuse goiter the hyperactivity of the thyroid is believed to be secondary to some unknown extrathyroidal abnormal stimulus.

Toxic Adenoma. Toxic adenoma of the thyroid gland usually occurs in middle-aged women and elderly patients The nodular growth and the toxic adenoma are the manifestations of endemic goiter, whereas hyperthyroidism occurs throughout the general population In regions of endemic goiter the repeated hyperplasia and involution to which the gland is exposed are the result of iodine deficiency which predisposes to the development of adenoma

In adenoma of the thyroid there is a proliferation of tissue in well-defined, circumscribed and encapsulated masses seen in adenomas of other tissues. Both nodules and adenomas occur in the thyroid gland. The nodule is the most commonly encountered; it is simply a region of colloid hyperplasia. The adenoma is a true neoplastic growth. Adenomas are divided clinically into benign and toxic types, depending on the symptoms present It is impossible, except by histologic methods, to distinguish a simple nodule from an adenoma

Pathologists may classify adenomas of the thyroid as papillary, fetal and simple colloid goiters. There is little clinical value to be derived from such a classification

A toxic adenoma originates the symptoms of thyrotoxicosis without exophthalmos and abnormal psychic disturbances The symptoms of hyperthyroidism are considered in the discussion of exophthalmic goiter in this text.

Toxic adenoma of the thyroid is often the cause of heart disease and of congestive heart failure Heart failure is due solely to cardiac overwork induced by the elevated metabolism and increased demand on the cardiovascular system

In thyrotoxic heart disease the symptoms of hyperthyroidism may be masked entirely by cardiac failure The determination of the basal metabolic rate in these cases is of little significance, for, in the presence of congestive heart failure, this may [illegible]

[illegible]

goiter or Graves' disease occurs uniformly throughout the population Its incidence is the same in regions of endemic goiter and in regions where endemic goiter does not prevail There is an opinion abroad that endemic goiter and exophthalmic goiter are etiologically different Exophthalmic goiter is rare in tropical and subtropical areas It is commoner in urban than in rural populations No race is immune to it. Epidemics have been described

Exophthalmic goiter affects women 10 to 15 times more frequently than men It usually becomes evident after puberty. However, children and even infants may have the disease

There is a familial tendency and the disease is commonest in those in whom there is a family history of neurosis and psychosis There is a strong clinical impression too that often there may be a constitutional predisposition which when combined with an environmental maladjustment results in hyperthyroidism

In an overactive thyroid gland the blood supply is increased The colloid becomes thinner and disappears, being replaced by a thin fluid which stains poorly with eosin. The epithelial cells become columnar. The alveoli enlarge, papillary infoldings of the [illegible]

[illegible] hyperthyroidism are goiter, exophthalmos, tremor and tachycardia. However, in some instances the goiter may be hard to demonstrate These manifestations in association with other symptoms—irritability, purposeless movements, hyperhidrosis, loss of body weight, dyspnea,

the glabrous skin. The hair is dry, brittle, without gloss, and grows slowly. Fingernails tend to be brittle

The skin is cool, dry, rough, scaly, atrophic, inelastic and puffy. In the early phases of the disease there is no pitting of the skin although it is definitely swollen Cutaneous wounds heal slowly In an occasional patient marked accumulations of desquamated skin may form thick crusts In a few patients the skin is smooth and glistening

The thyroid gland usually is impalpable, but occasionally it is enlarged. In such instances there usually is thyroiditis, or an endemic goiter or malignancy present.

The pulse rate and occasionally the pulse pressure are decreased Hypertension often is present in the myxedematous patient Occasionally there is hypotension Fluids tend to accumulate in the serosal cavities in patients who have had myxedema for a long time Congestive heart failure is infrequent in the absence of intrinsic heart disease The heart sounds are distant Electrocardiograms show a decrease in the amplitude of the complexes; flattening of the T waves is particularly common.

Slight atrophy of the gonads is observed occasionally Usually there is a decrease in libido and fertility Impotence is common in men

Slow mentation is one of the most characteristic manifestations. Comprehension is markedly impaired and there is a decrease in the perceptibility of general and special sensory stimuli Drowsiness and stupor are often present, but instead there may occasionally be nervousness and apprehension

There may be a decrease in the plasma volume and an increase in the concentration of protein

In myxedema the total cholesterol, cholesterol esters and phospholipid of the plasma may be increased The protein-bound iodine of the plasma is usually less than 3 5 micrograms per 100 ml In myxedema no concentration of radioiodine is found in the thyroid region Moreover, the patients usually excrete more of the isotope in 24 hours than do euthyroid or hyperthyroid persons

The urine may be scant in quantity and albuminous

DIAGNOSIS The basal metabolic rate of patients with fully developed myxedema is usually between −30 and −40 per cent In a few patients who have heart disease, infection or other condition as a complication, the basal rate may not be less than −15 per cent, even though the clinical manifestations of myxedema seem clear

A therapeutic test with desiccated thyroid is sometimes of advantage in patients who look and act myxedematous, who cannot take a satisfactory basal metabolism test, and who have a normal serum cholesterol When the patient has myxedema, a clear-cut clinical response is obtained within 3 weeks after administration of standard doses of thyroid It is not usually necessary to test by means of radioiodine

Toxic Goiter: Hyperthyroidism or Thyrotoxicosis. Hyperthyroidism may be produced by the administration of thyroxin Hyperthyroidism occurs clinically as the result of (1) an excessive secretion of thyroxin by adenomatous nodules, single or multiple, in the thyroid gland or in aberrant thyroid tissue (struma ovarii) and (2) diffuse overactivity of the thyroid gland In the first instance the hyperthyroidism is designated as due to toxic adenoma, and in the second instance the hyperthyroidism is termed exophthalmic goiter

Hyperthyroidism results from a variety of unknown mechanisms which have in common an exaggeration of the normal secretory activity of the thyroid The gland responds to these unknown mechanisms with an exaggerated secretion which in turn gives rise to most of the symptoms, while some of the symptoms are due only partly (exophthalmos) or perhaps not at all to the overactivity of the gland In every instance the term hyperthyroidism indicates an overactivity of the gland with production of an excess of the thyroid hormone The term toxic does not imply the production of an abnormal secretion by the entire gland

In toxic adenomatous goiter the thyroid is the site of a hyperfunctioning

The changes in the skin constitute one of the most characteristic aspects of the disease. In thyrotoxicosis the hands are usually warm and moist, but they may be cold and moist, as is observed in neurocirculatory asthenia The glabrous skin is flushed, hot, moist, fine and smooth The cutaneous alterations result chiefly from the increased peripheral circulation and perspiration and the increased dissipation of heat.

There is a weakness of the voluntary muscles in hyperthyroidism The leg muscles are often too weak for the patient to ascend one step upward to the examining table. In an occasional patient there is a degree of muscular atrophy, weakness and reflex changes which simulate progressive muscular atrophy. Myasthenia secondary to thyrotoxicosis may or may not respond to neostigmine, whereas primary myasthenia usually responds With the production of a complete remission of thyrotoxicosis, some of these myopathies become milder while others are unimproved or worsen. Comparable myopathies may occur at the time of the menopause with or without hyperthyroidism

The fingers show a rapid, finely vibratory tremor when they are voluntarily spread apart The tremor of hyperthyroidism is not distinctive A comparable form of vibratory tremor may be present in tense individuals who do not have hyperthyroidism The tremor of hyperthyroidism is of low amplitude and always of high frequency. Moreover, psychic instability is not helpful in distinguishing the tremor of hyperthyroidism, for all of those who have fine tremors are unstable individuals

The nails and scalp hair tend to be friable A decrease or absence of axillary hair is found in many of these patients, this phenomenon usually antedates the thyrotoxicosis

The reflexes in almost all thyrotoxic individuals are markedly hyperactive The required time for the performance of many activities is increased despite the apparent nimbleness of locomotor action

An increase in the pulse volume, resulting from an increase in the systolic blood pressure, is common The systolic blood pressure is increased to 160 or 170 measured in millimeters of mercury The diastolic blood pressure remains unchanged.

Pulse rates from 90 to 110 are common Auricular fibrillation is present in some patients; occasionally auricular flutter is found The heart contractions are forceful. There is increased cardiac output, accomplished by an increase in rate and stroke volume Systolic murmurs are frequent

Congestive heart failure occurs commonly with thyrotoxicosis, particularly in the older age group. Often the congestive failure is unrelated to the hyperthyroidism except for the extra load placed on the heart by the thyrotoxicosis

When ocular changes are associated with hyperthyroidism, these changes consist of a widening of the palpebral fissures, exophthalmos and a stare The degree of widening of the palpebral fissures and the amount of exophthalmos vary with emotional stress There is a lid lag on downward rotation of the eyeballs; convergence is poor.

On examination, lid lag or von Graefe's sign is manifested by a failure of the upper lid to follow the eyeball steadily downward when the gaze is directed slowly downward by following a gradually lowered finger. The sclera shows above the iris

Leukopenia may be present The total leukocyte count is occasionally found to be as low as 3,200 *per* cubic millimeter. Not infrequently there are granulocytopenia, lymphocytosis and monocytosis

The plasma volume is increased, attributable chiefly to an increase in water. The concentration of serum protein is decreased slightly Hyperglycemia and decreased

presented. Some patients do not complain of illness. It is the appearance of exophthalmos or loss of weight, noticed by the family, or a tremor interfering with work which may force the patient to seek relief.

The increased requirement for food stimulates the appetite. The hyperphagia, however, does not usually compensate for the hypermetabolism, and loss of weight ensues. The amount of weight lost varies from 1 pound to more than 100 pounds A loss of from 10 to 30 pounds occurs with great regularity.

Acute emotional upsets due, for example, to an automobile accident, or a sudden death in the family, seem to precipitate the symptoms. In other instances there may be a long period of stress and anxiety such as a prolonged illness in the family. However, emotional strain plays only a contributory role, for in only a very small proportion of persons experiencing psychic trauma does thyrotoxicosis ensue

Often there is a simultaneous appearance of restlessness, palpitation, intolerance of heat, and increased appetite In a few there may be a sudden onset of severe diarrhea, which the patient cannot relate to a specific item of diet. In still others all of the disturbances may be manifested by the cardiovascular system In rare instances psychosis or myopathy with great muscular weakness is the first symptom to develop The symptoms may subside to recur at intervals for years. In some the symptoms may disappear spontaneously. Some patients do not seem to be disturbed by the symptoms until some complication of the disease forces them to be aware. A few patients maintain that they feel much better when they are mildly hyperthyroid than when they are euthyroid This is more frequently observed in those who have heart failure

These patients are "nervous" and prone to have psychoneurosis and "nervous breakdown." Agitation, delirium and other forms of toxic psychoses develop easily. Manic-depressive states, schizophrenia and paranoid reactions are observed in a great many of these patients It is probable, however, that most of these psychic states are already present and are intensified by the thyrotoxicosis

In women the menstrual flow tends to be scanty and infrequent Estrogen antagonizes thyroid function by inhibiting the production of thyrotropin. Testosterone tends to stimulate the thyroid and to increase the metabolic rate

Almost all of the patients complain of increased sensitivity and decreased tolerance to heat They are comfortable in lower temperatures when the room or weather is hot (above 65 F) They tend to wear fewer clothes, use less bed covering, put their feet from under the covers, and want less heat in their rooms than do persons in normal health

There are many unrestrained emotional surges There may be silly outbursts of laughter, loquacity, euphoria and great exuberance Weeping is common, usually appearing spontaneously and sometimes to the disgust of the patient

The patient may complain that the eyeballs begin to protrude (exophthalmos). The protruding eyeballs give the patient an appearance of surprise or terror and the discomforts of chronic conjunctivitis

CRISES. Sometimes in the course of exophthalmic goiter or in toxic adenoma a crisis may occur. The crisis consists of severe psychomotor reactions, protracted vomiting, oliguria, tachycardia, hyperpyrexia and an elevation of the blood pressure, both systolic and diastolic The crises or the fulminating form of hyperthyroidism may arise after the discontinuance of iodine therapy, or after thyroidectomy On rare occasions a crisis will occur in a patient who has minimal or no recognized symptoms of hyperthyroidism

EXAMINATION. The peripheral [illegible]

are dilated

symptoms of thyrotoxicity. The oculopathy varies considerably in different patients In a few the ocular symptoms may be much more troublesome than the thyrotoxicosis, even though the latter is severe Long-continued exophthalmos may lead to ulceration, extrusion of the lens, or panophthalmia The severe orbital complications have been designated as malignant exophthalmos, exophthalmic ophthalmoplegia, and hyperophthalmopathic hyperthyroidism

Malignant exophthalmos develops either spontaneously or after thyroidectomy The etiology of this type of exophthalmos is different from that of the exophthalmos seen in thyrotoxicosis. It is a distinct syndrome The term malignant exophthalmos is supposed to cover a group of cases in which exophthalmos and loss of ocular movement occur together, sometimes associated with, at others independently of, thyrotoxicosis. Patients who have the spontaneous type are not improved by surgical removal of the thyroid.

The exophthalmos-promoting effect of anterior lobe of the pituitary body is brought about by action on other end-organs than the thyroid gland The knowledge of such experimental data is the origin of the term thyrotropic or pituitary type of exophthalmos.

The characteristic syndrome is varying degrees of exophthalmos and paralysis limited to ocular muscles and engorged conjunctivae (see p 125)

MALIGNANT TUMORS

Malignant tumors of the thyroid gland are less common than are benign tumors (adenomas). Malignant tumors of the thyroid usually do not give rise to any important symptoms that can be attributed to hyperthyroidism or hypothyroidism

Adenocarcinoma constitutes 9 of every 10 of all malignant lesions of the gland. Sarcoma of the thyroid may originate in the lymphatic tissue (lymphosarcoma) or in the stroma or capsule (spindle cell sarcoma or fibrosarcoma)

Some adenocarcinomas of the thyroid manifest a low grade of malignancy, so much so that both the adenoma and its metastatic growths resemble benign adenoma These tumors have been designated malignant adenoma and benign metastasizing adenoma. They are best designated adenocarcinoma, grade I (Broders) A similar tendency to low-grade malignancy is sometimes present in the lateral aberrant thyroid tissues

In 8 of every 10 cases adenocarcinoma originates in adenomatous nodules of the thyroid gland as the result of malignant changes

The adenocarcinomas may be divided into the papillary and diffuse types Scirrhous carcinoma and mixed carcinoma and sarcoma rarely are observed

An adenocarcinoma in the thyroid may remain localized for a long time before it metastasizes. The metastasis is by direct extension or by lymphatic invasion to the cervical lymph nodes or into the mediastinum or by extension into the veins with metastasis to the bones, lungs or brain Carcinoma of the thyroid may metastasize by way of the blood stream. The process is progressive and debilitating

The incidence of carcinoma in nodular goiter varies somewhat in different sections of the country and in different reports It is about 4 per cent

There is considerable variation in the age of the patients who have carcinoma of the thyroid Pemberton and Lovelace recorded an average age of 48.1 years in women and 52.8 years in men There seems to be some evidence that as the diagnosis and thus the incidence of cancer increases, the tumor afflicts younger persons. Carcinoma of the thyroid, unlike carcinoma in most other organs, may appear in young people, including children In 62 children 14 years of age or less who had nodular goiter, Kennedy reported carcinoma present in 12. All these carcinomas were in nontoxic nodular glands

Goiter of all types is commoner in women than in men. The incidence of carcinoma of the thyroid is higher in men than in women. The incidence of nodular goiter is higher in women.

The incidence of carcinoma of the thyroid is much higher in nontoxic nodular

glucose tolerance are found more commonly than in the average euthyroid patient There is a tendency to polyuria and an increased excretion of nitrogen, phosphorus, calcium, potassium, sodium, chloride and creatine. Glycosuria is observed occasionally. [illegible]

There [illegible]
disease, c [illegible]
function of the pituitary perhaps contribute to the abnormal dextrose tolerance reactions. Diabetes among patients who have thyrotoxicosis is twice as common as among the general population. In some patients who have thyrotoxicosis, hyperglycemia and glycosuria disappear after a complete remission The diabetic patient who has thyrotoxicosis has difficulty in controlling the diabetes and often has insulin reactions.

DIAGNOSIS. The presence of goiter, exophthalmos, rapid heart action and tremor is sufficient evidence for a clinical diagnosis of hyperthyroidism Add to any one or any combination of these symptoms a definitely increased basal metabolic rate, and the diagnosis of hyperthyroidism is reasonably certain. In mild degrees of hyperthyroidism a period of observation accompanied by a series of basal metabolic determinations may be necessary An increased basal metabolic rate alone is not sufficient for the diagnosis of hyperthyroidism.

Hyperthyroidism Without Apparent Hypermetabolism. Patients who have diffuse and nodular goiter and who have a normal basal metabolic rate may have an increased serum iodine concentration. However, detailed iodine tolerance tests and the relatively high incidence of elevated values of serum iodine in euthyroid persons make it difficult to accept serum iodine concentration as a final diagnostic criterion for hyperthyroidism in individual patients Moreover, the clinical differentiation between hyperthyroidism and anxiety, chronic alcoholism or other psychoneurotic states has made for skepticism toward a diagnosis of apparent hyperthyroidism unless there is more evidence than increased concentration of serum iodides at hand.

In order to be more certain of the presence of hyperthyroidism without hypermetabolism, Werner and Hamilton required a definite response to therapy in addition to laboratory evidence from the radioiodine tracer, serum precipitable iodine and basal metabolic rate determinations before making a final diagnosis of hyperthyroidism without apparent hypermetabolism All patients were seen by Werner either in the hospital or in the thyroid clinic Adequate follow-up was possible after initiation of therapy in all but 1 case. The data in this case were included in the authors' tables since there was little doubt as to the correctness of the diagnosis It seems, therefore, that in rare instances hyperthyroidism without apparent hypermetabolism may exist. However, it seems better to ignore this diagnostic possibility and not to treat any patient for hyperthyroidism who does not have hypermetabolism

Exophthalmos and Thyrotoxicosis. Chronic progressive exophthalmos in thyrotoxicosis is a highly complex phenomenon, its cause has not been completely elucidated. This exophthalmos may show considerable variation from day to day in its early stages The degenerative and inflammatory changes and edema present in the orbital contents are the result rather than the cause of the exophthalmos

Exophthalmos accompanies hyperthyroidism but does not necessarily parallel it. Often it is absent but it may appear after subtotal thyroidectomy. Exophthalmos may make its first appearance, and may progress, even when the basal metabolic rate is low. When rapidly progressive, an exophthalmos may become so severe as to threaten vision by exposure of the cornea, by papilledema, and by changes in the optic nerve. Unilateral exophthalmos may occur in hyperthyroidism, and if so the right eye is more often affected than the left eye The presence of an orbital tumor should be excluded in all those who have unilateral exophthalmos.

The majority of patients exhibit orbital changes, which usually appear with the

with the normal state. In hyperthyroidism relatively large amounts of this element are taken up by the gland.

Radioactive Iodine. The normal range of radioiodine uptake by the thyroid gland is from 10 per cent to 25 per cent. Radioiodine uptake levels below 10 per cent are considered low (myxedema), between 30 and 50 per cent borderline, and in hyperthyroidism 50 to 80 per cent, of the total dose will be stored in the gland in 24 hours. The usual tracer dose is 100 microcuries of I^{131}

Antithyroid medication gives a false normal uptake value A strong iodine solution or propylthiouracil, recent roentgenologic examinations such as cholecystography, intravenous pyelography or injections of iodized oil will give false normal uptake in the radioiodine values Radiopaque substances *containing iodine administered for roentgenologic* study may cause high blood iodine levels as long as 2 or more years afterward

Radioactive iodine (I^{131}) is useful in diagnostic studies of the biosynthesis of the thyroid hormone, the role of the thyrotropic hormone of the pituitary gland, and the action of goitrogens, as well as the functioning capacity of thyroid tumors. With proper shielding of the Geiger-Muller tube the individual lobes of the thyroid and parts thereof, as well as aberrant and intrathoracic extensions of the thyroid and solitary nodules in one of the thyroid lobes, can be formed Similar use has been made of radioactive iodine uptake in the diagnosis of a lingual thyroid The recently introduced scintillating counter seems to be superior to the Geiger-Muller tube

The diagnostic value of radioactive iodine depends on the measurement of the fraction of the tracer dose collected by the thyroid gland, the determination of blood concentrations of radioactive iodine in a given period of time after the administration of a test dose, and the determination of the rate and degree of urinary excretion of radioactive iodine. The difference in these results in various disorders of thyroid function may give precise information of diagnostic value Following the ingestion of a test dose, radioactive iodine disappears from the blood most nearly completely in cases of hyperthyroidism, least nearly completely in hypothyroidism Euthyroidism falls somewhere between these extremes. Eight hours after ingestion the mean concentration of radioactive iodine in the serum of hyperthyroid patients may be 0 5 per cent of the test dose per liter, 1 0 per cent in euthyroid individuals, and 2 per cent in patients with myxedema The exponential rate of disappearance of radioactive iodine from the blood in hyperthyroidism is about 40 per cent per hour, in euthyroidism 17 per cent per hour, while in myxedema it may be about 9 per cent per hour

Twenty per cent of an administered dose of radioactive iodine is excreted in the urine in hyperthyroidism, 60 per cent in euthyroidism, and 90 per cent of the dose is excreted in the urine in hypothyroidism by the end of a 72 hour period provided there is normal renal function.

The concentration of radioactive iodine in the blood that is bound to protein reaches about 75 per cent or more of the ingested dose in 24 hours in hyperthyroid patients, is less than 45 per cent of the ingested dose in euthyroid persons, and is negligible in patients who have myxedema

In summary: An overactive thyroid gland promptly collects a large part of administered radioactive iodine. The gland utilizes this iodine in the formation of thyroid hormones. As the result of the protein binding, less iodine is lost in the urine. The processes in the case of hypothyroidism are the converse.

The methods for the determination of protein-bound iodine are technically difficult and often uncertain The use of radioactive iodine requires acquired skill in the use of technical apparatus which is not generally available

Determination of the basal metabolic rate remains the most practical method for determination of the status of thyroid activity available for clinical use.

THE BASAL METABOLIC RATE

The Basal Metabolic Rate. Determining the basal metabolic rate is an integral part of the evaluation of the thyroid disease About 75 per cent of persons without thyroid disease have a basal metabolism within the limits +10 to −10 per cent Ninety-five per cent will have a rate within the limits of +15 to −15 per cent (Boothby and Sandiford using DuBois standards). Aside from thyroid disorders there are many condi-

goiter than in toxic nodular goiter. The solitary nodule is much more dangerou from the standpoint of malignant change than in the multinodular gland The rela tionship of fetal adenomas to the genesis of malignant disease of the thyroid canno be stated

Often the patient is unaware of any symptoms or that there is a tumor of th thyroid In other instances there is a history of a sudden or gradual growth durin the several months immediately preceding the time when the patient sought medica aid Often the symptoms bringing the patient to the physician are voice change difficulty in swallowing or breathing, or some other manifestation of extension o the malignant process beyond the thyroid gland A common early symptom is a choking sensation which frequently awakes the patient from sleep.

As the tumor grows, there is evidence of pressure, with interference in respiration, and pain and swelling of the neck These symptoms may also be produced by benign growths. The symptoms of nontoxic and mildly toxic malignant goiter are so meager that it may be impossible to identify one from the other Such symptoms as slight nervousness, tachycardia, weakness, dyspnea and increase in sweating which have developed insidiously may be so mild that they are scarcely appreciated by the patient until after operation, when pronounced improvement ensues

In the early course of carcinoma of the thyroid palpation reveals a nodular tumor or tumors of the gland The sense of touch is not acute enough to permit diagnosis of malignancy by the degree of hardness of the tumor Later, when there is fixation of the thyroid to surrounding structures, and when metastasis has occurred, the physical findings are suggestive

The diagnosis of malignancy of the thyroid gland is established by histologic examination Any adenoma of the thyroid which suddenly begins rapid growth and produces pressure symptoms suggests malignancy The hard gland of Riedel's thyroiditis or the gland of Hashimoto's struma is easily differentiated from carcinoma by the fact that the normal anatomic shape of the gland is preserved in these conditions in contrast with the distortion observed in carcinoma

IODINE, PROTEIN-BOUND IODINE, AND RADIOACTIVE IODINE IN THE DIAGNOSIS OF DISORDERS OF THE THYROID GLAND

Iodine in the Blood. Human blood maintains a rather constant iodine content which ranges between 3 and 20 micrograms per *100 ml* *The concentration of iodine in* the blood is a rough measure of the release of the thyroid hormone The concentration varies with the geographic area in which the individual resides and with the method of determination Blood iodine is increased by gestation normally and in toxic nodular goiter and exophthalmic goiter In hypothyroidism the whole-blood iodine is often within normal limits whereas the acetone-insoluble fraction, the protein-bound iodine, which probably represents the iodine of the thyroid hormone, is diminished to about one half of its normal concentration

Protein-bound Iodine. Protein-bound iodine values in the blood of less than 5 micrograms per 100 *ml* are considered low, and those of more than 7 micrograms per 100 ml are considered high

Between overt myxedema and hyperthyroidism is normal thyroid activity or euthyroidism In many instances, in order to prove that euthyroidism prevails, extensive metabolic studies are necessary In cases of doubt, the determination of the protein-bound iodine and studies of radioactive iodine may be of diagnostic value

In nontoxic nodular goiter there is a linear relationship between the basal metabolic rate and the protein-bound iodine and also there is a significant relationship between the level of the protein-bound iodine and the duration of the goiter

The radioactive isotope of iodine is useful in studying the metabolism of iodine, for the gamma rays emitted from it can be detected by the Geiger counter. In this way the course of administered iodine may be followed in the intact organism. In hypothyroidism without goiter only small amounts of iodine are concentrated in the gland as compared

The functions of the parathyroid glands may be affected by developmental abnormalities or manifested by excess or insufficient secretion by the glands.

Parathyroid Insufficiency [illegible]

parathyroid glands as a result of operations on the thyroid gland

The symptoms of mild parathyroid insufficiency may commence with tingling sensations in the hands and feet, stiffness, dysphagia, fibrillary twitchings, constricted feeling in the throat, dyspnea, fatigue, muscular weakness, and gastrointestinal irritability. As the disease progresses, psychotic symptoms and convulsive seizures may ensue. In some a toxic delirium with anxiety, depression, hallucinations and dementia is present.

A characteristic symptom or series of symptoms is tetany (see Tetany in Chapter 22). In parathyroid tetany there is an increased susceptibility of the nervous system to external stimuli (see Strychnine Poisoning in Chapter 19, and Infections by *Clostridium tetani* in Chapter 6) Ordinarily insignificant stimuli such as tapping on a muscle or groups of muscles with a finger may cause a painful tonic spasm of the musculature. Carpopedal spasm, laryngospasm and convulsions are frequently subjects of complaint.

In chronic tetany, paresthesia is the most constant symptom It may be associated with nervousness, weakness and fatigue upon which are superimposed occasional attacks of carpal spasm and the other manifestations of acute tetany When it is long-continued, chronic tetany results in trophic changes such as softening of the teeth, poor healing of fractures, fragility of the nails, cataracts, loss of hair, and cutaneous changes.

On examination there may be no obvious evidence of tetany, for it may be latent. Latent tetany may be elicited by either mechanical or electrical stimuli

There are certain physical signs which may be elicited in latent tetany (1) Chvostek's sign is elicited by tapping the skin, thereby stimulating the facial nerve just anterior to the external auditory meatus A twitching of the facial muscles is Chvostek's phenomenon (2) Trousseau's phenomenon may be produced by pressure over any nerve trunk If pressure is applied to the median nerve, the patient's fingers and hands assume a typical contraction with fingers folded about the thumb This position of the hands has been designated as the main d'accoucheur or obstetric position and is characteristic of tetany. (3) Schlesinger's sign or Pool's leg phenomenon is elicited in latent tetany by holding the leg at the knee and flexing strongly at the hip joint This maneuver is followed by extensor spasm at the knee joint with supination of the foot

The convulsions of tetany consist of tonic contractions of one or more muscle groups which last for a few minutes to several hours, during which there is intense pain The limbs and face are mostly affected, rarely the muscles of the abdomen, trunk, or neck. The feet may be extended Laryngospasm, due to spastic narrowing of the glottis, may produce a loud high-toned inspiratory noise

Hypocalcemia induces a prolongation of systole in the heart and can be recognized by an increase of the QT interval in the electrocardiogram

The bl [illegible]
hyperphos [illegible]
of serum. [illegible]
serum The [illegible]
100 ml

A low calcium content of the blood may be observed in some instances of rickets, osteomalacia, infantile tetany and renal insufficiency

The hyperphosphatemia of nephritis and uremia may be accompanied by hypocalcemia. This hypocalcemia is probably secondary to the increased phosphate content of the blood, which directly influences the state of the calcium. The removal of the protein-calcium-phosphate complex formed in the presence of excess phos-

tions which elevate this rate, such as febrile illnesses, cardiac failure, leukemia, lymphomas, and acromegaly, while in Addison's disease, cretinism, hypothyroidism secondary to panhypopituitarism, and in the presence of the nephrotic syndrome the metabolic rate will be abnormally low. Common causes too of aberrations in basal metabolic estimations are the escape of oxygen through a poorly fitting mouthpiece or through a punctured ear drum, entrance of other gases into the system, and depletion of the soda lime in the apparatus.

The basal metabolic rate is found to be in error in about one third of all of the determinations in the borderline cases as revealed by radioiodine studies. Approximately one half of these errors are found to be false high basal metabolism reading, and the other half are false normal or false low basal metabolism reading. In studies of comparisons of radioiodine studies with metabolic rates, values of more than +20 per cent are considered false high readings. If the basal metabolic rate is less than −20 per cent, this is considered a false normal or false low basal metabolism reading Once the true basal metabolic rate is known for an individual patient, the efficacy of treatment for hyperthyroidism and hypothyroidism can be gauged by *frequent determinations of the basal metabolic rate*

The clinical evidence for thyroid disease and the basal metabolism are still the basis for the diagnosis of these conditions except in the borderline cases.

THE PARATHYROID GLANDS

The parathyroid glands are four in number, each about 0 5 cm, in size. Normally they are situated one at each of the upper and the lower poles of the two lobes of the thyroid gland. However, they may be situated in other parts of the neck or in the anterior mediastinum

The only known function of the parathyroid glands is to produce and to release the *parathyroid hormone, a function performed without the aid of trophic hormones from* any other gland. The hormone regulates the excretion of inorganic phosphate in the urine.

If parathyroid hormone is administered to a patient who has no parathyroid glands, the *following sequence of events takes place.* (1) a marked excretion of urine containing an increased amount of phosphorus accompanied by a decrease in the concentration of the serum inorganic phosphorus, (2) an increase in resorption of calcium and phosphorus from bone which restores the phosphorus concentration of the serum to normal and increases the calcium concentration of the serum above normal limits The hypercalciuria is present because of the hypercalcemia The parathyroid hormone may exert its primary action directly on bone and cause its dissolution so that the serum electrolyte changes are secondary to the bone changes This is indicated by the observation that *parathyroid hyperplasia* occurs in conditions which produce a low serum calcium level (see Bone Diseases, Chapter 6).

Parathyroid hormone can be replaced in therapeutics by sterols such as dihydrotachysterol (A T 10) and calciferol (vitamin D_2) Both of these are irradiation products of ergosterol

The actions of calciferol and dihydrotachysterol resemble each other. Calciferol has a more definite effect on calcium absorption than on phosphorus diuresis Dihydro- [illegible] diuresis than to promote [illegible] dihydrotachysterol [illegible] with *calciferol is* due to increased absorption from the gastrointestinal tract Since the first action of dihydrotachysterol is on phosphorus excretion in the urine, *it much more closely* resembles parathyroid hormone than calciferol. It differs from parathyroid hormone in that it does cause some calcium absorption from the gastrointestinal *tract, whereas the* parathyroid hormone causes none. Since dihydrotachysterol induces hypercalcemia by mobilizing calcium from bone, it has no antirachitic action, whereas calciferol, which causes hypercalcemia chiefly by increasing absorption from the gastrointestinal tract, is antirachitic.

serum calcium. The serum calcium may reach concentrations of 15 or more mg per 100 ml. of serum. As a sequence of the increased concentrations of serum calcium larger quantities of calcium are excreted by the kidneys. The excess excretion of calcium leads to rarefaction of the bones or osteoporosis

In observing the sequence of the disturbance caused by an excess of parathyroid hormone it becomes obvious that the clinical manifestations may be attributable to. (1) a disturbance in the electrolyte equilibria which may become manifest before there are detectable changes in either the bones or disturbances in renal functional activity. When this sequence of events occurs the condition is termed the syndrome of hyperparathyroid intoxication (2) Excessive action of parathyroid hormone may be manifest by bone disease without quantitatively measurable disturbances in the electrolyte equilibria or renal functional activity or the presence of bilateral renal stones. This is a common form of the disease (3) Excessive parathyroid hormone may have renal stones as its sole or principal manifestation Commonly, however, there may be a combination of disturbances of electrolyte equilibria, bone changes and renal disease.

The pathologic changes in the parathyroids may consist of a generalized hypertrophy and hyperplasia—idiopathic hyperparathyroidism More commonly the pathologic condition consists of a single adenoma or multiple adenomas of one or more of the glands The adenomas have endocrine functional capacity They arise usually from the chief cells of the gland. However, occasionally an adenoma arises from either the transitional or the oxyphil cells. All adenomas are enclosed in normal gland tissue In rare instances a carcinoma will be present These carcinomas metastasize to the lymph nodes of the neck, to the shoulders and to more distant parts

The bone cysts occurring in hyperparathyroidism have no distinctive features Both giant cell tumors and bone cysts may be present in the same bone The cysts seem to represent quiescent bone lesions while the giant cell tumors represent activity Osteoporosis is eventually present to a degree in all the bones

Hyperparathyroidism is a rare disease which affects women more frequently than men Children may have the disease

Symptoms The symptoms are more conveniently discussed as they occur in association with the outstanding manifestations of the disease

The *syndrome of hyperparathyroid intoxication* may occur acutely, but never without evidence of a chronic illness indicative of hyperparathyroidism having been present for some time. It may be the first manifestation of osteitis fibrosa cystica or of renal stones or calcinosis. In any event the symptoms of hyperparathyroidism result from hypercalcemia and its ensuing injury consisting of increased excretion of calcium and phosphorus in the urine and skeletal changes The symptoms due to *hypercalcemia* are weakness, anorexia, nausea, vomiting, loss of weight, pains in muscles, joints and abdomen and incoordination, bradycardia and cardiac irregularities. Often there is a history of attacks of nausea and vomiting, polyuria and polydipsia, renal colic, constipation, and anemia Atonia of the muscles and hyperextensibility of the joints may be excessive Renal calcinosis may be an early symptom as the result of excessive calcium excretion in the urine. Hypercalcemia has occurred in those who are under treatment for peptic ulcer by a diet high in calcium and phosphorus

Parathyroid intoxication is manifested by fever, dehydration, nausea and vomiting, and mental confusion which proceeds to coma and death. This intoxication may also occur as an acute complication in chronic hyperparathyroidism.

Skeletal changes associated with osteitis fibrosa cystica (osteodystrophia fibrosa, parathyroid osteosis) consist of the process of generalized decalcification (osteoporosis), cysts and giant cell tumors, fractures, deformities and epulides The bones of the skull, the vertebrae, femora, radii, ulnae and pelvis are affected. There is thinning of the cortex and trabeculae of the long bones with cyst formation in the

anism whereby this occurs

ed if there is present in a young person numbness of the fingers, laryngeal stridor and convulsive seizures. If the young patient has mental retardation in addition to paresthesias, stridor and fits, the diagnosis is more strongly suspected. Acute hypoparathyroidism may occur after operations on the thyroid gland Paralysis of the vocal cords often is present too if there is hypoparathyroidism postoperatively, the recurrent laryngeal nerves having been injured at the same operation.

The criteria for the diagnosis of chronic hypoparathyroidism include the presence of tetany, a low serum calcium and an increased concentration of phosphate, the existence of normal bone texture, and the absence of renal insufficiency. Hypocalcemia also accompanies conditions of hypoproteinemia but in these tetany is not present.

Secondary Disturbances of the Parathyroid Glands. Enlargement of the parathyroid glands is not synonymous with idiopathic hyperparathyroidism (see below), for as a compensatory mechanism the parathyroids enlarge in osteomalacia, rickets, multiple myeloma, osteoporosis and osteitis fibrosa. All of these conditions are characterized by loss of calcium phosphate from the bones. In osteomalacia and rickets there is a faulty calcification of the skeleton due to vitamin deprivation In multiple myeloma the bone is destroyed by a malignant process

Basophilic adenomas of the hypophysis (Cushing's syndrome) and ovarian deficiencies are often accompanied by osteoporosis. The osteoporosis which occurs in the aged is referable to the cessation of reproductive activity The effects of pregnancy or lactation in aggravating latent tetany are due to the extra requirements which these conditions entail on the calcium supply of the organism

Administration of thyroid substance increases the calcium excretion through the intestine and results in a negative calcium balance without materially influencing the concentration of calcium in the blood

Deficiency of renal function stimulates hyperfunction and hyperplasia of the parathyroid glands, while hyperparathyroidism may produce renal lesions and renal failure. Certain renal diseases of long duration are accompanied by changes in the bones which resemble those due to parathyroid adenomas.

A failure of the kidneys to maintain a normal acid-base balance may induce osseous changes resembling those observed in osteitis fibrosa. Phosphate retention may affect the calcium-ion concentration of the blood and interfere with the absorption of calcium from the intestine As the result of renal disturbances the mechanisms of normal calcium and phosphate metabolism may affect the skeleton and give rise to osteodystrophy.

In both parathyroid insufficiency and vitamin D deficiency there may be a diminished calcium content of the blood, and there are changes in the skeletal system Hypertrophy of the parathyroids is observed only in low calcium rickets, and not in low phosphorus rickets Hypocalcemia rather than hyperphosphatemia is the primary cause of enlargement of the parathyroid glands in these conditions

Pseudohypoparathyroidism. Albright and his collaborators have reported instances of hypoparathyroidism in which there was evidence of failure of the organism to respond to the hormone. They suggested that the disturbance was not a lack of the hormone but a resistance to it

Hyp[illegible]

crease of the concentration of the serum phosphate (less than [illegible] 4 mg per 100 ml. of serum in infants) Because of the reciprocal relationship between serum calcium and serum phosphorus there is subsequent increase in the

serves as an aid in detecting suspected hyperparathyroidism before the typical skeletal changes have appeared.

Table 14-1. The Alterations in the Calcium, Phosphate and Phosphatase Observed in Several Common Disorders of the Bones

	Blood Serum Calcium	Blood Inorganic Phosphate	Alkaline Blood Phosphatase	Calcium Excretion in Urine
Hypoparathyroidism	Low	High	Normal	Low
Hyperparathyroidism	High	Low	High	High
Paget's disease	Normal	Normal	Very high	Normal
Osteomalacia	Low or normal	Low or normal	Increased	Low
Metastatic carcinoma of bone	May be high	May be low	May be high	High
Senile osteoporosis	Normal or slightly low	Normal	Normal	Normal
Multiple myeloma	High	Normal	Normal or slightly elevated	High

From Grollman, A, Essentials of Endocrinology, Ed 2, J B Lippincott Company, 1947.

In Table 14-1 are listed the changes in the blood and urinary calcium levels and in the blood phosphatase level seen in parathyroid and other common bone disorders.

Result of the Sulkowitch test for excessive calcium in the urine is positive If this test is performed, it is best to have the patient prepared by the Aub diet.

The inorganic phosphate concentration of the blood in hyperparathyroidism is usually reduced to 1.5 to 2.5 mg per 100 ml, compared with the normal concentration of 2 5 to 4 in adults, and 4 to 6 in infants and children The phosphatase level may be 20 units or more, compared with the normal level of 1.5 to 4 units.

DIAGNOSIS The diagnosis of hyperparathyroidism is based on the concentrations of the calcium and phosphorus in the blood, provided the diseases resembling hyperparathyroidism such as adolescent rickets, osteomalacia, senile osteoporosis, extensive metastatic carcinoma, multiple myeloma, Paget's disease, and polyostotic fibrous dysplasia are excluded Some of these disorders, however, can be differentiated by chemical examination of the blood (see Table 14-1). The rest can be differentiated by roentgenograms and clinical manifestations In polyostotic fibrous dysplasia the bone cysts resemble those seen in hypoparathyroidism, but the lesions in this condition are unilateral and the osteoporosis is limited to the region surrounding the lesion. In hyperparathyroidism there is usually generalized rarefaction of the cortex of the bones Hyperparathyroidism may occur without marked decalcification, the presenting symptoms being renal lithiasis or an anemia

The generalized decalcification of the bones, the hypercalcemia and the spontaneous fractures seen in multiple myeloma may suggest hyperparathyroidism However, the presence of Bence Jones protein in the urine (in about two thirds of the patients), the absence of hypophosphatemia, the hyperproteinemia of the blood, a biopsy, and the roentgenologic appearance of the bones will delineate multiple myeloma in most instances.

In metastatic carcinoma of the bone increased values for calcium and phosphatase in the blood and the presence of localized regions of osteoporosis may suggest hyperparathyroidism. In carcinoma the decalcification is irregular, and a primary lesion in a breast, a kidney or the prostate may be obvious If such a lesion is not obvious, the rapid failure of health soon will permit of a definite diagnosis

center of the shaft Owing to softening of the skeleton, devastating deformities result from gradual collapse of the spinal column, pelvis and thoracic cage (see Bone Diseases in Chapter 6).

The osseous changes in the disease result in deformities of the skeleton, and multiple fractures occur spontaneously or as a result of minor injuries The disease is commonest in middle life. It begins with generalized weakness, excessive thirst and frequent urination Pains in the back, pelvis and legs develop so that locomotion may become difficult or impossible. The skull is enlarged, the spinal column shortened and kyphotic Irregular deformities of the extremities appear. Atonia and general muscular weakness develop

The symptoms of osteitis fibrosa cystica are referable mainly to the locomotor system and comprise muscular weakness and bone pains. Sharp pain may follow slight trauma Later it is discovered that a pathologic fracture has occurred Deep pains in the heels, legs, and hips, and extending upward to the lumbar portion of the spinal column, are present after exercise and seemingly are worse after retiring for the night. The patient may observe that his stature has changed The body height lessens and there is excessive bulging of the breast bone Owing to a shortened, thickened neck, a larger collar may be necessary Pains in the shoulders, arms and hands may be present alone or may accompany those of back, legs and feet.

Often there is the history of having had a bone tumor diagnosed as a cyst by the surgeon After removal of the cyst the bone pains continue

Urinary lithiasis is frequent in those who have hyperparathyroidism However, only a fraction of the patients who present themselves with renal stones are found to be suffering from hyperparathyroidism In all cases of bilateral urinary lithiasis the possible existence of hyperparathyroidism as the causative agent is considered Polyuria, polydipsia, dysuria, albuminuria and hematuria are frequently present. In long-standing hyperparathyroidism, nephrocalcinosis may result and death may occur from renal insufficiency The deposition of calcium in the kidneys is usually interstitial with secondary obstruction of the tubules

EXAMINATION The parathyroid tumors, one or more, which are responsible for hyperparathyroidism are rarely palpable Frequently they are imbedded in the thyroid gland or present in the mediastinum

Examination of the mouth and the jaws reveals epulides or other soft-tissue tumors of the gums and the jaw There may be malocclusion and distortion of the normal arrangement of the teeth with prognathism of the mandible

On examination of the bones usually no gross abnormalities are present A fracture may be the occasion for the examination, and the nature of the fracture is revealed on roentgenologic examination In the jaws the roentgenograms reveal cystlike cavities, presence of dental caries, osteoporosis, closely meshed trabeculae of the mandible and maxilla and absence of the lamina dura of the teeth The bone cysts which are observed in patients suffering from hyperparathyroidism resemble ordinary solitary benign cysts seen in other conditions

Hyperparathyroidism is almost always associated with an increase of the concentration of calcium in the blood to 12 mg per 100 ml or more Values of more than 20 mg. have been reported in parathyroid intoxication Occasionally, however, the blood calcium concentration is within normal limits, but this occurs only if the serum protein level is abnormally low, or if there is phosphate retention due to secondary renal insufficiency Under these conditions there is actually an effective hypercalcemia despite the apparently normal concentration of the total calcium.

Normally about 70 to 95 per cent of the total calcium ingested is excreted in the feces, only a small amount appearing in the urine In hyperparathyroidism as much as 70 to 90 per cent of the ingested calcium may appear in the urine The total calcium excreted is increased so that there is a negative calcium balance The existence of this negative calcium balance in patients maintained on a low calcium diet

neogenesis) is enhanced. This conversion of amino-acid radicals to dextrose is anti-anabolic, but it is not catabolic. Cortisone increases the mobilization and utilization of fat, thereby sparing carbohydrate There is a diminished oxidation of the available carbohydrate. The sum total of the foregoing mechanisms results in an increase in the concentration of blood sugar.

Cortisone has an action on sodium and potassium metabolism which is quantitatively about 3 per cent of that of desoxycorticosterone The mechanism of action of the two is different, however; and when they are given together in certain relative dosages, they may tend to neutralize each other in electrolyte effect

Cortisone also causes lysis of lymphoid tissue, with diminution in size of the lymph nodes and the thymus. It produces a lymphocytopenia, a sharp drop in eosinophil count, and a neutrophilic leukocytosis which is usually sufficient to cause a slight increase in the total white blood cell count. The steroid also increases the renal excretion of uric acid.

The gluco-corticoids play an important part in meeting certain types of stress, such as infection, trauma (including burns), solar and roentgen irradiation, intoxications of various sorts, extremes of temperature, excessive exertion, strong emotion, malnutrition, and the effects of some drugs.

The ability of the 11, 17-oxycorticoids to counteract the effects of damaging agents is strikingly shown in the results of administration of cortisone and of ACTH in rheumatoid arthritis, rheumatic fever, gout, lupus erythematosus, and other diseases In rheumatoid arthritis, for instance, the daily injection of 100 mg or more of cortisone acetate is followed within a few days by reduction of stiffness, diminution in articular tenderness and pain on motion, reduction of swelling, and great improvement in articular and muscular function; improved appetite and gain in weight, increase in feeling of well-being sometimes amounting to euphoria, great reduction (sometimes to normal) in blood sedimentation rate; improvement in anemia, and return toward normal in plasma protein level and distribution. However, the effects seldom outlast the period of administration.

Large doses of cortisone (of the order of 100 mg daily) are capable of producing Cushing's syndrome. If administration of the drug is stopped promptly, the manifestations cease Similar doses have also induced psychoses of various types, some of which have persisted after withdrawal of medication Diabetes mellitus has also been precipitated in susceptible individuals

Lipocorticoid. The compounds, such as 11-dehydrocorticosterone (compound A of Kendall), probably influence the metabolism of fat Although some clinical and experimental evidence indicates that the adrenal cortex is involved in the metabolism of fat, this is one of the least explored aspects of the function of the adrenal cortex. Obesity is one of the outstanding features of some patients who have hyperfunctioning lesions of the adrenal cortex On the contrary, patients who have Addison's disease have difficulty in gaining weight. Thorn has observed a decrease in the fecal excretion of fat by patients with Addison's disease who are treated with compound A Some evidence indicates that these compounds are a part of the group of hormones, the urinary excretion products of which are measured collectively as the so-called glycogenic corticoids or corticosteroids

Figuratively speaking, in times of stress epinephrine and norepinephrine prepare the body for fight or flight, whichever the cerebral cortex decides is expedient in the given situation and circumstances However, if the stress is prolonged or if the body constituents are damaged, the cortical hormones function to produce, or aid in the production of, resistance to the damaging influences. Cortical hormones tend to hold in check tissue reaction to damage

Exposure to cold, heat, burns or trauma, prolonged muscular activity, fasting, chemical and bacterial agents, or disease processes cause at first an increase in the production of cortical hormones, followed by hypertrophy and increased activity of the adrenal cortex These hormones assure an adequate production and supply of blood glucose, even at the expense of the body protein causing a negative nitrogen balance if the need for glucose is great enough. Increased production of adreno-

THE ADRENAL GLANDS

Cross section of an adrenal gland reveals the two component parts, an external (or cortical) and an internal (or medullary) portion. The gland elaborates certain androgens from its cortex and epinephrine from its medulla.

ADRENOCORTICAL HORMONES. Adrenocortical hormones are grouped chemically under the term steroids The fundamental organic chemical ring system of the sterols, bile acids, sex hormones and adrenal hormones is the perhydrocyclopentenophenanthrene ring system which has a system of identification of its compounds unlike other organic ring systems.

All of the adrenocortical steroids that have been isolated are derivatives of pregnane Progesterone and estrone have been isolated from adrenal extracts but they are also ovarian products Androgenic substances with the same number of carbon atoms as androsterone also have been isolated from adrenal extracts Many compounds have been isolated from cortical extracts of the adrenal glands. However, here brief description will be given of only the commoner ones.

Mineralo-corticoids The steroids which have as their predominant action an influence on sodium and potassium metabolism are 11-desoxycorticosterone (desoxycorticosterone) and 11-desoxy-17-hydroxycorticosterone (Reichstein's Compound S)

The mineralo-corticoids cause retention of sodium and elimination of potassium. Most of this effect is exerted through the kidneys, in which these steroids act specifically on the cells of the proximal convoluted tubules to stimulate reabsorption of sodium, chloride and water are reabsorbed secondarily, and there is an increase in volume of the plasma and interstitial fluid. The renal excretion of potassium is increased, but the mechanism is not understood In addition, the mineralo-corticoids influence capillary permeability and tissue affinity for electrolytes and water These actions are associated with a decreased concentration of sodium and chloride in the sweat Both the mineralo-corticoids and the gluco-corticoids exert slight androgenic and progestational effects.

Desoxycorticosterone is the most potent. It is made synthetically and occurs in the adrenal cortex in minute quantities only, if at all It is the only mineralo-corticoid now generally available.

Desoxycorticosterone acetate (DCA, Doca, Cortate, Percorten) is employed clinically in the treatment of Addison's disease It is usually injected intramuscularly in oil solution The average dose is 2 to 3 mg daily, but in every case the dosage must be individualized to meet the needs of the patient at the time After the drug has been given for a considerable period and the requirement has been thoroughly established, pellets may be implanted in those patients whose requirements show little fluctuation

Patients receiving desoxycorticosterone should have a definite intake of sodium, which may be in the form of the chloride, bicarbonate, or citrate The usual intake is 3 to 5 gm. in addition to that needed to season the food Increasing the dose of sodium salts diminishes the requirement of hormone, and vice versa Patients receiving hormonal therapy should also take up to 2 gm of potassium daily in the diet to prevent potassium deficiency.

Hypopotassemia may cause replacement of tissue potassium with sodium, the result is muscular weakness or paralysis Prolonged overdosage may induce degenerative changes in the arteries, including nephrosclerosis These manifestations are rare if patients receive the minimal effective dosage (2 gm daily)

Desoxycorticosterone has no effect on carbohydrate metabolism, it is especially important that patients who have Addison's disease and who are receiving desoxycorticosterone have a high carbohydrate intake There should be frequent feedings, including one at bedtime.

Gluco-corticoids. The two best known gluco-corticoids are corticosterone and cortisone. Being the most readily available of the gluco-corticoids, cortisone is discussed as typical of the group

Cortisone (Kendall's Compound E) effects increase in conversion of exogenous carbohydrate to glycogen. The conversion of endogenous protein to carbohydrate (gluco-

of the tubercle bacilli Extensive tuberculous destruction of both adrenals may be encountered with comparatively little tuberculosis in other organs.

In one fourth of those who have Addison's disease there is primary atrophy of the glands or an amyloid disease. The attributable causes of secondary atrophy of the glands are neoplasms, fatty degeneration, pressure atrophy, venous thrombosis, arterial embolism and syphilis.

Characteristic findings, other than those observed in the adrenal glands, are extreme emaciation, small and atrophic heart, hypoplasia of the aorta and large vessels, atrophy of the mucosa, enlarged lymphoid follicles of the stomach and intestines, persistent thymus, and often enlargement of the spleen Renal tubular atrophy may account for the renal dysfunction responsible for the disturbance in the water-and-salt metabolism observed in the disease. The gonads may show atrophic changes

SYMPTOMS. Fatigue is the early symptom The patient becomes incapable of physical or mental effort. The patient is often apathetic and subject to depression, and irritability is increased Headaches, tinnitus, vertigo and insomnia, and pains in the lumbar region, epigastrium, and extremities are common Anorexia, nausea, and constipation alternating with diarrhea may begin early and recur with increasing frequency and severity. Thus asthenia, gastrointestinal disturbances and pigmentation constitute the cardinal symptoms of Addison's disease. Loss of weight and abdominal or lumbar pain are also common complaints

The so-called crises are common In an acute crisis the gastrointestinal disturbances such as nausea, vomiting, diarrhea, and abdominal pains may be severe.

Loss of weight is due to dehydration secondary to excessive loss of sodium, chloride and water, and impaired gastrointestinal function with anorexia and inanition

Characteristic of Addison's disease is the occurrence of spontaneous remissions. Patients who have the disease may live for 10 to 20 years without treatment after the onset of the initial symptoms

EXAMINATION. The pigmentary abnormalities of the skin are an increased pigmentation, and in some a complete loss of cutaneous pigment (vitiligo) in areas or spots Excessive tanning following exposure to the sun with a persistence of the sun tan is frequently observed Dark-skinned persons with a given degree of adrenal insufficiency will show much more pigmentation than those who have blond skin. Increase in pigmentation is common in the anogenital region and in the areolae about the nipples; in scars; over the knees, elbows, and buttocks, in brown to bluish black areas on the lips, gums, and ocular fundi, and on the buccal, rectal and vaginal surfaces The hair darkens The pigment changes in the skin may be absent throughout the course of the disease

Reduction in blood pressure is present in all patients who have Addison's disease It is to be recalled that many normal persons have systolic blood pressures between 90 and 100, measured in millimeters of mercury. Profound hypotension develops late in the course of the disease A patient who has an existing hypertension at the time of onset may exhibit all of the clinical signs of advanced Addison's disease and yet present a normal blood pressure. The heart characteristically is small

Addison's disease is accompanied by a moderate neutropenia, lymphocytosis, and an eosinophil count varying from high normal upward. After excessive loss of sodium, chloride and water, the levels of sodium and chloride tend to be low with an increased serum potassium and nonprotein nitrogen.

In severe Addison's disease, hypoglycemia is observed.

Patients who have Addison's disease are extremely sensitive to insulin, and severe reactions may be induced by the administration of quantities as small as 3 to 5 units

The secondary sex characteristics are not specifically affected by adrenal cortical insufficiency. The menstrual cycle and gonadal functions are maintained.

cortical hormones, if sustained, causes atrophy of the thymus and of other lymphoid tissues. The polymorohonuclear count is increased and the lymphocytes and eosinophils are decre[illegible] of uric acid is increased in the blood and urine

The response of t[illegible] through the pituitary gland by [illegible] The cerebral cortex, the adrenal medulla, [illegible] form a closely knitted unit in the protection of the individual [illegible] in the repair of injury sustained from trauma or infection

The response of the body tissues to epinephrine is mediated through the sympathetic nervous system, the stimuli having reached the cortex through the sense organs.

Adrenal Insufficiency (Hypofunction of Adrenal Cortex) Adrenal cortical insufficiency occurs in both acute and chronic forms.

Acute Cortical Adrenal Insufficiency. Acute collapse associated with bilateral adrenal hemorrhages may occur in the newborn, and is characterized by fever, tachypnea, cyanosis and convulsions. The condition is often associated with difficult prolonged labor which requires manipulation or instrumentation in order to accomplish delivery

The Waterhouse-Friderichsen Syndrome The Waterhouse-Friderichsen syndrome occurs in overwhelming sepsis, resulting as a rule from meningococcal infection, but may occur in a variety of other fulminating septicemias also There are dehydration, purpura, shock, a decrease in serum sodium, and an increase in the nonprotein nitrogen At necropsy the adrenal glands are hemorrhagic

In children and adults alike the insufficiency occurs most frequently in association with severe infections such as staphylococcal septicemia, meningococcemia, influenza, and streptococcal infections There is almost always an associated generalized hemorrhagic manifestation

Shortly after the onset there is a generalized cyanosis It is soon followed by a rash, which is petechial at first, but may soon become blotchy and confluent over the whole body The rash, characteristically, does not fade on pressure Fever at first is moderate but it becomes extreme Temperatures of 107 to 108 F (41 7 to 42 2 C) may be reached prior to death As in sunstroke, brain tumors and other conditions associated with such high fevers, symptoms due to the central nervous system such as stiffness of the neck, increased irritability, and finally convulsions, stupor, coma and death quickly ensue In other cases the temperature may fall, the pulse becomes weak and thready, the blood pressure may become unobtainable, and the patient dies in shock In most instances the entire course of events occurs in 12 to 24 hours

Laboratory studies usually reveal a marked polymorphonuclear leukocytosis with normal eosinophil counts Hypoglycemia is severe There may be an increase of nonprotein nitrogen concentration of the blood The concentrations of serum sodium and potassium are within normal limits

Acute adrenal cortical insufficiency which may follow operative procedures on the adrenal glands may be anticipated and therapy tried

Addison's Disease (*Chronic Cortical Adrenal Insufficiency*). Addison's disease is a rare disease which is due to a chronic adrenal cortical insufficiency. It occurs usually in men between the ages of 20 and 40 years, but it may be encountered at any age. The patients usually live long enough to visit several institutions and thus to be recorded several times.

In half of the patients who have Addison's disease the destructive process of the adrenal glands is tuberculosis.

The tuberculous lesion of the adrenal glands is originated by hematogenous spread

voided during any one of the one-hour periods of the morning (that is, of the specimens collected at 9:30, 10.30, 11:30 and 12:30), the patient presumably does not have Addison's disease. If the volume of the night urine exceeds that of any single morning specimen, further chemical studies are indicated The urea and chloride contents of the night urine and of the blood plasma are determined These values expressed in the same units are then substituted in the following equation

$$A = \frac{\text{urea in night urine}}{\text{urea in plasma}} \times \frac{\text{chloride in plasma}}{\text{chloride in night urine}} \times \frac{\text{volume of day urine}}{\text{volume of night urine}}$$

If A is 25 or less, the patient probably has Addison's disease, if A is 30 or more, the disease is not likely to be present.

This procedure is not specific for in patients who have asthenia and exhaustion not of adrenal origin false positive results may be obtained

DIAGNOSIS. The presence of pigmentation, asthenia, hypotension, and gastric disturbances is suggestive of Addison's disease In instances in which the diagnosis is not certain some one, or all, of the special tests described, such as the salt deprivation test, may be employed Pigmentation similar to that which occurs in Addison's disease is most commonly observed in individuals of mixed races, dark-skinned and white-skinned. Sometimes in pregnancy, uterine disease, hemochromatosis, chronic arsenic poisoning, pernicious anemia, ochronosis and Recklinghausen's disease the distribution of pigmentation may resemble that present in Addison's disease. Asthenia and hypotension are accompaniments of most protracted debilitating illnesses, as are also digestive disturbances. Pernicious anemia and abdominal tuberculosis may show a superficial resemblance to Addison's disease

Hyperfunction of the Adrenal Cortex. The adrenal cortex may begin to function excessively without any demonstrable histologic changes in its structure. In some there may be present a cellular hyperplasia, in others overactivity can be accounted for on the basis of a benign or malignant tumor if the tumor cells secrete cortical hormones. However, either benign or malignant tumors may be present without glandular hyperfunction

After protracted infections *simple hyperplasia* of the adrenal glands frequently is observed. Cortical hyperplasia is considered to be simple hypertrophy in response to an increased demand on the part of the organism.

The syndromes of hyperfunction of the adrenal cortex are extremely protean in nature and presumably depend on the type and quantity of steroid hormones produced, the age and sex of the patient, and perhaps on other factors Anyway, these syndromes may defy the ability of the expert to separate them. The syndromes may be divided into two large categories as follows: (1) Cushing's syndrome and (2) the adrenogenital syndrome

Cushing's Snydrome (*Adrenal Cortical Hyperfunction*). The Cushing syndrome, believed by Cushing to be caused by a basophilic adenoma of the pituitary body, is now generally regarded as being associated with hyperplasia of the adrenal cortex or tumors of this tissue.

In a few of the cases there is a basophilic tumor. Occasionally the basophilic tumor has eroded the sella turcica In isolated instances there may be a chromophobe tumor or a mixed tumor. When a tumor is present the syndrome is then designated Cushing's disease

In adrenal cortical hyperfunction many different combinations of manifestations are possible and it is for this reason that so much has been written about the Cushing syndrome. An overproduction of the mineralo-corticoids may result in hypertension, edema, decreased concentrations of plasma potassium (less than 15 mg per 100 ml.) and occasionally increase in sodium (more than 350 mg. per 100

Sclerotic changes in the pinnas of the ears may be present in long-standing ison's disease.

In Addison's disease there is a reduced 17-ketosteroid excretion. However, : 17-ketosteroids are found to be decreased in the presence of wasting disease, w 17-ketosteroid excretion is not pathognomonic.

A number of tests have been advocated for aids in diagnosis if the findings on ical and laboratory examinations are inconclusive

The Response to Pituitary Adrenocorticotropic Hormone A test for adrenal cortical ficiency based on the failure of patients who have Addison's disease to secrete cal hormones in response to the pituitary adrenocorticotropic hormone has been loped by Thorn, Forsham, Prunty and Hills

The maximal fall in circulating eosinophils and the maximal increase in excretion of acid occur approximately four hours after the intramuscular injection of the ione Patients who have classic Addison's disease fail to show these changes after nistration of the hormone.

The 48-Hour ACTH Test This is the most reliable of the tests based on the response e normal adrenal cortex to its trophic hormone as described by Thorn and co-ers Twenty-five or more milligrams of ACTH is given intramuscularly or intra-usly at 6-hour intervals for a 2-day period. The excretion of 17-ketosteroids during econd 24-hour period during the administration of ACTH and the number of cir-ing eosinophils are compared to values obtained prior to the administration of H A rise of less than 3 or 4 mg in the 17-ketosteroid excretion in the urine accom-d by less than 40 to 50 per cent decrease in circulating eosinophils is indicative of ial cortical insufficiency

The Response of the Circulating Eosinophils to Administration of ACTH The normal s of the 17-ketosteroids for adult men between the ages of 20 and 40 years range 10 to 20 mg per 24-hour urine specimen, the normal female value for the same roup is from 8 to 15 mg In both boys and girls there is less than 1 mg per day at and concentrations between 1 and 2 mg. until the age of 8 years, thenceforward is a gradual increase until adult concentrations are attained In aging men and en there is a gradual decrease in the concentration of the 17-ketosteroids in the urine . low 17-ketosteroid concentration in the urine is compatible with the diagnosis of son's disease but not pathognomonic of it In hypopituitarism the concentration of tosteroid is very much decreased Also, low concentrations of 17-ketosteroid in rine may occur in chronic disease of various origins, as well as being decreased in resence of both hypothyroidism and hyperthyroidism

The concentration of the 11-oxysteroids is greatly decreased in both primary and dary adrenal cortical insufficiency The determination of the urinary 17-ketosteroids, ugh a less specific index of cortical activity, is more easily carried out and entirely actory for clinical purposes In women the adrenal cortex is the only important e of these compounds or their precursors, where in men the testes make additional ibution it is for this reason that 17-ketosteroid excretion is normally 50 per cent er in men than in women

Sodium Restriction Test Kepler, Robinson and Power described what is considered a *safe sodium restriction test* to supplant the test advocated by Cutler, Power and er This test may be performed if need be for diagnostic purposes In the so-called test the patient eats three ordinary meals on the day preceding the test, without g any extra salt. Nothing is eaten or drunk after 6 P.M on the day of the test At) P.M the bladder is emptied and the urine discarded At 7.30 the following morn-ne urine is collected, measured and set aside for analysis, if subsequently required. .30 A.M. the patient voids again This urine is discarded and 20 ml of water per ram of body weight (9 ml. per pound) is administered orally during the next 45 tes. The patient voids hourly at 9 30, 10.30, 11·30 A M. and 12 30 P M and each men is measured. The patient should remain at rest in bed throughout the period of est While the patient is fasting, blood samples are drawn for determinations of and chloride

The findings in the test just described are interpreted as follows: If the volume of : urine (that is, of the specimen collected at 7:30 A.M) is less than the volume

to the formation of renal calculi. Concentrations of the plasma calcium, phosphorus and phosphatase are within the normal limits.

Hypertension when present is usually grouped as benign. However, malignant hypertension with associated retinitis, edema of the optic disks, cardiac enlargement, heart failure and cerebrovascular accidents may occur and if so usually persist after the removal of the tumor.

There may be polycythemia, lymphopenia, and eosinopenia of varying degrees.

Diabetes often is present. An insulin resistant type of diabetes may be the only evidence of an adrenocortical tumor.

The concentration of the plasma potassium may be reduced and occasionally there is present hypochloremic alkalosis with or without an increased concentration of plasma sodium. The urinary 17-ketosteroids are usually normal in amount, but may be increased Bio-assay or chemical analysis of the urine for cortin-like substances usually reveals increased values

The patient who has Cushing's syndrome is not being injured by an excess of androgens and for this reason concentration of the 17-ketosteroids may be within the limits of normal. When Cushing's syndrome is due to bilateral adrenal hyperplasia, the concentration of the 17-ketosteroids in the urine is only slightly increased When Cushing's syndrome is caused by adrenal cortical adenoma the concentration of the 17-ketosteroids in the urine may be depressed; whereas in a patient who has adrenal cortical carcinoma, the 17-ketosteroid concentration in the urine is greatly increased. Decreased concentration of the 17-ketosteroids in the urine in the presence of adrenal cortical adenoma seems to be accounted for by the presence of atrophy of the contralateral adrenal gland

DIAGNOSIS The diagnosis when classic manifestations of Cushing's syndrome are present seems to be made frequently These manifestations are obesity (moon face), shrunken weak legs and arms, thin skin, hypertension, virilism, diabetes, osteoporosis and an increase in the excretion of 17-ketosteroids. The definite diagnosis of the varying degrees or syndromes which may be present in cortical hyperplasia and in tumor is difficult The isolation of dehydroisoandrosterone or the finding of a high ratio of the beta to the alpha ketosteroids is evidence of the presence of an adrenal tumor The excretion of pregnanediol may be increased: 30 mg. daily in cases of hyperplasia of the adrenal, compared with 5 to 10 mg. at the peak of the normal menstrual cycle In the absence of pregnancy this is significant.

Roentgenograms of the sella turcica should be made to rule out Cushing's disease. Negative roentgenograms of the kidneys and suprarenal areas will help to eliminate the possibility of adrenal tumor

The Adrenogenital Syndrome. The term adrenogenital syndrome is applied to cases of hyperadrenocorticism in which there is usually excessive masculinization attended by rapid growth, particularly in height, muscular development and accelerated epiphysial ossification Here there seems to be an increased protein anabolism due to excessive production of androgen, whereas in the Cushing syndrome there seems to be an increase of the glycogenetic hormone causing amino acids to be utilized for the formation of carbohydrate rather than building of protein tissues. Masculine hirsutism is present in both the adrenogenital and the Cushing syndrome

The adrenal cortical extracts contain estrogens, androgens, progesterone-like substances and cortilactin which acts on the breasts Despite the presence of these substances in cortical extracts there is no proof that the adrenal cortex is normally concerned with the regulation of sexual functions In disease excessive amounts of one or more of the sex hormones may be present in the adrenal cortex with consequent derangement of sexual function.

As in Cushing's syndrome the changes in the adrenal cortex in the adreno-

ml.) of the plasma. An increase of 11-dehydro-17-hydroxycorticosterone causes a wasting of the bone (osteoporosis) and muscles; lymphopenia, eosinopenia, a thin skin, ecchymosis and in some cases diabetes mellitus. In women there are amenorrhea, hirsutism and increased vigor.

In all instances there are changes in the cortical tissue of the adrenal glands consisting of a benign hyperplasia or neoplasm either benign or malignant.

In the pituitary body there are cytoplasmic hyalinization of the basophilic cells, disappearance of the basophilic granules, excessive vacuolization, ballooning of the nuclei, and general enlargement of the cells

Gross and often severe disease of the pancreas frequently is present. Infiltration of the liver with fat, and chronic passive hepatic congestion are noted frequently. There is a high incidence of nephrosclerosis, renal calcinosis and renal calculi The incidence of the presence of renal calcinosis with formation of calculi is an expected accompaniment of the osteoporosis and the calciuria. Hypertrophy of the heart is frequent Occasionally infiltration of the parathyroid bodies with fat is observed.

SYMPTOMS. Cushing's syndrome is uncommon in children. It commonly occurs in young women but may affect boys or men. The symptoms may arise from any one of the many manifestations of the disease The disease may have begun and progressed slowly so that the young woman comes to the physician because of disgust with her hairy fat face, feelings of tension in the head and nosebleeds In others the increased deposits of fat around the neck and face may have become painful There may be symptoms of hypertension, diabetes or deep aching pains of the bones arising from the osteoporosis. The flesh may bruise easily, the skin is thin and bleeds excessively from shallow cuts or abrasions

A wide variety of mental symptoms may be present These range from mild reactive depressions to severe and profound depressed states. Severe mental disorders may be present in patients who have Cushing's syndrome.

EXAMINATION On examination usually there is a pad of fat over the lower cervical and upper thoracic regions of the back The upper lids and the corners of the mouth droop The cheeks are florid, full, and large enough to obscure the ears when the face is viewed from the front (the so-called moon face). In children the neck may be obscured by drooping fat cheeks. The fat cheeks extend forward and sag enough so that the mouth appears small and deeply set in the face There are wasting and weakness of the muscles combined with obesity in which there is an abnormal distribution of fat, the combination of which makes the trunk, face and neck appear obese and the extremities thin. Extreme obesity is not commonly observed in Cushing's syndrome except when the disease occurs in childhood.

There are muscular weakness and atrophy in the legs. There is a relationship of the muscular weakness and the concentration of the plasma potassium. The potassium is decreased.

The skin is so thin that the superficial veins are made evident by their contrasting bluish color. All degrees of acne may be present, including acne pustulosa and acne indurata. The acne is made more evident by red thin skin (androgenic flush).

The skin over the lower part of the abdomen, the anterior lateral aspect of the thighs, the upper part of the arms, the axillae, pectoral regions and breasts is striped with purplish parallel linear striations These striae develop rapidly and may become ecchymotic, infected and necrotic.

There are hirsutism, hypertension, osteoporosis, diabetes, either latent or manifest, ecchymoses, and amenorrhea or impotence. Except for the presence of hirsutism, there is little or no evidence of masculinization

The osteoporosis of Cushing's syndrome as described by the roentgenologist is present in the vertebral column, the skull, the ribs and other bones. Compression fractures of the spinal column may occur. Hypercalciuria, when present, may lead

Precocious puberty is often one of the initial symptoms which induce the parents of children who have hyperfunctioning adrenocortical lesions to consult a physician Among afflicted girls the puberty proceeds along masculine lines. Hair appears on the pubes, the extremities and the face, the clitoris enlarges, the larynx enlarges and the voice deepens, and in cases of long standing the musculature, the skeletal framework and the distribution of subcutaneous fat all become masculine in type. In some cases of adrenocortical tumor puberty seems to be dissociated so that it proceeds along both masculine and feminine lines with masculine traits predominating. However, in some there is a mixture of masculine and feminine characteristics, including vaginal bleeding and development of the breasts A pure homologous sexual precocity does not occur in the female sex as the result of adrenal cortical hyperfunction Homologous sexual precocity in the female is due either to a granulosa cell tumor of the ovary or to one or several intracranial lesions (internal hydrocephalus, and tumors of the hypothalamus, pineal body or contiguous structures).

In girls there are hypertrophy of the labia majora, projection of the labia minora and enlargement of the clitoris, which may resemble a penis in structure In boys, in whom the disease is infrequent, there are excessive muscular development, deepening of the voice and hirsutism. There is enlargement of the penis, but the testes remain immature. There is usually a luxuriant growth of the pubic and sometimes of the facial hair, giving the impression of maturity

In the adrenogenital syndrome there is no true precocious puberty as observed in tumors of the testes and ovaries and in the pineal and hypothalamic disorders. There is neither menstruation nor spermatogenesis as observed in true precocious puberty.

On examination if there is a single meatus situated between the labial folds it should be determined whether this is a urogenital sinus or a normal urethra. This is determined by passage of a urethroscope with skilled hands In some instances the communication is delineated by means of roentgenograms In still other instances when physical examinations are impossible it may be well to ask the surgeon to explore and biopsy the gonads to determine their histologic structure The surgeon who performs an exploratory operation on such a patient is acquainted with the different abnormal embryonic developments which attend, congenital adrenal hyperplasia in females, the hermaphrodites (intersexes), the pseudohermaphrodites (male and female)

The congenital hormonal reversal in the female or those reversals occurring after birth are attended by masculinizing characteristics, increased bone growth and excessive excretion of 17-ketosteroids

The Adult Form (Adrenal Virilism). In the adult the adrenogenital syndrome almost always occurs in girls during the latter years of adolescence or in women at the time of the menopause

Virilism may occur in women who have (1) adrenal cortical hyperfunction, (2) arrhenoblastomas of the ovaries and (3) after prolonged administration of testosterone. Arrhenoblastomas manifest none of the distinctive features of the adrenogenital syndrome or distinctive metabolic features The administration of testosterone is determined by the history

In adrenal virilism, hirsutism may be the most annoying manifestation to the patient Hirsutism without virilism is usually hereditary in origin. Likewise hirsutism, obesity and oligomenorrhea without other symptoms of virilism are rarely attributable to adrenal cortical hyperfunction

Women who have hirsutism, mild virilism including muscular strength, and sterility usually enjoy environmental adjustment and make good wives.

In the adult form of the adrenogenital syndrome there is a retrogression of the

genital syndrome are variable. There may be no detectable anatomic changes or hyperplasia or a tumor. Tumors of the adrenals accompanied by changes in the reproductive system and somatic type indicative of sexual reversal are more frequent in the female than in the male.

As in Cushing's syndrome the manifestations depend on the sex and the age of the patient at the time of the inception of the disorder. The adrenogenital syndrome, therefore, can be classified into the female pseudohermaphroditic and the juvenile types, as it occurs in children before puberty; the adult type, which gives rise to virilism in adolescent girls and women

The Female Pseudohermaphroditic Type (Adrenal Virilism). The pseudohermaphroditism as it occurs in congenital adrenal hyperplasia is the commonest adrenal cortical disorder encountered during childhood. The condition is characterized by prenatal abnormalities of the sex organs which are followed by an excessive production of androgen thereafter.

The prenatal abnormality consists of a persistent genital duct in the female which forms a urogenital sinus as in the male The vulva is but a shallow groove between hypertrophied labia majora. The labia minora are rudimentary The clitoris, by the time of birth, is hypertrophied

Due to the excessive secretion of androgen, growth, muscular development and epiphysial ossification advance more rapidly than in the normal.

Some infants may have normally formed genitals but have an excess of cortical hormones at birth The manifestations of excess of cortical hormones at birth are divisible into (1) those who develop an adrenogenital syndrome early in life which may be followed by the development of Addison's disease; (2) those who have manifestations of Addison's disease at birth and usually die soon thereafter. Symptomatically the infants of the latter group resemble those whose condition arises from atresia of the duodenum or atresia in the proximal portion of the small intestine

Virilism and pseudohermaphroditism may affect either sex. Feminine pseudohermaphroditism is most often associated with adrenocortical hyperplasia and is rarely found in cases of adrenocortical tumor

In pseudomasculine hermaphroditism there are secondary male characters with female generative organs. The male characters may be the result of an androgenic activity of the adrenal glands which may be a part of the congenital maldevelopment If this be the case, these glands exert their androgenic influences early in embryonic life, for it is only at this time that the observed relationships of the organs could have assumed their abnormal forms

From birth on, these infants show evidences of increased secretion of androgen. Somatic growth, muscular development and epiphysial ossification become far advanced for the age of the patient. Frequently pubic and axillary hair and acne appear by the age of 2 to 5 years At the age of adolescence, development of the breasts and menstruation do not appear. Owing to early epiphysial fusion these patients are short, stocky, and muscular, with coarse hair on the face, abdomen, thighs and legs.

The Juvenile Form (Adrenal Virilism) The juvenile form of the adrenogenital syndrome usually occurs in girls. It rarely occurs in boys When it does occur in boys several children of the same family may be affected

In juvenile virilism the child may have been thought to be a pseudohermaphrodite from birth or the anomaly may have gone unobserved until evidences of virilism appear.

The growth of the long bones usually has proceeded rapidly but subsequently ceases because of premature closure of the epiphyses. Elongation of the spinal column follows The adolescent consequently may be tall with long arms and legs

Precocious puberty is often one of the initial symptoms which induce the parents of children who have hyperfunctioning adrenocortical lesions to consult a physician. Among afflicted girls the puberty proceeds along masculine lines Hair appears on the pubes, the extremities and the face, the clitoris enlarges, the larynx enlarges and the voice deepens, and in cases of long standing the musculature, the skeletal framework and the distribution of subcutaneous fat all become masculine in type. In some cases of adrenocortical tumor puberty seems to be dissociated so that it proceeds along both masculine and feminine lines with masculine traits predominating However, in some there is a mixture of masculine and feminine characteristics, including vaginal bleeding and development of the breasts A pure homologous sexual precocity does not occur in the female sex as the result of adrenal cortical hyperfunction. Homologous sexual precocity in the female is due either to a granulosa cell tumor of the ovary or to one or several intracranial lesions (internal hydrocephalus, and tumors of the hypothalamus, pineal body or contiguous structures).

In girls there are hypertrophy of the labia majora, projection of the labia minora and enlargement of the clitoris, which may resemble a penis in structure. In boys, in whom the disease is infrequent, there are excessive muscular development, deepening of the voice and hirsutism There is enlargement of the penis, but the testes remain immature. There is usually a luxuriant growth of the pubic and sometimes of the facial hair, giving the impression of maturity

In the adrenogenital syndrome there is no true precocious puberty as observed in tumors of the testes and ovaries and in the pineal and hypothalamic disorders There is neither menstruation nor spermatogenesis as observed in true precocious puberty.

On examination if there is a single meatus situated between the labial folds it should be determined whether this is a urogenital sinus or a normal urethra This is determined by passage of a urethroscope with skilled hands In some instances the communication is delineated by means of roentgenograms In still other instances when physical examinations are impossible it may be well to ask the surgeon to explore and biopsy the gonads to determine their histologic structure The surgeon who performs an exploratory operation on such a patient is acquainted with the different abnormal embryonic developments which attend, congenital adrenal hyperplasia in females, the hermaphrodites (intersexes), the pseudohermaphrodites (male and female).

The congenital hormonal reversal in the female or those reversals occurring after birth are attended by masculinizing characteristics, increased bone growth and excessive excretion of 17-ketosteroids

The Adult Form (Adrenal Virilism) In the adult the adrenogenital syndrome almost always occurs in girls during the latter years of adolescence or in women at the time of the menopause.

Virilism may occur in women who have (1) adrenal cortical hyperfunction, (2) arrhenoblastomas of the ovaries and (3) after prolonged administration of testosterone. Arrhenoblastomas manifest none of the distinctive features of the adrenogenital syndrome or distinctive metabolic features. The administration of testosterone is determined by the history.

In adrenal virilism, hirsutism may be the most annoying manifestation to the patient Hirsutism without virilism is usually hereditary in origin Likewise hirsutism, obesity and oligomenorrhea without other symptoms of virilism are rarely attributable to adrenal cortical hyperfunction

Women who have hirsutism, mild virilism including muscular strength, and sterility usually enjoy environmental adjustment and make good wives.

In the adult form of the adrenogenital syndrome there is a retrogression of the

normal female sex characteristics. The female sex characters are gradually replaced by the male type of bodily contour and voice, and by hypertrophy of the clitoris and cessation of the menses. The mental perspective is that of a man. There is a striation of the thighs and abdomen similar to that which occurs in the Cushing syndrome.

In the androgenital syndrome, or adrenal virilism, the concentration of the 17-ketosteroids in the urine is definitely increased In the presence of bilateral hyperplasia of the adrenal cortex the concentration of 17-ketosteroids in the urine is from 5 to 30 times the normal In the presence of adrenal adenoma the concentration of the 17-ketosteroids in the urine may reach 100 mg per day. In the presence of adrenal carcinoma the concentration may exceed 200 mg. per day. The beta reaction of the 17-ketosteroids (mainly dehydroisoandrosterone) is markedly increased over its usual 5 to 15 per cent of the total 17-ketosteroids in the presence of adrenal cortical adenoma or carcinoma.

The administration of cortisone to a patient who has adrenal virilism will reduce the concentration of the 17-ketosteroids If the adrenal virilism is due to carcinoma, administration of cortisone is without effect on the urinary steroid content

In boys, as has been stated, precocious puberty may be due to hypothalamic lesions, constitutional precociousness or tumors of the Leydig cells of the testis In these conditions the concentration of the 17-ketosteroids is consistent with the sexual development of the child On occasions the concentration will be increased to 100 mg per day in the presence of Leydig cell tumors In precociousness due to hyperfunctioning of the adrenal cortex the concentration of the 17-ketosteroids is greatly increased.

Tumors of the Adrenal Cortex. The manifestations of adrenal cortical hyperfunction as observed in Cushing's syndrome and the adrenogenital syndrome have been briefly described Moreover, it was emphasized in these descriptions that *hyperfunction of the adrenal cortex was often due to hyperplasia but might be* due to adenomas or adenocarcinomas.

In cortical adrenal tumors the patient may have features of both Cushing's syndrome and the adrenogenital syndrome In the presence of a hyperfunctioning adrenal cortical tumor the symptoms may be dependent on age and sex For instance, in boys there is sexual and somatic precocity In girls there is a type represented by heterologous sexual and somatic precocity and a type represented by homologous precocity characterized by uterine bleeding and enlargement of the breasts. In men hyperfunctioning tumors may produce feminization, while in women there may occur varying degrees of virilism. A hyperfunctioning adrenal cortex may produce symptoms which are independent of age and sex In these patients there is an altered habitus dependent on facial and abdominal obesity, kyphosis and thin arms and legs.

Either oligomenorrhea or amenorrhea is often an early symptom of hyperfunctioning adrenocortical lesions among adults. Generally hot flushes do not occur Impotence of men may be regarded as the homologue of the amenorrhea that occurs among women. Amenorrhea or impotence may occur in conjunction with either adrenocortical tumor or hyperplasia

In most instances of slowly developing adrenocortical tumors the patients are women after the age of puberty and before the menopause These women tend to acquire masculine physical attributes such as hirsutism and enlargement of the clitoris, and tend to become mesomorphic in somatic type.

In rare instances a man may have an adrenocortical tumor *which causes* enlargement of the breasts, impotence and feminine habitus.

Either men or women who are affected by these tumors are usually miserable *because of their* repulsive appearance. However, some show a remarkable capacity to make the necessary psychic adjustments.

The diagnosis of virilism associated with adrenal cortical tumor is made definite only by histologic examination of the tissue obtained by surgical exploration and biopsy. In some instances diagnostic information may be had by the performance of intravenous pyelography which may reveal displacement of the kidney downward with flattening of the upper calyx.

The information obtained from hormonal determinations is as follows Increased excretion of urinary gonadotropin is indicative of the menopause or a tumor composed of chorionic cells and excludes adrenal cortical hyperfunction. Normal concentration of estrogen is of no diagnostic significance. Increased concentration suggests adrenal cortical hyperfunction (tumor)

Steroid Diabetes. Sprague defines steroid diabetes as a diabetic state resulting from an excess of adrenal steroids (cortisone and hydrocortisone). These steroids impair both carbohydrate and protein metabolism and interfere with the action of insulin.

It seems that the presence of some adrenal steroids is necessary for the maintenance of diabetes mellitus for many of the features of the disease disappear if the adrenals of the diabetic are destroyed or removed, and the diabetic state is restored if cortisone or hydrocortisone is administered

Steroid diabetes is limited to patients with spontaneous adrenal cortical hyperfunction of the type with Cushing's syndrome and to some patients who are receiving cortisone, hydrocortisone or corticotropin in large doses In diabetes mellitus there is no convincing evidence of hyperfunction of the adrenal cortex, except transiently, or during severe diabetic acidosis Insufficiency of the islet tissue increases the likelihood that diabetes will result from the presence of excessive amounts of adrenal steroids

Tumors of the Adrenal Medulla (Hyperadrenalism). The adrenal medulla elaborates epinephrine, which stimulates the sympathetic nervous system and, briefly stated, instantly prepares the individual for fight or flight or whatever response the situation demands This preparation is manifested by a dilatation of the pupils, increased cardiac output, contraction of the arterioles, dilatation of the bronchioles and mobilization of blood sugar from the stores of glycogen

The chemically and pharmacologically closely related compound norepinephrine also is present in the medulla as well as throughout the mammalian body

Epinephrine and the corresponding primary amine 1-norepinephrine (noradrenaline, arterenol) normally exist in the mammalian body Norepinephrine was first shown to be present in significant amounts in human beings by pharmacologic and chemical methods 1-norepinephrine is believed to function as excitor sympathin

Epinephrine, within a physiologic and therapeutic range, acts as an over-all vasodilator and causes hypertension only by increase of cardiac output. Norepinephrine functions as an over-all vasoconstrictor without change or only slight decrease of cardiac output It may therefore be conceived as being the sympathetic mediator of over-all vasoconstriction in human beings

The injection of norepinephrine causes within 30 seconds an abrupt rise in the blood pressure which lasts 5 to 8 minutes However, the ventricular rate shows only a slight and transient increase The average increase in the ventricular rate in 10 patients with complete heart block studied by Nathanson and Miller was 5 beats per minute After the administration of epinephrine, there was a pronounced and sustained increase in the ventricular rate, the average increase being 29 3 beats per minute.

It appears, therefore, that epinephrine, in contrast to norepinephrine, possesses both a potent pressor and a cardiac-stimulating action. One of the deductions to be made from these observations is that the presence in the body of a potent sympathomimetic pressor agent with little or no cardiac-stimulating action suggests the possible participation of the sympathetic nervous system in the genesis of essential hypertension

There are four types of tumors which arise in the adrenal medulla: (1) the ganglioneuroma, (2) the sympathogonioma or neurogonioma, (3) the sympathoblastoma and (4) the pheochromocytoma or chromaffinoma

The ganglioneuroma is benign and usually gives no symptoms. The sympathogonioma and sympathoblastoma are highly malignant and occur in infancy or childhood.

Pheochromocytoma (*Chromaffinoma*). The pheochromocytoma or chromaffinoma is the only one of the tumors of the adrenal medulla having hormonal activity. The tumor arises from differentiated chromophil cells which secrete epinephrine or norepinephrine Its symptoms are accounted for by the excessive secretion of combinations of these compounds These tumors may be present in many parts of the body, wherever sympathetic ganglia are situated Pheochromocytomas occur in both adrenals in some cases When the tumors cause hypertension they have been situated in or near the adrenal gland or glands

Paroxysmal attacks of hypertension are characteristic. They may recur at long intervals or as often as several times a day They last minutes to hours, tend to increase in frequency and are often precipitated by emotion, pressure over the tumor, straining, or lying in certain positions These attacks are not present in more than one third of patients who have pheochromocytoma and similar attacks may occur in those who do not have pheochromocytoma

The attack commences with a feeling of weakness and apprehension, palpitation and headache, progressing to a pounding in the chest and throbbing in the head so severe that prostration ensues. These symptoms are commonly associated with pain in the abdomen, chest, back or extremities, nausea, vomiting, drenching sweats and exhaustion

have an excessive rise in blood pressure after immersing a hand in ice water one minute Elevated pressures of 20 mm in systole and 15 mm in diastole are considered abnormal, whereas, a normal or a negative response is common in patients who have pheochromocytoma In the upright position the systolic and diastolic pressure of ordinary hypertensive patients does not commonly fall below the levels in the horizontal position Similarly, the pulse rate does not rise more than 20 or more beats per minute. Most patients with pheochromocytoma have postural tachycardia and, in addition, about half of these have postural hypotension. An intermittent elevation of the body temperature, not necessarily related to paroxysmal symptoms, is found in more than 7 of every 10 of these patients. The determination of the concentration of blood sugar is diagnostically useful A greater concentration than 120 mg per 100 ml is significant Glycosuria may also be found with or without increased blood sugar. An increased basal metabolic rate of +20 per cent is frequent in those who have pheochromocytoma

Roth and Kvale observed that patients with pheochromocytoma responded to the intravenous injection of 0.0125 to 0.025 mg. histamine base with a sudden rise of blood pressure, amounting to as much as 200 mm. systolic and 100 mm. diastolic. The characteristic symptoms of a paroxysmal attack, including circumoral pallor, pilo-erection and sweating, were reproduced

Diagnosis. The diagnosis of pheochromocytoma can be made if there are paroxysmal attacks of hypertension, excessive sweating, peripheral vasomotor phenomena, a normal cold-pressor response, postural tachycardia and hypotension, and elevation of temperature, blood sugar and basal metabolism. *The induction of an attack of paroxysmal hypertension at will by the injection of histamine confirms the diagnosis of pheochromocytoma.*

Adrenal tumors, other than pheochromocytoma, sometimes cause hypertension. Elevated blood pressure is one of the symptoms of Cushing's syndrome, whether due to adrenal tumor or of pituitary origin

The pituitary gland (hypophysis cerebri) is situated within the small cavity of the sphenoid bone (the sella turcica). It is an ovoid reddish gray mass which is readily separated into the anterior and posterior lobes.

The staining reactions of the cells of the pituitary gland are often referred to in discussion of the origin of the pituitary hormones For instance, some of the cells react to the acid dye, eosin, and therefore are spoken of as acidophilic or eosinophilic. Other cells react to the basic dyes, methylene blue or hematoxylin, and are called basophilic Still other cells possess the quality of staining very poorly or not at all and these are designated chromophobic cells

The chromophobes do not produce hormones but are probably precursors of basophils or acidophils. The *growth hormone* is produced by eosinophils; the *follicle-stimulating hormone* is produced by basophils, and *vasopressin* and *oxytocin* are produced by pituicytes The pituicyte is any one of the fusiform cells composing most of the pars nervosa of the pituitary body The origin of the other hormones is indeterminate at the present.

The adrenal medulla and the neurohypophysis are derived from the nervous system, possess a rich nerve supply, and are directly affected by neural impulses It seems likely that much of the nervous control of the endocrine system is mediated through the pituitary The glands which are specifically susceptible to the pituitary hormones are the thyroid, the adrenals, and the gonads These glands are referred to as *target glands*

The concentration in the blood and tissues of the pituitary hormones seems to regulate pituitary function as well as the production of hormones by the thyroid, gonads and adrenal glands. A circulating hormone from some other gland, if of sufficient concentration, may inhibit the secretion of its specific tropin by the pituitary gland and may stimulate the pituitary to secrete a different tropin Such a relationship between the pituitary gland and the ovaries is believed to be responsible for the menstrual cycle

Hypersecretion or deficiency of the thyroid gland, the adrenal glands or the gonads may be due to a disorder in one of these glands, in the pituitary, or in the brain. It is thus evident that the same symptoms may result from a lesion in any of these three different organs

Lesions in the *hypothalamus* may be accompanied by either excessive or diminished activity of the pituitary

The pituitary may be affected by *metabolic disturbances* such as severe malnutrition, vitamin deprivation, or disease Such deprivations may lead to the symptoms of generalized pituitary deficiency with termination of the menses

HORMONES OF THE PITUITARY GLAND Six distinct hormones are elaborated by the *anterior lobe* of the pituitary, namely, thyrotropic, adrenocorticotropic, follicle-stimulating, luteinizing, luteotropic, and the growth hormone. The posterior lobe of the pituitary elaborates one hormone which contains the active principles oxytocin and pitressin.

The *thyrotropic hormone* (TSH or TTH) by stimulating the thyroid causes hypertrophy and hyperplasia of this gland and thus increases its ability to take up and fix iodine. The concentration of total and protein-bound iodine in the serum also is increased The effects are similar to those produced by thyroid substance

The *adrenocorticotropic hormone* (ACTH) determines the carbohydrate-regulating function of the adrenals Another tropic hormone in addition to ACTH may influence the secretion of the adrenal androgen

The *follicle-stimulating hormone* (FSH) is necessary for the growth of graafian follicles after they have reached the stage of formation of antra. This hormone, acting with the *luteinizing hormone* (LH), influences secretion of estrogen, maturation of the follicle, ovulation, and formation of luteal tissue. In the male, FSH with LH stimulates the development of the seminiferous tubules and the production of spermatozoa

The *luteinizing hormone* (LH) induces ovulation and the formation of a nonfunctioning corpus luteum It controls the secretion of testicular androgen

The *luteotropic hormone* (LTH), *lactogenic hormone* or *prolactin* maintains the corpus luteum for about 2 weeks and causes the release of progesterone from it It

initiates lactation in mammary glands which *have undergone alveolar development* during pregnancy.

The follicle-stimulating, luteinizing and luteotropic hormones are all called gonadotropic hormones. Estrogen, which is responsible for most of the development of the female sex organs, is dependent primarily on follicle-stimulating hormone, whereas male sexual development *is brought about by androgen under the influence of luteinizing* hormone.

The *growth hormone* or *somatotropic hormone* (SST or STH) acts directly on the growth of body tissues without the mediation of other glands. It exerts a specific influence on the proliferation of cartilage and bone, probably through its ability to increase *protein anabolism* The growth hormone exerts important effects on carbohydrate metabolism

The *posterior lobe* of the pituitary gland elaborates one hormone which contains two principles, oxytocin (pitocin) and vasopressin (pitressin). Oxytocin acts mainly on the muscle of the uterus Vasopressin has little or no action on the uterus but acts more vigorously on the musculature of the intestines It exerts a profound influence on salt and water metabolism

Diseases of the Pituitary Gland. Symptoms of pituitary disease may arise from primary disease of the pituitary gland itself or from disease of the adjacent brain tissue When the gland itself is affected, the symptoms are primarily endocrine in nature, while those of the adjacent brain tissue may be manifested as either endocrine disturbances or those of intracranial hypertension In some instances there is a combination of intracranial hypertension and endocrine disturbance In a discussion of diseases of the pituitary gland there can be no categorical separation *of the diseases which give mainly endocrine disturbances from those which give* symptoms predominantly of intracranial hypertension

There are a number of diseases of the pituitary, usually tumors, which produce symptoms from pressure on the brain tissue and nerve tracts about the pituitary. These disorders are enumerated as (1) adenomas of the anterior lobe, (2) congenital tumors arising from the hypophysial duct and (3) other intracranial growths in the region of the sella turcica such as aneurysms of the circle of Willis, gliomas and gummas *Secondary growths, often metastatic from carcinoma of the breast or* pancreas are occasionally present in the posterior lobe, by their pressure effects, these as well as other pituitary tumors may destroy the pars nervosa and give rise to diabetes insipidus

Symptoms attributable to pressure on the hypothalamus are obesity and failure of the reproductive organs Interruption of the hypothalamicohypophysial tract results in polyuria and diabetes insipidus by interfering with the function of the pars neuralis *Involvement of the corpora mammillaria and the adjacent structures* produces somnolence

Endocrine Diseases of the Pituitary Gland. Endocrine diseases of the pituitary are classified as (1) those due to a deficiency of the hormone of the anterior lobe such as Simmonds' disease and infantilism, (2) those due to excessive activity of the hormone such as acromegaly and gigantism, (3) those due to *deficiency of* the posterior lobe and (4) those due to associated disorders of the pituitary and hypothalamus

Hypopituitarism (*Anterior Lobe*) The essential lesion of hypopituitarism is the destruction of the anterior lobe of the pituitary gland Conditions capable of causing necrosis of the pituitary consist of tumors, cysts, gumma, massive tuberculous necrosis, granulomas of unknown etiology, hypophysectomy and healed postpartum necrosis of the anterior lobe of the pituitary However, *a common cause of* hypopituitarism is massive focal atrophy, which occurs only in women and is nearly always of postpartum *origin. The necrosis is present in* patients who have severe hemorrhage and circulatory collapse These patients die at any time within a few hours postpartum onward.

Hypophysial Cachexia (*Simmonds' Disease*) The occurrence of loss of weight, amenorrhea and a low basal metabolic rate in a woman whose symptoms date from postpartum hemorrhage and collapse warrants, in the opinion of Escamilla and Lisser, a clinical diagnosis of Simmonds' disease These workers emphasized a confusion of Simmonds' disease with anorexia nervosa Anorexia nervosa may occur in either sex at any age but it occurs more frequently in young girls who have not been pregnant than in other persons

Severe deficiency of the pituitary function is manifested clinically, according to Sheehan, by a syndrome made up of the following characteristics. in many cases a history of severe circulatory collapse as a result of hemorrhage and shock at a delivery; atrophy of the gonads and genital tract with complete amenorrhea; impotence and loss of libido; complete loss of pubic and axillary hair, absence of normal skin pigment; a typical flabby facies with thinning of the eyebrows and pallor, increased sensitivity to cold, weakness, mental torpidity with slow speech; a low basal metabolic rate; very low urinary excretion of 17-ketosteroids, insulin sensitivity and hypoglycemia unresponsiveness, and a tendency to spontaneous hypoglycemia and coma Sheehan has stressed that patients with hypopituitarism face the grave danger of a particular type of coma which is often fatal

On *examination* the patient is apathetic and exhausted, assumes all the appearance of extreme senility, and may appear to be suffering from myxedema or Addison's disease. The administration of desiccated thyroid often induces hypoglycemia or an addisonian crisis There is marked sensitivity to insulin, a fraction of the usual dose will induce a reaction. This sensitivity is utilized as a test for the differentiation of hypopituitarism and Simmonds' disease from myxedema and other cachectic conditions which resemble it clinically The response of this hypoglycemia to epinephrine is slight.

In moderate degrees of pituitary insufficiency the excretion of 17-ketosteroids is reduced to less than 2 mg per day In extreme hypopituitarism, as in Simmonds' disease, the excretion is less than 0 5 mg per day In anorexia nervosa the excretion usually varies from 2 to 15 mg. per day In myxedema also it may be as low as 1 to 2 mg.

The *diagnosis* of hypopituitary cachexia (Simmonds' disease) depends on the presence of a low basal metabolic rate and on failure of the blood sugar to return to within 10 per cent of its fasting level in 2 hours after the intravenous injection of insulin. There is a low urinary excretion of 17-ketosteroids, and a positive result of the water test for adrenal insufficiency

In differential diagnosis it will be remembered that abnormal insulin tolerance curves are also present in hyperinsulinism, Addison's disease, anorexia nervosa, severe hepatic disease and malnutrition

The treatment of anterior pituitary necrosis has thus far been disappointing since the administration of the hormonal secretions of anterior pituitary extracts has not been efficacious

Hyperpituitarism (*Gigantism and Acromegaly*) Gigantism and acromegaly are associated with eosinophil cell or mixed cell adenoma which may extend out of the sella turcica and involve the base of the brain, or may encroach upon or penetrate the sphenoidal sinuses In some the pituitary remains normal in size, but in such cases there is an increase in the number of eosinophilic cells Hyperactivity of the anterior lobe of the pituitary gland causes gigantism in the adolescent and acromegaly in the adult In about one half of these patients the disease first appears in the third decade of life, but it does not develop fully before 45 to 50 years of age. Acromegaly may be present for thirty to fifty years and never pass into a hypopituitary stage, and it is therefore compatible with normal physical and intellectual vigor.

The *symptoms* develop slowly in *gigantism*. The growth during childhood is not

noticeable, for it is uniform and symmetric. The first parental suspicion that there is something wrong with the rapidly growing child is aroused when they realize that it has reached giant proportions for the age On examination the signs of the pituitary disturbance manifested by weakness, a dry skin, subnormal temperature, low basal metabolic rate, low blood pressure, a high sugar tolerance, and a low resistance to infection are revealed. The presence of a superimposed acromegalic gait and the other unequal growth characteristics of acromegaly may be evident.

The average age at death of giants is 21 years, though an occasional one may live to 40 or 50 years

There are six diagnostic features of gigantism. (1) *The patient usually is less* than 20 years of age (2) There is an overgrowth of cancellous bones and delayed union of the epiphyses (3) The hands and feet are very large. (4) The jaws are elongated and the cheek bones and supra-orbital ridges are prominent (5) Gonadal atrophy is present (6) The sella turcica is enlarged and may be eroded.

In diagnosis it is remembered that the patient who has pituitary gigantism differs from the genetically large individual in length of the extremities and size of the viscera Moreover, the pituitary giant is less likely to have the genealogic history of tall men and women in the family

The first *symptoms of acromegaly* are often increased appetite, fatigue, muscle pains, headache, apathy, disturbances of vision, somnolence, polyuria and voice changes occurring in an adult The symptoms of acromegaly commence so insidiously that the patient is unaware of his voracious appetite His complaints of fatigue may cause his family to remind him of the excessive amounts of food consumed. Soon the patient and his family are aware of the changes in his facial features The supra-orbital ridges are enlarged, the lower jaw elongates and becomes wider and extends forward, the head, the hands, the feet enlarge, the gait is an awkward one and the muscles tire easily

The symptoms of intracranial hypertension may supervene at any time during the course of the illness Those due to the pressure of the intracranial tumor (headache, visual defects, fits and vomiting) are *common* *Often, however,* there are no symptoms except increase [illegible]
of the hat, gloves or shoes [illegible]
of acromegaly may appear during pregnancy. This has been referred to as a [illegible]tive type

On *examination* of the acromegalic there may be no noticeable increase in size. There is only disproportionate increase in the size of the head, particularly the lower *jaw, and the hands An occasional patient may be of excessive size* which was obtained prior to the disproportion in the size of the parts

There is thickening of the epidermis with hypertrophy of the papillae of the skin As the result of thickening of the subcutaneous tissues there are furrowing of the skin and coarsening of the features As the disease progresses, there are impotence and sterility due to atrophy of the testes or ovaries.

The growth of the mandible separates the teeth of the lower jaw and gives prognathism. The *chin is curved and turns upward The nose,* lips, and tongue are broadened and enlarged The malar bones and the supra-orbital ridges are prominent. The hands and feet enlarge and broaden, and the ends of the phalanges thicken and become broad (spade-shaped) There is an enlargement of the viscera The larynx may become enormously enlarged

The roentgenologic examination in acromegaly reveals the enlargement of the sella turcica, the jaw, head, and extremities There is an increase in the anterior dimensions of the bodies of the vertebrae, *particularly as seen in lateral films* of the thoracolumbar portion of the spinal column.

Exostoses due to periosteal overgrowth are frequent The *flat bones,* particularly the calvarium, may be greatly thickened, and the frontal sinuses become enlarged.

The concentration of phosphate in the blood is increased (4 to 6 mg per 100 ml), but other biochemical laboratory studies are of little aid in the diagnosis of the condition.

The hypersecretory activity of the hypophysis induces certain metabolic changes. Exophthalmos is common with an elevation of the basal metabolic rate. The thyroid is enlarged and may undergo colloid degeneration Glycosuria is frequent. True diabetes occurs in about one eighth of all cases This diabetes differs, however, from ordinary diabetes mellitus, for it may spontaneously undergo a permanent or temporary amelioration of all the symptoms of diabetes

There are six diagnostic features of acromegaly. (1) The patient is more than 20 years of age. (2) There is enlargement of the acral parts of the body (bones and soft parts of the hands, feet and face) (3) There is enlargement of the sella turcica by roentgenologic examination (4) There is thickening of the epidermis with infiltration of the subcutaneous tissues resulting in wrinkling of the skin of the face and scalp (5) There are associated endocrine disturbances, for instance, increased metabolic rate and perhaps diabetes mellitus but rarely diabetes insipidus. (6) Intracranial hypertension, exophthalmos, increase in anterior dimensions of the vertebrae of the thoracolumbar spine—one or all may be present

In the diagnosis of either gigantism or acromegaly there may be no evidence of pituitary adenoma or hyperpituitarism at the time of the examination Both of these conditions can occur presumably from an increase in the eosinophilic cells attended by a decrease or an absence of the basophilic cells of the anterior pituitary part of the gland. The hyperpituitarism may have run its course and been supplanted by the symptoms of pituitary insufficiency

Hypogenitalism and Puberty in Boys. The testes are thought to be dependent on two pituitary gonadotropic hormones The first, the follicle-stimulating hormone, acts on the tubules; the second, the luteinizing hormone, affects the Leydig or interstitial cells Spermatogenesis, therefore, cannot take place without function of the Leydig cells, so that the two hormones must be present to produce normal sexual function and development

The term hypogenitalism means a disproportionate smallness of the external genitalia in relation to somatic development Up to the age of 11 or 12 years the testes and the penis undergo little change in size The testicle is approximately 1 7 cm long and 0 8 cm wide. With puberty, which usually begins at 11 or 12 years of age but may be delayed to 14 or 15 years of age, even though growth is normal, the testes may not increase in size

In the fat boy, even with beginning pubescence, the genitalia often appear small because they are partially submerged in adipose tissue The size of the testicle may be estimated by volume and by linear measurements The volume of the testicle is determined by drawing the scrotal skin tightly over the testicle and comparing its volume with that of known standards Any testicle which is approximately 2 ml in volume before pubescence may be considered normal, but those of less than 2 ml volume are regarded as instances of hypogenitalism

The *body types* which may result from *delay or failure of pubescence* are. (1) slight eunuchoid skeletal proportions, but these are outgrown and eventually maturity is normal, (2) eunuchoid with hypogenitalism and eunuchoid skeletal proportions, namely, long arms and legs, when eunuchoidism is due to primary testicular failure there are occasionally more body hair and sexual hair and fewer skeletal changes, (3) gynecomastia and varying degrees of eunuchoidal changes Aspermia is present owing to tubular hyalinization, at least late in the disorder. The breasts show well marked and pigmented areolae

Boys of 14 years of age may show a wide range of skeletal maturation, which as a rule accompanies genital development If obese boys of 14 with retarded pubes-

cence are of average or greater height, only delayed pubescence and eunuchoidis need to be considered

Enlargement of the breasts in the fat boy may be due to adipose tissue only a is unimport [illegible] aid, but in the nonobese child this is a fairly reliab sign of pube [illegible] subsides spontaneously in the norm pubescent, [illegible] gynecomast with aspermia is suspected (see [illegible]

Determination of *urinary 17-ketosteroids* at this age, [illegible] ubtful val in distinguishing between delayed puberty and true eunuchoidism, for the valu obtained in both conditions should be at prepubescent levels. Rarely, in tru eunuchoidism of testicular origin, they may be increased

Roentgenograms of the hand and wrist or other joints are of little value until th age of 18 or 20 years When eunuchoid persons have reached the age of 18 or 2 years, the epiphyses are usually still open, but the variation is too great at the ag of 13 to 15 years to be of value in differentiating true eunuchoidism from delaye pubescence

Diseases of the Posterior Lobe of the Pituitary (Neural Division). Th posterior lobe of the pituitary elaborates (1) the antidiuretic hormone, which con trols the secretion of urine by the kidneys and regulates the water and electrolyt balance of the body fluids, (2) the oxytocic hormone, which stimulates the uteru during parturition, (3) the combined extract of the posterior pituitary, which act on smooth muscles in many parts of the body including those of the arteries Th effect is one of smooth muscle contraction

There are no known diseases which result from *hyperfunctioning* of the pos terior lobe of the pituitary gland

Hypofunction of the Posterior Lobe of the Pituitary Gland (*Diabete Insipidus*). Diabetes insipidus may appear at any time during infancy or adult life In some families more than one member is affected Traumatic lesions, especially ones associated with fracture of the base of the skull, and infections such as men ingitis or encephalitis may cause the syndrome Once the entity has appeared, i persists However, remissions may be observed A normal life span may then be enjoyed

The *symptoms* of the disease are due to a deficiency of antidiuretic hormone. There is intense thirst, polyuria, and dryness of the mouth and skin

The quantity of urine excreted per day depends on the extent of satisfaction of the thirst Excretion of 8 to 12 liters is common The loss of a large quantity of urine results in an excessive loss of heat The heat loss accounts for the hypothermia and the hyperorexia The fatigue and loss of strength and ambition are related to the nervous tension Obstinate constipation is consequent to the dehydration Head- ache, dizziness, and pain in the back and legs may occur Often the patient is tired, apathetic and irritable

On *examination* there may be found intracranial disturbances such as visual field defects, papilledema, ocular palsies, nausea, vomiting and dizziness Usually the blood pressure is normal

The urine is pale and free of sugar, sediment and albumin The specific gravity is 1.001 or 1.002, never more than 1 005 The excretion of chloride is reduced The phenolsulfonphthalein excretion, glomerular filtration rate, urea clearance, creatinine clearance, and results of intravenous urography tend to be normal

The concentration of blood cells and of chemical constituents of the blood varies in different patients. The sodium chloride and hematocrit may be decreased

After the injection of 1 ml of pituitrin the urine volume and specific gravity usually become normal in the patient who has diabetes insipidus

In *diagnosis* the specific gravity of the urine in diabetes insipidus is *less than* 1.005. If the specific gravity exceeds 1 005, the condition is probably a polyuria

associated with psychic disturbances or nephritis Patients who have polyuria associated with nephritis rarely excrete more than 5 liters in 24 hours. There usually is a history suggesting nephritis, hypertension, retinitis, sedimentary changes in urine, decreased urea clearance, and decreased phenolsulfonphthalein excretion.

The polyuria due to a lack of psychic control varies more in degree than does that of diabetes insipidus or nephritis. When water is withheld for 12 hours, the patient who has diabetes insipidus complains of intense thirst, nervousness, apprehension, weakness and hypothermia. Moreover, there is a continued excretion of large quantities of hyposthenuric urine. The person who has psychogenic polydipsia and polyuria can tolerate the water deprivation without any great discomfort

Tumors of the Pituitary Gland. ***Adenomas.*** The adenomas of the pituitary gland arise from the anterior lobe They are composed of cells giving both chromophil and chromophobe reactions

Chromophobe adenomas are the commonest of the lesions in the region of the optic chiasm Lesions in this region occur in the following order of frequency adenoma of the pituitary, *suprasellar cysts* and *craniopharyngioma, glioma* of the chiasm, meningioma arising from the floor of the third ventricle, rare tumors (chordoma, cholesteatoma), chronic arachnoiditis and aneurysmal dilatation of the carotid artery.

Chromophobe adenomas occur from the third to the fifth decades of life, and cause great enlargements of the sella They do not give rise to symptoms which might be attributed to hypersecretion of some humoral principle

These adenomas are benign growths, but malignant tumors occasionally are encountered. The malignant growths do not metastasize but may give rise to a rapid progression of symptoms with extension of the tumor into the adjacent skull, brain and nasopharynx.

The *symptoms* of the chromophobe adenomas result from the pressure which these growths exert on the adjacent regions of the hypothalamus, the optic chiasm, or on the rest of the gland Impairment of vision is an early symptom, with atrophy of the optic nerve head as observed by the ophthalmoscope, perimetric bitemporal field defects, and inability to read when the macular bundle is affected Obesity, amenorrhea and impotence are frequently early symptoms, which are probably hypothalamic in origin The atrophic changes in the skin and hair and the evidences of general cachexia observed as the tumor enlarges are attributable to hypophysial deficiency due to destruction of the chromophilic cells Symptoms of intracranial hypertension may be present

On *examination* there often are found evidences of intracranial hypertension There is bitemporal hemianopsia The visual field defects in chromophobe tumors tend to be regular and symmetric in outline

The roentgenogram reveals the enlarged sella The final diagnosis is established by histologic study of the adenoma, which has been localized by means of the ventriculogram and removed surgically

Craniopharyngiomas comprise a variety of growths which appear in the middle line above the sella adjacent to the infundibulum and optic chiasm They are of congenital origin and arise from cellular rests of the embryonic hypophysial duct. They may be designated as cysts of Rathke's pouch, interpeduncular or suprasellar cysts Rare tumors, giving rise to manifestations similar to those produced by craniopharyngiomas, are cholesteatomas, dermoid cysts, chordomas, and teratomas

Associated Disorders of the Pituitary Gland and the Hypothalamus. The association between the pituitary gland and the other endocrine organs is dependent on the direct anatomic and physiologic connections between them These connections are presided over by the autonomic nervous system The hypothalamus participates in both metabolic and reproductive functions which are also involved in endocrine disorders The close proximity of the pituitary and the hypothalamus predisposes to lesions of either tissue affecting the function of the other.

The hypothalamus is the central neuroglandular mechanism which controls the basic rhythms of organic life The fundamental patterns of personality are situated

cence are of average or greater height, only delayed pubescence and eunuchoidism need to be considered

Enlargement of the breasts in the fat boy may be due to adipose tissue only and is unimportant as a diagnostic aid, but in the nonobese child this is a fairly reliable [illegible]

[illegible] Diseases of the Breast, Chapter [illegible]).

Determination of *urinary 17-ketosteroids* at this age, too, is of doubtful value in distinguishing between delayed puberty and true eunuchoidism, for the values obtained in both conditions should be at prepubescent levels. Rarely, in true eunuchoidism of testicular origin, they may be increased

Roentgenograms of the hand and wrist or other joints are of little value until the age of 18 or 20 years When eunuchoid persons have reached the age of 18 or 20 years, the epiphyses are usually still open, but the variation is too great at the age of 13 to 15 years to be of value in differentiating true eunuchoidism from delayed pubescence

Diseases of the Posterior Lobe of the Pituitary (Neural Division). The posterior lobe of the pituitary elaborates (1) the antidiuretic hormone, which controls the secretion of urine by the kidneys and regulates the water and electrolyte balance of the body fluids, (2) the oxytocic hormone, which stimulates the uterus during parturition, (3) the combined extract of the posterior pituitary, which acts on smooth muscles in many parts of the body including those of the arteries The effect is one of smooth muscle contraction

There are no known diseases which result from *hyperfunctioning* of the posterior lobe of the pituitary gland

Hypofunction of the Posterior Lobe of the Pituitary Gland (*Diabetes Insipidus*) Diabetes insipidus may appear at any time during infancy or adult life. In some families more than one member is affected Traumatic lesions, especially ones associated with fracture of the base of the skull, and infections such as meningitis or encephalitis may cause the syndrome. Once the entity has appeared, it persists However, remissions may be observed A normal life span may then be enjoyed

The *symptoms* of the disease are due to a deficiency of antidiuretic hormone. There is intense thirst, polyuria, and dryness of the mouth and skin

The quantity of urine excreted per day depends on the extent of satisfaction of the thirst. Excretion of 8 to 12 liters is common The loss of a large quantity of urine results in an excessive loss of heat The heat loss accounts for the hypothermia and the hyperorexia The fatigue and loss of strength and ambition are related to the nervous tension Obstinate constipation is consequent to the dehydration Headache, dizziness, and pain in the back and legs may occur. Often the patient is tired, apathetic and irritable

On *examination* there may be found intracranial disturbances such as visual field defects, papilledema, ocular palsies, nausea, vomiting and dizziness. Usually the blood pressure is normal

The urine is pale and free of sugar, sediment and albumin. The specific gravity is 1.001 or 1 002, never more than 1 005 The excretion of chloride is reduced The phenolsulfonphthalein excretion, glomerular filtration rate, urea clearance, creatinine [illegible] ...e blood varies [illegible] ...creased

After the injection of 1 ml of pituitrin the urine volume and specific gravity usually become normal in the patient who has diabetes insipidus

In *diagnosis* the specific gravity of the urine in diabetes insipidus is less than 1.005. If the specific gravity exceeds 1.005, the condition is probably a polyuria

gens or estrogens with an increased excretion of gonadotropic substance, whereas in primary pituitary deficiencies there may be a diminished excretion of both

There may be an increased carbohydrate tolerance due to decrease in the secretion of an insulin-antagonizing hormone. The basal metabolic rate is variable. There may be retention of fluid or the other extreme, diabetes insipidus may be present. Often the concentrations of plasma chlorides and uric acid are increased.

Roentgenograms of the skull rarely reveal abnormal changes Occasionally enlargement and erosion of the sella indicative of an expanding lesion, calcification within the sella, or a sella considerably smaller than normal may be present.

The *diagnosis* of adiposogenital dystrophy is established by combination of symptoms and findings as described. Many patients do not present the characteristic findings.

The Hypothalamus and Hypergonadism (*Precocious Puberty*) Precocious sexual development may result from tumors or disease of the hypothalamus.

Precocious puberty secondary to hypothalamic disorders may follow encephalitis, in association with cysts of the third ventricle At any age precocity may be the presenting symptom in cases of tumors of the hypothalamus without recognizable evidence of intracranial disease. This precocity may be accompanied by somnolence, adiposity, diabetes insipidus and polyphagia

In hypothalamic precocity there is maturity of both gonads and secondary sex characters. This development may be a result of hypothalamic disease, or may occur in association with the pineal tumors and paraphyseal cysts, or without any demonstrable lesion.

Precocity secondary to adrenal and gonadal disturbances is characterized by normally developed external genitalia and secondary sex characters but without gonadal maturity.

Syndrome of Sexual Precocity, Areas of Skin Pigmentation and Fibrous Dysplasia of Bone. This syndrome occurs in girls There are sexual precocity and unilateral brown macular skin lesions associated with disseminated areas of osseous rarefaction The skin lesions are present at birth or soon thereafter. The bone lesions are not manifested until pathologic fractures occur Deformities of bones may be incident to rarefaction or to overgrowths Overgrowths of bone may impinge on the optic nerves, causing visual field disturbances, if situated in the orbit they may cause unilateral proptosis. Overgrowth of the facial bones may obliterate the nasal sinuses and cause facial asymmetry Sclerotic overgrowth of bone at the base of the skull may occur.

The areas of rarefaction occur most commonly in the long bones Calcium and phosphorus metabolism are normal

Nonendocrine Disorders of the Hypothalamus. ***The Hypothalamic Syndrome.*** This syndrome, a nonendocrine disorder, is characterized by the presence of proptosis, paresis of the muscles of the eyelids, edema of the conjunctivae, and retrobulbar pain.

The hypothalamic syndrome may be combined with affective psychic and vegetative disturbances involving sleep, body temperature, and vasomotor and secretory functions. Abnormalities in fat metabolism and sexual function, narcolepsy, diencephalic epilepsy, catalepsy, affective loss of tone, and the Wilson and the Korsakow syndromes are associated with lesions in the hypothalamus, and also interference with other parts of the brain connected to the hypothalamus is concerned in these disorders.

Body Temperature. The hypothalamus is the center for *temperature control* of the body. There are other secondary centers for temperature control. This exact location is disputed Anteriorly situated lesions are likely to impair the regulation against heat, while the regulation against cold remains intact; posteriorly placed lesions involve a disturbance in regulation of both heat and cold. Lesions, too, of the

in the hypothalamus, though they are presided over by the frontal lobe Lesions of distant parts of the brain with which the hypothalamus is connected or endocrine disease may produce the symptoms attributed to the hypothalamus. Likewise disease of the hypothalamus may produce syndromes similar to those caused by endocrine glands or diseases of distant parts of the brain.

Through its connections the hypothalamus and its supra-optic nucleus form a functional unit. Lesions in any part of this tract result in *diabetes insipidus Gonadal functions* are mediated through the hypothalamus Lesions of the floor of the third ventricle may cause hyperglycemia and glycosuria, and similar effects may be induced by excitation of the hypothalamus and its tuberal component

Diseases of the hypothalamus may have as manifestations obesity, sexual precocity, or genital dystrophy in which the initial symptoms were referred to abnormalities in other vegetative functions, or in affective psychic disorders Lesions of the hypothalamus are prone to originate disturbances in psychiatric and vegetative functions which seem to be of an endocrine origin

The hypothalamic disorders may arise from tumors of the third ventricle and from infections, particularly encephalitis lethargica, syphilitic meningo-encephalitis and intoxications Trauma rarely causes prolonged hypothalamic manifestations.

Dystrophia Adiposogenitalis (*Frohlich's Syndrome*). The pituitary and the region of the hypothalamus are concerned with growth, sexual development, certain phases of metabolism, and obesity.

The cause of dystrophia adiposogenitalis may be intracranial hemorrhage, encephalitis, or possibly toxic suppression or degeneration of the pituitary or adjacent structures following infectious diseases of childhood There are many instances in which no pathologic lesion is demonstrable clinically or at necropsy.

Adiposogenital dystrophy occurs more often in females than in males, but the latter are seen by physicians more frequently because genital infantilism is more conspicuous. The onset may occur at any age Rarely there is a history of excessive weight at birth Often there is a rather sudden and progressive increase in weight, beginning between the ages of 7 and 10 years, which is out of proportion to the food intake

The *symptoms in children* include obesity and genital hypoplasia with regression in the size of the genitalia Patients in whom the disease has been present for some time may become cachectic, owing to the development of Simmonds' disease resulting from destruction of the pituitary gland.

The chief symptoms observed in Frohlich's syndrome in *adult patients* are obesity, faulty skeletal development and genital hypoplasia Polydipsia, polyuria and polyphagia are common, with diabetes insipidus in some cases

The intelligence is normal except for the introspection and self-consciousness which are due to the physical appearance

When the disorder is due to a neoplasm or craniopharyngioma, symptoms arising from increased intracranial pressure, bitemporal hemianopsia, optic atrophy, headaches and somnolence are present

On *examination* the obesity is of the female type with deposition of fat over the mons veneris, mammae, hips, upper part of the thighs, and lower part of the abdomen The reproductive organs have failed to develop. The skin is soft; the hair often is scanty. The hands are plump with tapering fingers The patient is often short, owing to the epiphyses remaining open In men the voice remains effeminate and gynecomastia is prominent.

The genitalia of the male patient should be examined for the presence of undescended testes. If possible the testes should be manipulated in the scrotum and their size estimated. In men the prostate and seminal vesicles, and in the female the pelvic organs, are infantile Hormone assay of the urine may suggest an endocrine disturbance. In primary hypogonadism there may be diminished excretion of either andro-

A *sex reversal in a female child* may have begun in fetal life and the child is a pseudohermaphrodite, or the child may have a persistent urogenital sinus, shallow vagina and hypertrophied labia majora There is too rapid growth in size, muscular development, hirsutism and thus the girl attains the appearances of a male. A sex reversal in postnatal life in a female who is normally developed may be caused by adrenal cortical hyperplasia, or tumor, or it may have resulted from an arrhenoblastoma of the ovary.

When a *sex reversal* occurs in a *normal male* it may result from a feminizing adrenal cortical tumor or perhaps from a chorio-epithelioma There is gynecomastia and perhaps testicular atrophy If the boy is affected when born there is male pseudohermaphroditism The cause in the latter cases is uncertain

The sex traits which are genetically determined and are not directly under the influence of hormones give rise to *sexual dimorphism,* the condition of having some of the properties of both sexes, as in the early embryo and in some hermaphrodites. Persons who have sexual dimorphism or intersexes show no development of secondary sexual characteristics until the usual age of puberty. Prior to puberty a prediction of whether the secondary sexual characteristics will be masculine or feminine cannot be made from the type of gonad present The relative importance of heredity, intrauterine hormones and other endocrine influences cannot be determined Sexual dimorphism includes the early descriptions of the hermaphrodites There are many different types—heterosexual differentiation

The distribution and the degree of growth of hair, aside from that of the scalp, is sexually distinctive. However, an occasional girl or woman who gives no evidence of any endocrine disorder may have a beard or may have a profuse growth of the hair on the body. Growth of hair on the face and the body of women, except in cases in which this is due to a masculinizing tumor of the ovary or adrenal, is likewise hereditary, and endocrine therapy is ineffective treatment In rare instances such a growth of hair will occur as the result of an excessive secretion of androgens

The Sex Hormones. There seems to be an interdependence of the action of the sex hormones with the hormones of the other endocrine glands, for all of the hormones are necessary for the normal growth, development and function of the reproductive system In the absence of the thyroid hormone or the adrenal hormone, for instance, reproductive activities are affected or annulled Deprivation of the essential vitamins or dietary deficiencies cause changes in the gonads Certain hormones that are produced by the gonads, by the hypophysis and by the chorionic tissue exert important action on the reproductive system A variety of these substances is known and they may be assigned, according to their origin, into (1) the pituitary hormones or gonadotropins, (2) the pituitary-like gonadotropic substances and (3) the sex hormones

The *pituitary sex hormones* are derived from the pituitary gland They have been discussed in the section on the description of this gland

The *pituitary-like gonadotropic substances* are formed by the chorionic tissues of the placenta They are found in the placenta, the urine or the blood serum during pregnancy.

The *sex hormones* are the products of the gonads They comprise (1) the androgens, or male hormones, (2) the estrogens, or female hormones and (3) the progestational hormone derived from the corpus luteum

The Androgens or Male Sex Hormones. An androgen is a hormone which possesses masculinizing activities The testicular tissue and urine of men contain the androgens, the male sex hormones It is the present consensus that testosterone represents the male sex hormones However, large doses of testosterone are required in substitution therapy in contrast with the small doses of other hormones Large doses of testosterone will induce normal growth of the prostate and the seminal vesicles in the castrate but fail to prevent hypertrophy of the hypophysis These observations may well indicate that testosterone is only a part or a derivative of the genuine male sex hormone Androsterone, too, probably represents a derivative of the hormone, but retains some of its androgenic activity

gray matter surrounding the third ventricle behind the optic chiasm may induce hyperthermia

Disturbances in temperature regulation and somnia may be observed in craniopharyngiomas, cysts of the third ventricle, and other lesions affecting the hypothalamus.

The hyperpyrexia of hypothalamic origin is not accompanied by the general symptoms resulting from fevers of infectious origin Despite this fact, a *neurogenic hyperpyrexia* accompanied by an increase in the erythrocyte count and an alteration of the differential leukocyte count from the normal may make the neurogenic fever difficult to differentiate from one of an infectious origin However, the neurogenic fever may subside after the administration of phenobarbital. The *infectious fever* may subside after the administration of aspirin (acetylsalicylic acid)

Hypersomnia. Like the hypothalamic syndrome, hypersomnia is nonendocrine in origin There is an inversion of the sleep rhythm, and occasionally narcolepsy, with or without cataplexy, are observed in hypothalamic disorders incident to a viral encephalitis Hypersomnia is frequently present in those who have craniopharyngioma or gliomas involving the floor of the third ventricle Profound sleep may follow surgical operations or an injury in this region

Ulcerations of the lower part of the esophagus, the stomach and the duodenum occur in some who have hypothalamic lesions Disturbances in hepatic function, for instance hyperglycemia and cirrhosis of the liver (Wilson's disease), may be associated with hypothalamic disease

THE GONADS

The gonads, the organs of sex, comprise the testes and ovaries These organs furnish the exocrine elements, the sperm and the ovum, and elaborate hormones for the maintenance of the accessory organs of sex as well as the secondary sex characters.

There are certain terms referring to sex which require mention Ambisexual refers to a trait pertaining to both sexes A secondary sex character occurs normally in but one sex but can develop in either sex A secondary sex character is contrasted with a sex-limited character, a trait which is limited to one sex only The term sex-linked refers to the genes which transmit traits contained in the sex chromosomes An acquired character is a modification produced as a result of the person's (or animal's) own activities or environment. A compound character is one which is dependent on two or more genes for its production A dominant character can develop through the agency of a single gene. It thus appears in the first filial generation and in three fourths of the members of the second filial generation A recessive character is one which requires two allelomorphic genes for full development Thus it often fails to appear (is recessive) in the first filial generation, but reappears in part in the second filial generation

Sexual precocity is sexual maturity at an age younger than expected for the family and the race It is due to disorders arising in either (1) the hypothalamic region of the brain, (2) the pituitary or (3) the gonads In those in whom the disorder is due to a lesion of the brain or the pituitary there is a normal pituitary-adrenal-gonadal relationship and the gonads show normal gametogenic function, whereas in those in whom the disorder is due to an excessive and early production of a sex hormone by a neoplasm or tumor or hyperplasia of the adrenal gland the gonads do not show normal gametogenic function.

Sexual infantilism is the persistence of the infant type of genitalia into adulthood without development of secondary sex characteristics A wide variation exists in the age at which some boys and girls reach maturity—adolescence The normal age for pubescence is controlled by genetic influences (heredity). Permanent sexual infantilism is due to a disorder of (1) hypothalamus, (2) pituitary gland or (3) the gonads

The *congenital absence* of both testes is rare Absence of one testis, with compensatory hypertrophy of the other, and the presence of more than two testes also are rare, while a failure of a testis to descend into its normal position in the scrotum or its displacement in an abnormal position is a common occurrence

Cryptorchism results ultimately in the degeneration of the seminiferous tissue, only the Sertoli and Leydig cells remaining intact A cryptorchid testis is unproductive of spermatozoa, but it usually elaborates the male hormone so that the secondary sex characters remain normal. When cryptorchism is accompanied with evidence of eunuchoidism, there is hypoplasia of the interstitial tissue Destruction of the seminiferous tubules in cryptorchism is apparently due to the elevated temperature of the testicle This can be produced by applying heat to the scrotum

A failure of normal maturation of the gonads at puberty gives rise to a eunuchoid individual with failure of development of the secondary sex characters The voice is feminine, the breasts enlarge, the hair of the head has a feminine contour, and there is neither beard nor body hair The condition is thus comparable with that induced by prepubertal castration If the defect in development involves only the seminiferous tubules, development of the secondary sex characters is normal

In human beings *castration* performed after adolescence does not result in detectable abnormality of body growth Castration of the adult does not always lead to impotence, and the sexual instinct may persist. Eunuchs may copulate up to 25 to 30 years after castration Among castrates because of injuries sexual vigor remains undiminished in some, but in most instances it is decreased from normal, and in many there is almost complete suppression of libido and potentia Castration before puberty initiates an excessively long growth of the bones with a lack of proportion between the length of the trunk and extremities. The epiphysial synarthroses persist beyond the normal age The pelvis resembles the female type, the skull is acromegalic The larynx remains small, the thyroid and cricoid cartilages never ossify, and there is an absence of the pomum adami. The pubic hair is of the female type, the hair on the face and body is scanty. The mammary glands are enlarged and of a virginal female type except that there are small nipples

Hypogonadism may be *acquired* Chronic inanition or avitaminotic deficiencies may induce testicular deficiency Mumps and smallpox may affect the testes, to be followed by extensive fibrosis and atrophy Gonorrhea involves the testes usually by an ascending infection of the urogenital canal, syphilis gives rise to a fibrous orchitis or gummas of the testes, tuberculosis affects the testes, usually secondarily to infection of the epididymis All of these conditions may result in destruction of both the seminiferous tubules and the interstitial tissue and thus lead to hypogonadism. Alcohol and lead may be cited as examples of toxins which may involve the testes Chronic or debilitating disease or malnutrition in childhood may interfere with the normal development of the testes and thus give rise to hypogonadism in the adult Hypogonadism may also arise secondarily to failure of the thyroid, pituitary, hypothalamus or adrenal glands.

Among normal persons the male excretes androgens and estrogens in the urine in a ratio of approximately 2.1, while in the female the ratio is approximately 1:7. In male hypogonadism if testosterone has not been administered there is a reduced excretion of androgenic substances in the urine

The *male climacteric,* presumed to be analogous to the condition commonly observed in women at the menopause, is observed infrequently. Subjective nervousness is the principal manifestation of the disorder Other prominent symptoms in the order of their frequency are loss of potentia, depression, defective memory, fatigability, lassitude, loss of confidence, disturbances in sleep, irritability, fear of impending danger, numbness and tingling of the skin, vertigo, hot flushes, headache, tachycardia, palpitation, fits of crying, and urinary symptoms (Werner).

In some instances, however, an organic basis for justifying the claim that the male climacteric or hypogonadism gives rise to a true clinical entity may be demon-

The male sex hormone seems to be elaborated by the germinal tissue of the testes The testes also contain large amounts of estrogen, the significance of which is unknown

Urinary Excretion of Male Hormone (Androgens). The urine of both the male and the female is androgenic, as manifested by the presence of 17-ketosteroid bodies The normal urinary androgen excretion in men varies from 63 to 68 international units; in women from 42 to 56 units. In male castrates exceedingly small amounts of sex hormone (1 to 3.5 units) are excreted In adrenal virilism there is an exceedingly variable excretion, high (500 units) in some cases, but in others, low or normal. In prostatism the excretion of androgens is decreased below normal. The average daily urinary excretion of estrogen corresponds to from 9 to 12 micrograms of estrone in men and from 18 to 36 micrograms in women. The significance of estrogens in the male organism is unknown

Small amounts of androgens are excreted in the urine prior to puberty, and the greater part of these amounts probably originates in the adrenal glands The sudden appearance at puberty of the secondary sex characters is due to an increased responsiveness on the part of the tissues to androgen. During sexual maturity the androgens maintain the sex characters The androgen output again declines with advancing age. Spermatogenesis, however, may continue to an advanced age. Spermatogenesis is dependent on a mutual interrelation of pituitary-gonadotropic and testicular-androgenic activity

17-Ketosteroids The known metabolites of testosterone are included in the group of compounds known as the neutral (to distinguish them from estrogenic phenols) 17-ketosteroids The androgen excreted in the urine differs in many respects from that extracted from testes It consists principally of androsterone, which is a 17-ketosteroid body

Normally about 15 mg of ketosteroid bodies are excreted in the urine daily by an adult. Of this amount about 9 mg. are derived from the adrenals, the remainder from the testes After testicular atrophy a considerable fraction of these ketosteroids remains. Since pituitary insufficiency induces both testicular and adrenocortical insufficiency, however, 17-ketosteroid bodies disappear from the urine in this condition In severe adrenocortical insufficiency the excretion falls to about 5 mg daily There is an increase in 17-ketosteroid excretion in Cushing's syndrome and in adrenocortical hyperactivity.

Pubescence. The onset of pubescence varies in normal boys from 10 to 16 years of age, and in rare isolated cases may begin even later Most prepubescents manifesting small genitalia, excessive obesity or similar disturbances often attributed to endocrine deficiency grow into normal adults and require only an adequate diet and the usual hygienic measures to insure their normal development It is important to be aware that sexual development beginning in girls aged less than 8 years and boys aged less than 10 years requires explanation if such can be had by examinations and the family history These studies will usually reveal that about 9 of every 10 cases of sexual precocity are due to pituitary activation by unknown causes Sexual precocity due to intracranial tumor runs a rapidly fatal course and is commoner in girls than in boys. However, pineal tumors are commoner in boys than in girls.

While there are essential statistical differences in the anthropologic measurements of the somatic diameters of the male and female bodies, it is essential to realize that these differences may not denote abnormalities in body shapes, sizes and functions. The rough, strong, visibly breastless woman with some beard, large feet and hands, and long straight legs and arms may bear children as well as, if not better than, her delicately contoured sister In the extremes of normal limits, therefore, the main differences between men and women which are termed secondary sex characteristics are statistical figures and do not indicate functional performances The early development of a body type is more attributable to heredity than to the influence of gonadal hormones.

Male Hypogonadism (Eunuchoidism). *Failure of testicular function* and deficiency of the male hormone give rise to varying degrees of eunuchoidism or, in some, to the same symptoms that follow castration.

and women. Those of the second group occur in the body fluids of pregnant women and their detection is the basis of the Aschheim-Zondek, Friedman and frog tests for pregnancy. These same gonadotropic hormones exist in greatly increased amount in the presence of pathologically proliferating chorionic tissue, such as hydatid mole, chorion-epithelioma, and in some tumors of the testicle

The *pituitary hormones* have not been isolated in pure form. Their presence is detected by biologic reactions and changes in the generative tract. The pituitary gland elaborates two gonadotropic hormones which have to do particularly with ovarian functions One stimulates the growth of the graafian follicle up to the time of maturation of the ovum and ovulation. This hormone is designated as the follicle-stimulating hormone. The other gonadotropic hormone has the function of luteinization of the follicle and thus produces the corpus luteum with the formation of progesterone. A third anterior pituitary hormone is luteotrophin, formerly known as prolactin In addition to its influence on the breasts it initiates and maintains the secretory activity of the corpus luteum (see p 1105).

Progesterone is a derivative of androstene The chief metabolite of progesterone is pregnane, which occurs in relatively large amounts in the urine during pregnancy The name pregnanediol is often used instead of progesterone Steroids of the progesterone group have been isolated from the adrenal glands and recovered from the urine of castrates of both sexes

As has been stated in the description of testicular hormones, small amounts of gonadotropic substance are found in the urine of both men and women, irrespective of age. Since this substance is present in greatest concentration after the menopause or castration, it is called the *hormone of castrate urine* to distinguish it from the hormone of pregnancy urine (see p. 1115)

Tests for Pregnancy. The urine of pregnant women contains a gonadotropic substance which is the basis of the urinary test for pregnancy In the mammals the intravenous injection of a few milliliters of the urine of a pregnant woman will cause the formation of hemorrhagic and ruptured follicles in 48 hours, the test is accurate in more than 90 per cent of cases The hormone is detected by its action on the ovaries of rats, mice (Aschheim-Zondek test), rabbits (Friedman test), and frogs (Hogben or xenopus test).

In the Hogben pregnancy test the South African clawed toad (*Xenopus laevis*), an animal that carries eggs at all times of the year but extrudes them only after coitus or after injection of gonadotropins, is utilized The injection (subcutaneous or into the dorsal lymph sac) of a suitably prepared extract of the urine of a pregnant woman is followed by the extrusion of eggs in from 4 to 6 hours These can be seen by the naked eye

The Hogben test is more rapid than the Friedman and the Aschheim-Zondek tests and is preferred by many gynecologists However, it is not reliable before the fortieth day of pregnancy and this limits its use

If the urine continues to show a high content of gonadotropic hormone after the termination of a normal pregnancy, or after operation for tubal pregnancy or curettage for incomplete abortion, the presence of hydatid mole or chorionepithelioma is strongly suspected The continued high titer of this hormone in cases of hydatid mole, chorion-epithelioma, or testicular tumor indicates that these growths have not been destroyed or removed, they are progressing either locally or by metastasis.

The Estrogenic Hormones. The ovarian control of the reproductive function and secondary sex characteristics is mediated by the ovarian hormones, estrogen and progesterone. The estrogen is produced by the graafian follicle, and the progesterone by the corpus luteum.

Estrogen is the growth hormone, stimulating the growth of the uterus, uterine tubes, vagina, and mammary glands, controlling the development of secondary sex characteristics, and presiding over the regeneration of the endometrium after each menstrual period From the influence of estrogen the female acquires sexual maturity, and conception and reproduction may be assured

Estrogens are elaborated by the ovaries for the most part during the first 2 weeks of the menstrual cycle and are inhibited by the action of progesterone during the rest

ł. In these there is an elevation of gonadotropic excretion in the urine com-
le with that observed in castrates, and histologic examination of the testes
s signs of atrophy or degeneration of the interstitial tissue. The intramuscular
iistration of 25 mg. of testosterone propionate for 5 days weekly for 2 weeks
ɔe used as a therapeutic test, with proper consideration of the possibility that
ɔserved effects may be due to suggestion.

the treatment of the male climacteric methyl testosterone in doses of 30 to
; daily sometimes is administered orally Such treatment is of no value.

ale Hypergonadism. Overproduction of the endocrine secretion of the testes
adult gives no symptoms attributable to an excess of the hormone The abnor-
exual urge observed in men who have criminal tendencies is not due to any
oduction of male hormone but is the result of some psychiatric abnormality,
ius these men may be unaffected by castration.

ypergonadism prior to puberty leads to precocious development. Interstitial
mors of the testes may secrete an excess of the male hormone in boys which
; the premature development of the secondary sex characters and in some
induces skeletal and muscular development This condition is rare, for most
ces of precocious sexual activity in the male are induced by abnormalities in
pothalamus, or pineal region of the brain By stimulating the testes, which
ie prematurely active, these affections of the nervous system give rise to true
l precocity with spermatogenesis Androgenic tumors of the adrenal occur
arely in boys and are not accompanied by spermatogenic activity

omosexuality. Homosexuality is a sexual perversion and not an endocrine
ɔance However, it has been attributed to a hormonal imbalance since some
exuals show eunuchoidal characters Many homosexuals are affected by hypo-
ism, which some have generously conceded might be, in part, responsible for
ndition In practice, however, the gonads and secondary sex characters of
iomosexuals are found to be normal. In each homosexual it is necessary to
ɔt an evaluation of the relative effects of psychogenic, acquired and endocrine
; in the pathogenesis of the disorder. There are often, however, a relative
se in estrogen and a decrease in the androgen content of the urine

ychiatric rather than endocrine therapy is the better form of treatment

e Female Sex Hormones. In the female, as in the male, endocrine glands
volved in the process of sexual maturation In women these are the ovaries and
yroid, parathyroid, adrenal and pituitary glands A failure of proper function
one of these in its development or activity may result in inadequate genital
pment or in irregularity of or no menstruation

xual maturity exists from adolescence until the menopause This period of
30 years is marked by the regular sequence of ovulation and menstruation
y the ability to conceive and reproduce If the hypophysis or the ovaries are
ed, menstruation ceases and the reproductive organs atrophy

the menopause the reproductive propensities cease, and during *this period*
rine imbalance and disturbance again may result in menstrual irregularities,
lar bleeding, vasomotor disturbances and metabolic and nervous instability.

the postmenopausal years there is established a stability of endocrine func-
Menstruation has ceased and there are varying degrees of progressive atrophy
uterus, ovaries and vagina

ie ovarian hormones concerned with the *functions of sexual* development and
luction are the gonadotropic, the estrogenic and the corpus luteum hormones

e Gonadotropic Hormones in the Female. *The gonadotropic* hormones in the
; are concerned with development of the reproductive ducts, the formation of ova,
uation, and the processes that make reproduction possible.

ere are two large groups of gonadotropic hormones The hormones in the first
are derived from the pituitary and occur in the blood and urine of normal men

and women. Those of the second group occur in the body fluids of pregnant women and their detection is the basis of the Aschheim-Zondek, Friedman and frog tests for pregnancy. These same gonadotropic hormones exist in greatly increased amount in the presence of pathologically proliferating chorionic tissue, such as hydatid mole, chorionepithelioma, and in some tumors of the testicle.

The *pituitary hormones* have not been isolated in pure form. Their presence is detected by biologic reactions and changes in the generative tract. The pituitary gland elaborates two gonadotropic hormones which have to do particularly with ovarian functions One stimulates the growth of the graafian follicle up to the time of maturation of the ovum and ovulation. This hormone is designated as the follicle-stimulating hormone. The other gonadotropic hormone has the function of luteinization of the follicle and thus produces the corpus luteum with the formation of progesterone A third anterior pituitary hormone is luteotrophin, formerly known as prolactin In addition to its influence on the breasts it initiates and maintains the secretory activity of the corpus luteum (see p. 1105).

Progesterone is a derivative of androstene The chief metabolite of progesterone is pregnane, which occurs in relatively large amounts in the urine during pregnancy. The name pregnanediol is often used instead of progesterone Steroids of the progesterone group have been isolated from the adrenal glands and recovered from the urine of castrates of both sexes.

As has been stated in the description of testicular hormones, small amounts of gonadotropic substance are found in the urine of both men and women, irrespective of age. Since this substance is present in greatest concentration after the menopause or castration, it is called the *hormone of castrate urine* to distinguish it from the hormone of pregnancy urine (see p. 1115)

Tests for Pregnancy. The urine of pregnant women contains a gonadotropic substance which is the basis of the urinary test for pregnancy In the mammals the intravenous injection of a few milliliters of the urine of a pregnant woman will cause the formation of hemorrhagic and ruptured follicles in 48 hours, the test is accurate in more than 90 per cent of cases The hormone is detected by its action on the ovaries of rats, mice (Aschheim-Zondek test), rabbits (Friedman test), and frogs (Hogben or xenopus test).

In the Hogben pregnancy test the South African clawed toad (*Xenopus laevis*), an animal that carries eggs at all times of the year but extrudes them only after coitus or after injection of gonadotropins, is utilized The injection (subcutaneous or into the dorsal lymph sac) of a suitably prepared extract of the urine of a pregnant woman is followed by the extrusion of eggs in from 4 to 6 hours These can be seen by the naked eye.

The Hogben test is more rapid than the Friedman and the Aschheim-Zondek tests and is preferred by many gynecologists However, it is not reliable before the fortieth day of pregnancy and this limits its use

If the urine continues to show a high content of gonadotropic hormone after the termination of a normal pregnancy, or after operation for tubal pregnancy or curettage for incomplete abortion, the presence of hydatid mole or chorionepithelioma is strongly suspected The continued high titer of this hormone in cases of hydatid mole, chorionepithelioma, or testicular tumor indicates that these growths have not been destroyed or removed, they are progressing either locally or by metastasis

The Estrogenic Hormones. The ovarian control of the reproductive function and secondary sex characteristics is mediated by the ovarian hormones, estrogen and progesterone The estrogen is produced by the graafian follicle, and the progesterone by the corpus luteum.

Estrogen is the growth hormone, stimulating the growth of the uterus, uterine tubes, vagina, and mammary glands, controlling the development of secondary sex characteristics, and presiding over the regeneration of the endometrium after each menstrual period From the influence of estrogen the female acquires sexual maturity, and conception and reproduction may be assured

Estrogens are elaborated by the ovaries for the most part during the first 2 weeks of the menstrual cycle and are inhibited by the action of progesterone during the rest

of the time. It is during the first 2 weeks of the cycle that the uterine muscle exhibits the greatest cyclic changes in motility. The increased motility is at its height during the period of follicular growth, it decreases during the last 2 weeks, under the influence of progesterone. Uterine motility is distinctly sluggish during the first trimester of pregnancy, as long as the corpus luteum exerts a controlling influence.

At the beginning of each menstrual cycle many immature follicles develop but only one or two reach full maturity. The rest degenerate. A single graafian follicle will not mature normally if smaller follicles are not present.

Within 5 or 6 days after the endometrium is cast off during menstruation, it is regenerated. This is the result of the natural tendency of tissue to heal This process may be stimulated and accelerated by estrogen

It is known that large amounts of estrogen are formed and excreted during pregnancy. The administration of large doses of estrogen early in pregnancy may cause nidation of the fertilized egg or later abortion or congenital malformation.

Hyperstimulation with estrogens after the menopause may produce endometrial hyperplasia and uterine bleeding similar to that caused by certain ovarian tumors after the menopause.

The Corpus Luteum Hormones. A function of the corpus luteum hormone, *progesterone*, is the preparation of the endometrium for the nidation and nourishment of the fertilized ovum The endometrium is sensitized so that, in the presence of the embryo, it forms the maternal part of the placenta, the decidua The corpus luteum inhibits uterine motility in both the pregnant and the nonpregnant uterus

The menses can be suppressed by the use of progestin or progesterone or stilbestrol. Progestin also is a substitute for the ovarian secretions in maintaining pregnancy.

The corpus luteum seems to have no useful action except in either preparing the uterus for pregnancy or enabling the gestation to continue. Progesterone is not necessary for the health of the individual, likewise the administration of progesterone has not been followed by any harmful effects in either human beings or animals

Pregnanediol is the end product in the metabolism of progesterone and is derived from it Pregnanediol appears in the urine a day or two after ovulation. The excretion becomes greatest about a week before menstruation and usually disappears entirely 2 or 3 days before the onset of bleeding The curve of excretion of pregnanediol thus parallels the life history of the corpus luteum

Relaxin is a hormone secreted by the corpus luteum but its significance is not known

The Controls of Ovulation. Menstruation is generally accepted as an indication of ovarian function

Endocrine disorders such as dysfunction and diseases of the pituitary, thyroid and adrenal glands, and primary ovarian failure may prevent ovulation These disturbances also may stop normal female sexual function and impose masculine features Destructive diseases such as tuberculosis, tubo-ovarian abscess, or neoplasms may damage the ovarian cortex so severely that ovarian function is eliminated Ovarian damage by surgical operations or pathologic processes which disturb the blood supply of an ovary may cause it to become cystic If the ovary is injured sufficiently, menopausal symptoms develop

[illegible] functioning
[illegible] that ovula-
[illegible] However,

menstrual function or ovulation is extremely susceptible to external stimuli In the midst of a normal menstrual period the flow may be stopped abruptly by physical or psychic shock, or by getting chilled or fatigued Some young women may stop menstruating for months without any known cause Menstruation ceases during the course of many acute or chronic infections such as pulmonary tuberculosis or severe fevers, and in idiopathic ulcerative colitis or ileitis. The mode of action of such stimuli on ovulation is unknown Inhibition of ovulation by progesterone is the cause of nonovulation during pregnancy In rare instances a woman may menstruate without ovulation, or she may ovulate without menstruating Ovulation without menstruating occurs during the puerperium.

The Time of Ovulation; the "Safe Period." Ovulation normally occurs between menstrual periods. The commonest date is approximately between the eleventh and fourteenth days.

In recent years it has been taught by some that sexual intercourse may be practiced without fear of pregnancy and without the use of contraceptives during approximately the 2 weeks prior to the oncoming menstrual period This period has been designated the safe period. Physicians realize the uncertainty of such advice, for many women ovulate irregularly, and the practice of the safe period for them is often disappointing. Those who must use this method of contraception and who do not know when they ovulate may be told that the usual period of fertility extends from the eleventh to perhaps the fifteenth day of the cycle, at other times the likelihood of conception is more remote.

Periodic Intermenstrual Pain (Mittelschmerz). Periodic intermenstrual pain is usually limited to young women less than 30 years old It is characterized by a regular periodicity of the pain, occurring always the same number of days after menstruation. There is pain in the suprapubic region, in one or both iliac fossae Commonly it is diffuse through the whole pelvis and is said to resemble the pain of dysmenorrhea or very mild labor pain Some have the pain in the right and left sides alternately on successive months In some women the pain is severe and incapacitating and is followed by soreness and nervousness until the next menstrual period. In these cases the symptoms often simulate those of acute appendicitis or salpingitis A painful ovulation associated with severe intra-abdominal bleeding from the ruptured ovary is rare. Associated vaginal bleeding may be enough to be noticed by the patient and to require some protection

If the examination is made at a time when there is no discomfort, when the patient is not ovulating, the palpatory examination in cases of ovulatory pain may reveal nothing at all If the patient is examined while she is in the midst of ovulatory pain, there will be tenderness through the whole pelvis, the cul-de-sac, and both fornices

Without internal hemorrhage there is no leukocytosis In the presence of hemorrhage the leukocyte count may be very high, 15,000 to 25,000 per cubic millimeter.

The temperature drops just before the date of ovulation and then rises perhaps 1 F near the time of actual rupture of the follicle

The [illegible] In cases with abdominal bleedin [illegible]
extra-u [illegible]
sources, and other acute pelvic conditions

Menstruation. The ovarian hormones estrogen and progesterone are the direct controls of menstruation. The indirect control is vested in other glands of internal secretion. As has been stated, there are ovulatory and anovulatory menstruations

In *ovulatory menstruation* ovulation occurs during the menstrual cycle, with the formation of the corpus luteum and the consequent production of progestational reaction in the endometrium The bleeding is from a progestational endometrium

The length of the menstrual cycle, if measured from the first day of menstrual flow, averages about 28 days Variations up to 4 or 5 days are present in most women. Many women menstruate habitually at intervals of from 21 to 23 days, others every 35 or 40 days

The loss of blood during menstruation varies (average 50 mg. of iron) tremendously with individual women and from month to month in the same person. It is important to realize that a fairly constant amount of blood is lost during each period by a given woman, and that wide variations in the amount of blood lost are compatible with normal health and the reproductive function. Women generally can fairly accurately estimate the blood loss by the number of napkins they use per day The normal woman does not get up and change napkins at night.

of the time It is during the first 2 weeks of the cycle that the uterine muscle exhibits the greatest cyclic changes in motility. The increased motility is at its height during the period of follicular growth, it decreases during the last 2 weeks, under the influence of progesterone Uterine motility is distinctly sluggish during the first trimester of pregnancy, as long as the corpus luteum exerts a controlling influence.

At the beginning of each menstrual cycle *many immature follicles develop but only* one or two reach full maturity. The rest degenerate. A single graafian follicle will not mature normally if smaller follicles are not present.

Within 5 or 6 days after the endometrium is cast off during menstruation, it is regenerated This is the result of the natural tendency of tissue to heal. This process may be stimulated and accelerated by estrogen

It is known that large amounts of estrogen are formed and excreted during pregnancy. The administration of large doses of estrogen early in pregnancy may cause nidation of the fertilized egg or later abortion or congenital malformation.

Hyperstimulation with estrogens after the menopause may produce endometrial hyperplasia and uterine bleeding similar to that caused by certain ovarian tumors after the menopause

The Corpus Luteum Hormones. A function of the corpus luteum hormone, *progesterone,* is the preparation of the endometrium for the nidation and nourishment of the fertilized ovum The endometrium is sensitized so that, in the presence of the embryo, it forms the maternal part of the placenta, the decidua The corpus luteum inhibits uterine motility in both the pregnant and the nonpregnant uterus.

The menses can be suppressed by the use of progestin or progesterone or stilbestrol Progestin also is a substitute for the ovarian secretions in maintaining pregnancy.

The corpus luteum seems to have no useful action except in either preparing the uterus for pregnancy or enabling the gestation to continue. Progesterone is not necessary for the health of the individual, likewise the administration of progesterone has not been followed by any harmful effects in either human beings or animals

Pregnanediol is the end product in the metabolism of progesterone and is derived from it Pregnanediol appears in the urine a day or two after ovulation The excretion becomes greatest about a week before menstruation and usually disappears entirely 2 or 3 days before the onset of bleeding The curve of excretion of pregnanediol thus parallels the life history of the corpus luteum

Relaxin is a hormone secreted by the corpus luteum but its significance is not known

The Controls of Ovulation. Menstruation is generally accepted as an indication of ovarian function

Endocrine disorders such as dysfunction and diseases of the pituitary, thyroid and adrenal glands, and primary ovarian failure may prevent ovulation These disturbances also may stop normal female sexual function and impose masculine features Destructive diseases such as tuberculosis, tubo-ovarian abscess, or neoplasms may damage the ovarian cortex so severely that ovarian function is eliminated Ovarian damage by surgical operations or pathologic processes which disturb the blood supply of an ovary may cause it to become cystic. If the ovary is injured sufficiently, menopausal symptoms develop

It may be stated, then, that ovulation is controlled by a synchronized functioning of the pituitary gland and the ovary or ovaries Generally the indication that ovulation is proceeding normally is the cyclic appearance of the menstrual flow However, menstrual function or ovulation is extremely susceptible to external *stimuli In the* midst of a normal menstrual period the flow may be stopped abruptly by *physical* or psychic shock, or by getting chilled or fatigued Some young women may stop menstruating for months without any known cause Menstruation ceases during the course of many acute or chronic infections such as pulmonary tuberculosis or severe fevers, and in idiopathic ulcerative colitis or ileitis The mode of action *of such stimuli* on ovulation is unknown Inhibition of ovulation by progesterone is the cause of nonovulation during pregnancy. In rare instances a woman may *menstruate* without ovulation, or she may ovulate without menstruating. Ovulation without menstruating occurs during the puerperium

Cryptomenorrhea may occur in the ectopic endometrium in the ovary or elsewhere. In these cases of endometriosis menstrual blood is retained in the ovary, forming a hemorrhagic cyst, or collects in the pelvis to form a pelvic hematocele. If the cervical canal is occluded by operative scar, malignant lesion, or childbirth injury, the menstrual blood collects in the uterus (hematometra) or in the uterine tube (hematosalpinx). If there is an imperforate hymen, the menstrual fluids collect in the vagina (hematocolpos) and may be forced back into the uterus, uterine tubes, and pelvic cavity.

The presence of amenorrhea without organic disease has been attributed to psychic or physical shock. Amenorrhea in association with pulmonary tuberculosis, diabetes, heart disease and serious intestinal diseases is common Diseases of the endocrine glands are rare causes of amenorrhea

In *menorrhagia* there is not only an increase in the amount of flow, but often also a prolongation of the flow occurring at the regular menstrual time Menorrhagia is one of the commonest menstrual disorders of adolescence and the menopause, it is a cardinal symptom of endometrial hyperplasia Menorrhagia is often a symptom of uterine myomas, endometriosis, salpingitis, chronic subinvolution of the uterus, endometritis, retained placental tissue, uterine cancer, and pelvic tumors.

Metrorrhagia is found in a variety of conditions cervical polyp, myoma of the uterus, retained placenta, ovarian tumors, vaginal lesions, prolapse of the uterus with cervical ulceration, tubal pregnancy, hydatid mole, and occasionally in the rare condition of malignant disease of the uterus, and in other conditions It is also found in functional disorders, especially hyperplasia of the endometrium

Direct trauma or *laceration* of the genitals produces vaginal bleeding. After automobile accidents or falls there may be severe uterine bleeding, without any visible injury to the cervix, uterus, or external genitals The cause is not always clear. It may be due to rupture or injury to the graafian follicle or corpus luteum, which would be followed by uterine bleeding In such cases an abortion is always to be suspected.

In the presence of abnormal menstruation, and occasionally in the presence of normal menstruation, more specific data in regard to ovarian functions may be necessary for diagnosis. These data are obtained by several different methods By *endometrial biopsy* the competent pathologist can diagnose the presence of a functioning corpus luteum or determine whether follicular development is normal

Vaginal bleeding during ovulation is rare Microscopic vaginal bleeding, however, is not uncommon, and with these small amounts of vaginal bleeding during ovulation may be an accompanying observable increase in the amount of leukorrhea and also vague discomforts in the pelvic area (Mittelschmerz)

Vicarious menstruation perhaps occurs in some patients who do not menstruate normally but who have an ample production of the estrogenic hormone. Often there is rhinorrhea and other nasal symptoms and at times epistaxis occurring at the time of the menstrual bleeding Perhaps there is a relationship between genital stimuli, activity of the breasts and of the genital spots of the nasal mucosa. Vicarious menstruation is alleged to occur more frequently from the nose or the breasts.

MENSTRUAL IRREGULARITIES. Menstrual irregularities or functional uterine bleeding occurs most frequently in adolescence, and in this period all menstrual irregularities are considered to be of functional origin until they are proved otherwise In the *period of sexual activity functional* irregularities constitute one fifth of all causes of abnormal uterine bleeding

In the menopausal years menstrual irregularities are again frequent However, all irregular uterine bleeding which occurs during the menopause is considered to be due to organic diseases until proved otherwise

The menstrual period is often preceded and followed by a moderate, mucoid leukorrhea. The breasts often enlarge and become painful.

All normal nonneurotic women regard menstruation as an unavoidable inconvenience; only a small minority are incapacitated by it.

In *ovulatory menstruation* the endometrial changes during the *menstrual cycle* may be divided into four phases· proliferative, secretory, premenstrual regression and menstrual desquamation.

The proliferative phase begins with the end of the menstrual flow and extends to the time of ovulation This is the period of estrogenic stimulation, and at this time *the graafian follicle is ripening in the ovary*

The secretory phase extends from the time of ovulation until the regression of the corpus luteum During this phase the corpus luteum runs its active course, the endometrial growth is brought about by the secretion of the corpus luteum, progesterone

The premenstrual phase lasts for 2 or 3 days, beginning shortly after the degeneration of the corpus luteum and ending with the onset of menstrual flow.

The phase of desquamation is the period of menstrual bleeding

Anovulatory menstruation may be defined as a form of menstruation which is characterized by the lack of ovulation and the consequent absence of corpus luteum formation There is no secretory stage of endometrial growth, and the bleeding occurs from an endometrium that shows only the follicular stimulation. Anovulatory menstruation is therefore periodic uterine bleeding. The gross characteristic of anovulatory menstruation is a greater loss of blood

Possibly 1 woman in 12 may menstruate from an endometrium that shows no influence of corpus luteum Perhaps 1 in every 20 of all menstrual periods in healthy women with normal menstrual histories is an anovulatory menstruation

Anovulatory menstruation is observed more frequently in women who have obesity, endocrine disorders, and metabolic disorders produced by many conditions In these women ovarian function may be seriously disturbed for prolonged periods of time, and sterility is particularly common

Anovulatory menstruation is determined by biopsy of the endometrium obtained within 1 or 2 days before a menstrual period or on the first day of the flow. A proliferative type of endometrium at this period shows no progestational (corpus luteum) influence, and therefore it is concluded that the menstrual period is anovulatory

Precocious menstruation is associated with (1) adrenal tumors, (2) ovarian tumors, (3) lesions of the brain and (4) lack of any demonstrable pathologic lesion. This is not a true development of the reproductive organs but rather a false, precocious stimulation of certain elements in the reproductive organs, simulating a true growth The largest group of young girls who have precocious menstruation have no demonstrable disease

The average age at occurrence of the menarche is between 13 and 14 years, there is a wide normal variation, with ranges between 10 and 18 years *Heredity*, diet, climate, race, health and other factors all play a part

MENSTRUAL DISORDERS. Menstrual disorders and irregular uterine bleeding occur at all ages but most frequently during adolescence and the menopause (functional uterine bleeding)

Amenorrhea or complete absence of menstruation may develop suddenly, or it may be preceded by a gradual decrease in the amount of menstrual flow (oligomenorrhea), or decrease in the frequency of menstruation. Hidden or retained *menstruation* (cryptomenorrhea) is always to be considered in those who are of the correct age and do not have manifest periods. However, the occurrence of cryptomenorrhea is rare.

symptom of many gynecologic disorders. As a rule, any pelvic discomfort is exaggerated by menstruation.

Ovarian Hypogonadism. Subnormal endocrine activity of the ovaries, like that of the testes, cannot be judged by the patient

Ovarian deprivation is manifested by the asexual features of girls before puberty and changes that occur at the menopause or after the removal or inactivation of the ovaries during the period in which reproduction is possible The effects differ, depending on the age at which ovarian function is terminated and on the health of the ovaries at the time they are removed Before puberty, loss of ovarian function is followed by sexual infantilism, which is approximated in instances of ovarian failure due to hypopituitarism in adolescence and in follicular agenesis. During sexual maturity the characteristic changes that follow bilateral oophorectomy with the consequent loss of estrogenic substances in a young, sexually active woman are amenorrhea, hot flushes, nervousness, loss of libido, gain in weight, insomnia, and other nervous reactions. These are the symptoms of the menopause and they may appear whether the ovarian function is eliminated by bilateral oophorectomy, irradiation, disease, or normal processes which occur at the climacteric

The processes by which the young girl may be deprived of all or a part of the endocrine functions of the ovaries are many Some of these processes may be enumerated: agenesis of the ovaries, misplacement and degeneration of the ovaries in the inguinal canals, cystic degeneration and inflammatory disease Dysfunction of the ovaries may result from dysfunction of the pituitary or the thyroid gland, malnutrition, chronic disease, or toxic conditions and from indeterminate causes

In ovarian infantilism, at puberty the secondary sex organs and characteristics fail to develop. The uterus, vagina, and uterine tubes remain infantile The growth is greatly retarded

Ovarian eunuchoidism, in contrast to ovarian infantilism, is characterized by accentuation of growth due to delayed closure of the epiphyses with a disproportion in the length of the upper and lower extremities As in infantilism the secondary sex organs and characteristics do not develop

Menopause. *The menopause* is termed *induced* or *artificial* if it is brought on by surgical operation or irradiation It is *premature* if it occurs at an early age, and is *delayed* if menstruation continues past the usual age for menstruation

Amenorrhea follows the cessation of ovarian activity and production of estrogen However, estrogen continues to be produced somewhere in the body Menopausal amenorrhea may come on gradually; it may be preceded by a decrease in the amount of flow for a year or more. During this time occasional periods may be missed Finally amenorrhea is permanent and complete In other women the menses cease abruptly and permanently. Occasionally, months after the patient has had her last menstrual period, there may be a recurrence of bleeding for a few days Often this is due to endocrine therapy.

The age at the appearance of the menopause is inheritable The average age for the menopause is from 45 to 50 years Some women may menstruate till they approach 60. An occasional woman menstruates past the age of 60 years The menopause may also occur without apparent cause at almost any age after onset of menstruation

True menopausal symptoms include vasomotor disturbances, hot flushes, nerv-

of organic disturbances.

Some women never have hot flushes, others are made miserable by them As a rule, they make their appearance before the amenorrhea is fully established, are fairly frequent and annoying for 6 months or a year, and then gradually or rapidly

Irregular or functional uterine bleeding can come from any type of endome including normal estrogenic or proliferative; hyperestrogenic or hyperplastic; n progestational, atrophic (castrate or postmenopausal type); or mixed variet endometria.

The pelvic organs are often palpably normal in functional bleeding. In th vanced age groups normal size of internal genitalia may not be a safe criteri the health of these organs.

In some instances of menstrual irregularities endometrial studies are rec for diagnosis Adequate endometrial studies include examination, by a comp pathologist, of a specimen taken on the first day of the menstrual flow or just b menstruation, to include the progestational phase. The finding of progesta endometrium in many women who have functional bleeding suggests that la ovulation and deficient corpus luteum function may not always cause this ir larity.

The pathologist will often report the presence of *endometrial hyperplasia studies of uterine tissue removed by curettage In some instances of functional u* bleeding hyperplasia of the endometrium, due primarily to the stimulation by e gen, is present Endometrial hyperplasia often occurs in women approachin menopause. It occurs also, however, after the menopause and in infants Its o rence after the menopause may in some instances be due to the administrati estrogen or to ovarian tumor.

Excessive and prolonged menstruation is the characteristic symptom of h plasia. The menstrual flow may be so prolonged that it is practically contin After the menopause hyperplasia may be manifested by vaginal bleeding

The clinical significance of the diagnosis of hyperplasia varies with the a the patient In puberty hyperplasia is usually uncomplicated, and curettage erally confers relief from the irregular bleeding In the period of sexual mat associated pathologic lesions are commonly found, hence the hyperplasia is always to be accepted as the sole cause of bleeding. In the postmenopausal y a malignant lesion accompanies hyperplasia in almost one third of the cases Hy plasia as the final explanation of postmenopausal bleeding is not acceptable u malignant disease has been excluded by repeated examinations over a prolo period of time.

In adult and aged women who have functional uterine bleeding, if the resul physical examination are negative, curettage and biopsy of the cervix are neces If these and other examinations reveal nothing abnormal, the bleeding is tentati accepted as functional but not definitely diagnosed as such until sufficient time (eral months) has elapsed to prove that organic disease is not present. In adoles girls functional bleeding is the rule, and treatment for the condition is gene not advisable Maturity and not gestation may cure functional uterine bleedin girls. In the presence of diseases of the blood such as purpura, pernicious ane and leukemia, uterine bleeding may be serious

Dysmenorrhea (painful menstruation) is termed primary when it is not ass ated with any demonstrable pathologic disorder; it is designated as secondary w it is accompanied by organic gynecologic disease

In *primary dysmenorrhea* often the first few menses after the menarche normal. Pain ensues irregularly The degree of pain varies, and is described ... In severe dysmenorrhea the pain is present s

to these women that as they get ol

Secondary dysmenorrhea by definition is associated with organic pelvic dise It may not date from the onset of the pelvic disease, for many have always had In those who do not have a history of dysmenorrhea this symptom may then app after or during the course of some pelvic disease. Secondary dysmenorrhea

The Endocrine Assays Correlated With Clinical Manifestations Which Are Helpful in Diagnosis. The gonadotropin-follicle stimulating hormone is *increased* after the menopause, after castration, and in the presence of primary hypogonadism such as ovarian agenesis and secondarily in the presence of degeneration of the seminiferous tubules and tumors of the Leydig cells of the testicles. The gonadotropin-follicle stimulating hormone is *decreased* in pituitary infantilism, in anorexia nervosa, in the presence of profound psychoneurosis and in some psychoses This hormone is present in insignificant amounts or absent before puberty.

The chorionic gonadotropic hormone is *increased* during pregnancy and in the presence of chorionepithelioma and hydatiform moles.

Androgens or 17-ketosteroids which have a dual source of origin in the male—the adrenal cortex and the testicles—are *increased* in the adrenogenital syndrome, in adrenal tumors and in Cushing's syndrome due to cortical hyperplasia or carcinoma. In the presence of adenoma of the adrenal cortex when the contralateral adrenal is hypertrophied, the concentrations of 17-ketosteroids may be decreased In sexual precocity due to a hormone-producing tumor of the testicle, the 17-ketosteroids are increased In sexual precocity due to neurogenic or constitutional causes the 17-ketosteroids have normal values The 17-ketosteroids are *decreased* in Addison's disease, pituitary infantilism, primary hypogonadism, ovarian agenesis and testicular tubular degeneration

The adrenal glycogenic factor or neutral reducing lipids are *increased* in Cushing's syndrome and *decreased* in Addison's disease. The concentration of this substance is tested for by employment of sugar tolerance tests: response to insulin and ACTH Small doses of 5 to 10 units of insulin may cause hypoglycemia. The administration of ACTH, in the presence of reduced concentrations of the adrenal glycogenetic factor, causes an increase in the eosinophils in the circulating blood, increased excretion of uric acid and an increase of 17-ketosteroids in the urine

The adrenal electrolyte factor is occasionally *increased* in Cushing's syndrome. It is *decreased* in Addison's disease Its concentration is implied by determinations of the serum sodium, potassium and chloride and by the amount of carbon dioxide of the blood It may also be inferred by the results of the diuresis test of Kepler, Robinson and Power

The adrenal medulla or pressor factor (epinephrine and norepinephrine) is increased in the presence of the following tumors of the adrenal medulla sympathogonioma, neuroblastoma, ganglioneuroma and pheochromocytoma. The common tests employed for detection of excessive amounts of epinephrine and norepinephrine are the benzodioxane and the histamine tests.

The posterior pituitary and hypothalamic area may fail to produce adequate amounts of the antidiuretic factor and as a consequence diabetes insipidus may ensue. This condition is indicated by the consistent passage of urine with a specific gravity which is always less than 1 005

The estrogens are *increased* in the presence of pregnancy, granulosa or thecal cell tumor of the ovary, chorionepithelioma and some adrenal cortical tumors and hyperplasias Estrogens are *decreased* in sexual infantilism of either pituitary or ovarian origin and amenorrhea

Estrogenic excesses and deficiencies are often determined by a study of the vaginal smear, vaginal or endometrial biopsy and the histologic study of estrogen-producing tumors

Progestin is *increased* in the presence of pregnancy, luteoma of the ovary and some adrenal tumors It is *decreased* in the presence of anovulatory menstrual cycles. Excessive amounts are determined by a study of the basal temperature, vaginal smear and endometrial biopsy

disappear. They may be present in varying degree for 1 to 3 years. They may according to the history, 10, 20, or even 25 years A suspicion should alway aroused that in these instances of prolonged hot flushes there may be a desire of complainant to impress the "girls" with her youth.

The amount of inconvenience that a woman suffers depends largely on her attitude toward discomfort, her fortitude and mental stability The sudden depr tion of ovarian function precipitates a more marked menopausal reaction t occurs in the natural course of events Hot flushes after simple hysterectomy du menstrual life result from operative or postoperative injury or diseased ovaries

The postmenopausal ovary contains no follicles It seems to have no func whatever after the menopause, and its removal after that event causes no sympt of endocrine deprivation or imbalance

After the menopause the uterus becomes smaller, the endometrium inact thin, and atrophic The vaginal epithelium becomes very thin, not more than a th or quarter as thick as in normal sexual life The external genitalia become smal flabby, and lose *their subcutaneous fat and elastic tissue. The breasts atrophy.*

In the vagina the atrophy of the epithelium is accompanied by a decrease glycogen content, and the secretions become neutral or alkaline. After the me pause senile vaginitis is common and is manifested by irritation of the vaginal w which may lead to cicatricial constriction and eventual obliteration of the up part of the vagina. This senile irritation is benefited by the use of vaginal suppo tories containing estrogens

There is an increase in the amount of gonadotropins in the blood and uri

Postmenopausal Bleeding. Malignant disease is the cause of postmenopau bleeding in 6 of every 10 who have it. The commonest single cause of postmer pausal bleeding is cervical polyp Cancer of the cervix is next in importance Oth *causes are carcinoma of the uterine body, uterine prolapse with ulceration of t* cervix, ovarian tumors, endometrial polyp, and senile vaginitis There are numero other causes, a few of which are sarcoma of the endometrium, sarcoma in myom *chronic endometritis, hyperplasia of the endometrium,* ulceration from a vagin pessary, urethral caruncle, urethral prolapse, and primary vaginal malignant d ease, including metastatic tumors of the vagina. There will remain a number patients in whom no cause is revealed by curettage, biopsy, or pelvic examinati by physical means.

In a few patients diagnosis of postmenopausal bleeding *is established by exam* ination by physical means. The cause can be seen or felt When this is impossibl curettage is required. If the foregoing procedures do not reveal the cause, it *situated in the uterine wall, or in an inaccessible part of the endometrium,* or the adnexa In these cases the pelvis should be explored through a laparotomy.

Ovarian Hypergonadism (*Precocious Puberty*). Ovarian hypergonadism ca not be determined from the history Nymphomania is of psychic and not of endo crine origin.

The definite form of ovarian hypergonadism (*precocious puberty*) is encoun tered in childhood. In some girls early in childhood the secondary sex organs an characteristics develop and ovulation and menstruation proceed normally. Ther *is no evidence of tumors or abnormalities in the ovaries* or any of the ductles glands. This condition may be caused by disease of the hypothalamus, encephaliti or polyostotic fibrous dysplasia

There is an early closure of the epiphyses The bone age as revealed by roent genograms is several years in advance of the chronologic age.

Precocious puberty or ovarian hypergonadism *is differentiated* from that result ing from ovarian tumors because ovulation does not occur in the latter; and from adrenal tumors because true precociousness does not occur *as a result of these* tumors.

SOME DISORDERS INVOLVING THE CRANIAL PORTION OF THE CENTRAL NERVOUS SYSTEM

The descriptions of the diseases of the nervous system which follow are limited to the diseases of the cranial portion of the central nervous system The diseases of the spinal cord and the peripheral nerves and their association with the cranial portion of the central nervous system have been considered in connection with the locomotor system

The complexities of the central nervous system require knowledge of its structure and function in order to determine within it the localization of disease The diagnostic difficulties are increased because there are many parts of the system to which definite function or functions cannot be assigned. In the discussion of diseases of the nervous system which follows, it is hoped that the brevity of discussion will not be interpreted as implying that the diagnosis of disease of this system is always easy or that it can be quickly accomplished Diagnosis of disease of the central nervous system, with any degree of accuracy, requires the constant daily application of knowledge of neuro-anatomy and neurophysiology not possessed by those who have not had special training in this field of endeavor Even if special training has been received, proficiency in diagnosis cannot be maintained unless this training is in constant use

CONGENITAL AND HEREDITARY DISEASES OF THE NERVOUS SYSTEM

The terms congenital and prenatal are synonymous There are the prenatal diseases of the nervous system which arise or begin during intra-uterine life and those which are due to morbid heredity, for instance those which are passed along in the germ plasm Sometimes prenatal and hereditary diseases can be separated, and at other times separation and assignment to one or the other category is impossible.

In regard to intra-uterine causes for prenatal disease, it seems that defects of development may result from transient disturbances of embryonic metabolism possibly caused by defective implantation or infarction of the placenta and maternal toxemias Little is known about placental disorders and the destruction of parts of the nervous system during intra-uterine life. Some infections, such as toxoplasmosis, German measles and syphilis, of the mother may be transmitted to or their toxins may reach the fetus in utero. Roentgenotherapy of the pelvis during pregnancy may cause defects of the nervous system in the fetus. It may be difficult, however, to prove that the roentgenotherapy caused a particular defect.

Hereditary disease of the nervous system may be manifest at birth, and there often is a history of similar defects in relatives. If the disease is not manifest at birth, and occurs later in life, there should be no evidence of postnatal disease of the nervous system occurring during infancy which could account for the affliction if the disease is to be attributed to prenatal influences. However, a symptom-free

interval following birth is not against the diagnosis of defective development of the suprasegmental structures, for functions of these structures become evident as age advances Characteristically, a hereditarily defective nervous system reacts excessively to mild birth trauma, infections, and disturbances of nutrition Congenital defects of the germ plasm are often present despite a negative family history. Morbid heredity is much more evident in cases of progressive degeneration which begin in childhood, adolescence or even in adult life than those apparent at the time of birth or that appear during infancy.

The incidence of congenital anomalies, when calculated for the general population, is diluted to relatively insignificant figures there is one malformed child for every 200 infants born alive. The incidence of malformed infants born to parents who have had one malformed child is different According to Murphy and to Ballantyne, once a woman has given birth to a monster, for instance an anencephalic, subsequent children are more liable to show some form of monstrosity

Defects of Head and Nervous System at Birth. *Hydrocephalus.* Hydrocephalus is termed obstructive or communicative In obstructive hydrocephalus there are an immense variety of pathologic lesions productive of hydrocephalus all of which create an obstruction at some point in the pathway of the circulation of cerebrospinal fluid. The site of the obstruction may be difficult to identify

The terms communicating hydrocephalus, external hydrocephalus, and internal hydrocephalus have special meanings An external hydrocephalus is a condition in which excessive fluid accumulates in the subarachnoid space, whereas in internal hydrocephalus there is effusion of fluid within the ventricles

A *communicating hydrocephalus* arises when an excessive amount of cerebrospinal fluid is formed as the result of hyperemia of the choroid plexus with an ensuing excessive excretion or when there is a decreased amount of absorption of the normally formed fluid Common causes of this form of hydrocephalus are. infections and intracranial hypertension and occasionally increased intrathoracic pressure.

Hydrocephalus is often congenital in origin but it may be acquired, and often it is difficult to distinguish by clinical means the former from the latter.

In *congenital hydrocephalus* the developmental errors are usually situated at a point where there is normally a constricted passage for the flow of the cerebrospinal fluid, that is, at the foramen of Monro, the aqueduct of Sylvius, or the foramen of the fourth ventricle. The narrowed passage at one or more of these points is the result of a simple stenosis or an atresia Many of these developmental forms are truly internal hydrocephalus and affect the aqueduct of Sylvius "Forking" of the aqueduct is a common cause of congenital hydrocephalus, often associated with spina bifida, but compatible with long survival and minimal hydrocephalus should one of the channels be sufficiently well developed It has been clearly distinguished from so-called gliosis of the aqueduct, the essential pathologic changes of which are a proliferation of the subependymal glia and disruption of the ependyma

In the *Arnold-Chiari* malformations there is an elongation of the cerebellar tonsils, smallness and deformity of the medulla, smallness of the pons with degeneration of its transverse fibers and herniation of the cerebellum into the spinal cord Also a caudal displacement of the brain stem may cause this deformity

Many instances of the so-called idiopathic hydrocephalus are actually due to a low-grade meningitis, to thrombosis, or to hemorrhage which obstruct the flow of the cerebrospinal fluid

There are many infections which on healing may cause a hydrocephalus, for example, those due to the various pyogenic organisms, tuberculosis, syphilis, and toxoplasmosis. Extension of infection from the ear may cause a sinus thrombosis which is propagated into the tributaries or main venous sinuses and thus originates the so-called otitic hydrocephalus

Trauma and subdural hemorrhage are causes for hydrocephalus in some cases

Hydrocephalus causes a stretching and thinning of the cortex followed by atrophy and usually idiocy.

In congenital hydrocephalus, soon after birth the head begins to enlarge out of

proportion to the rest of the body. The fontanels bulge and later the lines of
of the skull separate. Vomiting and papilledema may be present in obstr
hydrocephalus.

On examination there are present all degrees of cranial enlargement. The
may be twice its normal size and actually weigh more than the body and ext
ties. Paralyses are rarely present. The cerebral ventricles are dilated and ther
atrophy of the brain and mental weakness.

The diagnosis is obvious in the well-developed instances of the disease.
differential diagnosis between the congenital and the acquired hydroceph
particularly that due to trauma and hemorrhage, may be made by aspiratio
the fluid and its replacement by air followed by roentgenologic examination

Ocular Hypertelorism (*Hereditary Craniofacial Dysostosis*). Ocular hype
rism is the result of an enlargement of the lesser wings of the sphenoid bone The
are set wide apart, the bridge of the nose is broad and, in some cases, flattened, the
diverge to an abnormal degree, frequently producing an external squint, exophtha
and optic atrophy The forehead is marked by a vertical groove extending upward
the root of the nose Mental deficiency of various degrees is usually associated How
when the deformity is mild, normal intelligence may prevail

Mild forms of this deformity are common and important because of the
pleasing appearance of the face

Platybasia. The essential feature of platybasia is the upward displacemen
the base of the posterior fossa formed by the basilar and condylar portions of
occipital bone This deformity in most instances represents a primary defec
development. However, it may result from rickets, osteomalacia and Paget's dise

In many instances there are no symptoms When symptoms are present,
are referable to the nervous system, and comprise weakness and spasticity of
extremities, from pressure on the pyramids. Clinical signs and symptoms cha
teristic of syringomyelia may occur in platybasia, and a syrinx in the cord may
present. Cerebellar ataxia, unsteadiness of gait and nystagmus are common S
nerve palsies and fifth nerve neuralgia may be present Papilledema and other s
of increased intracranial pressure may occur

The diagnosis depends on the demonstration by roentgenograms of the cha
teristic deformities of the skull

Congenital Defective Development of Integral Parts of the Nervous Syst
Defective development of integral parts of the nervous system occurs spontaneo
and may or may not be associated with birth injuries.

There may be defects in the development in the basal ganglia, or defects of
cerebellum may occur unilaterally and bilaterally and are associated with defic
development of the pons and olives.

The term nuclear aplasia is often applied to defects of the cranial nerve nuc
[illegible] amyotonia congenita

[illegible] by Josephy that if all ca
[illegible] of the brain, and som
times elsewhere, were collected in one group, there would exist a means of delimit
certain categories of disease For instance, many cases have been reported in wh
degeneration of the brain cells was associated with degeneration of the macula or w
retinitis pigmentosa, and in which degeneration of white matter was associated w
[illegible] From a consideration of these cases larger, rather fluid categories ha

names of one or more men who described them

The advantage of categoric arrangement is observed in Josephy's arrangement
the neuronal lipidoses. The changes characteristic of neuronal lipidoses include swelli
of ganglion cells, eccentricity of the nucleus, and replacement of peripheral Nissl bod
by prelipid granules

Essentially these changes are results of heredofamilial *disorder of lipid metabolis*

The neurologic manifestations cover a wide range, chiefly in the motor and intellectual spheres, and the retinal changes are those of a macular degeneration or atypical retinitis pigmentosa. Broadly speaking, the younger the patient, the more severe and of shorter duration is the disease, the older the patient, the less severe and of longer duration is the disease. The cherry red spot in the macula is more prominent in the former group of cases, the atypical retinitis pigmentosa, in the latter group

Some of the better known members of the group of diseases known as the neuronal lipidoses are: (1) Tay-Sachs (infantile type), (2) Spielmeyer-Vogt, (3) Batten-Mayou (juvenile type), (4) Kufs (late or adult type), (5) Refsum, (6) Niemann-Pick, (7) Hand-Schuller-Christian, (8) Gaucher, (9) Laurence-Moon-Biedl, (10) Pelizaeus-Merzbacher, (11) Krabbe (acute infantile), (12) Scholz (subacute juvenile), (13) Hallervorden-Spatz, (14) Greenfield and (15) Leber

Niemann-Pick, Hand-Schuller-Christian, Gaucher, Laurence-Moon-Biedl, and Pelizaeus-Merzbacher diseases are characterized by a lipoid reticuloendotheliosis and are described in this text with the diseases of metabolism (see Chapter 18)

Double hemiplegia is a bilateral paralysis with spasticity involving the arms more severely than the legs and often associated with pseudobulbar palsy and mental defect There is little tendency to improvement

The syndromes of *congenital athetosis, chorea,* and *rigidity* are attributed by Ford to defects of the basal ganglia

Double athetosis is recognized by the end of the first year when the child assumes strange postures and when the musculature becomes rigid when handled There is delay in holding up the head, sitting up and walking, and speech is delayed and imperfect In mild affections the child learns to walk and talk. During childhood there is an apparent improvement Before puberty improvement ceases and the condition remains stationary during the rest of life

The movements in *congenital chorea* resemble those of Sydenham's chorea, but the involuntary movements partake of the nature of athetosis, thus the term choreoathetosis Disturbances of speech, difficulty in swallowing, and facial grimaces may be prominent Mental development varies.

In *cerebellar ataxia,* when the child begins to walk, it falls frequently, and sways *from side to side as if sense of balance were defective. Strength may be good* and muscle tone may be normal or nearly so The difficulty in maintaining posture reveals an absence of postural tone The tendon reflexes are normal The rhythm of sp[illegible]

[illegible] If the symp[illegible] ife In many of the patients the disability is enhanced by the skeptical attitude taken by acquaintances Many of these patients improve year by year. In mild forms of the disease there may be almost complete recovery

Developmental Diseases of the Nervous System Manifested During Growth or During Adulthood. ***Friedreich's Ataxia.*** This is a heredofamilial disease of the nervous system which is transmitted by apparently normal as well as by affected individuals It is characterized by progressive degeneration of the spinocerebellar tracts, the corticospinal tracts and the posterior columns of the cord

The mode of transmission is obscure. The age of onset may vary within wide limits in different generations The disease occurs in both sexes

The first symptoms, occurring usually during childhood, are disturbances in gait consisting of a tendency to stagger and to fall The child is considered awkward Difficulties arise in learning to handle the utensils for eating, and in learning to write, and to speak distinctly

On examination it is observed that speech is often explosive and of irregular rhythm Articulation may be so defective as to be incomprehensible. There is a rhythmic nystagmus on lateral deviation, and the vision is impaired. A mild thoracic scoliosis of the spinal column is present. The feet have very high arches, pes cavus,

and hammer toe. The great toes are flexed at the distal joint and hyperextended the proximal joint Muscle tone is almost always reduced and postural tone especially affected The muscles may become wasted. In-co-ordination is prese All the tendon reflexes in the legs are lost early in the course of the disease. Th is cerebellar type of ataxia, more pronounced in the legs than in the arms. patient walks with a broad base. Oscillations of the head occur Station is unstea and swaying in the Romberg position is present.

The vibratory sense over the tibiae and the sense of position and of pass movements of the toes are lost or impaired. Two-point sense and stereognosis lost or diminished in the fingers

The patient becomes helpless and bedridden.

The presence of a positive family history, signs of cerebellar and tabetic ataxi disturbance in speech, nystagmus, positive Romberg's sign, loss of tendon reflex deformities of the feet and spinal column, terminal dementia, optic atrophy, bulb disturbances, and incontinence are diagnostic Second instances of the disease in family may be diagnosed on less evidence

In a few cases the disease seems to become arrested. The progress always so slow that death may occur from other causes before disability from the disea develops

Hereditary Spastic Paraplegia. Heredofamilial degenerative spastic par plegia is characterized by degeneration of the pyramidal tracts and clinically progressive spastic paraplegia

There may be a history that there was difficulty in learning to walk. There a tendency to walking on the toes and to pes equinus, equinovalgus or cavus, an claw toes are common Ankle clonus is easily elicited and the plantar response extensor. Later there is paraplegia-in-extension. This is followed by a position flexion at all joints of the legs and severe contractures The arms become spasti Dementia ensues.

Huntington's Chorea. Huntington's chorea is a chronic progressive chore associated with mental deterioration and inherited by both sexes as a dominan characteristic. There are sporadic instances of the disease which are clinically th same as the hereditary ones

This disease has been traced through many generations to its American origi in three brothers Both sexes are affected and either may transmit the disease

The symptoms, consisting of choreic movements, appear between the ages o 30 and 45 years, but a few patients have exhibited symptoms in childhood

On examination, in the beginning of the disease, the choreic movements ar abnormal only in their amplitude For instance, the normal movements of the face arms and hands appear at first as exaggerated gestures As the disease progresses the movements become rapid and violent and their amplitude is great In-co-ordination develops slowly until the patient is reduced to helplessness by it. Eventually the patient must be restrained to prevent injury, for the violent movements result in constant trauma Bulbar disorders such as loss of speech and inability to swallow ensue The mental disturbances include irritability, emotional instability and dementia

The diagnosis depends on the presence of chronic progressive chorea with dementia and often on the family history of similar sicknesses

The course of the disease is progressive and death results as a rule in from 10 to 15 years after the onset.

Developmental Disorders of Speech. The developmental disorders of speech are closely associated with the aphasias in adult life Orton attributed the following conditions to disturbances resulting from the failure to develop proper cerebral dominance which may be manifested by an uncertainty in the selection of a dominant hand; word deafness, word blindness, motor aphasia, agraphia, and

stuttering and stammering. These syndromes are found in pure or mixed form in all grades of severity.

Speech defects in the presence of normal hearing, intelligence, and the inability to understand speech when the speaker's lips are concealed, are idioglossia. Word deafness and idioglossia, without deafness, constitute an inability to understand spoken speech. Idioglossia affects boys more often than girls and occurs in all degrees of severity. The child develops a language of its own. The vowels are well formed and sometimes substituted for consonants, for only a few consonants are employed. The words are delivered very rapidly so that the effect is meaningless jabber even if sentences are properly formed. The prognosis is uncertain

Word blindness and mirror writing often affect several members of the same family, and members of several generations The child cannot learn to read and write, for it cannot distinguish between letters, such as *b* and *d*, *p* and *q* and *n* and *u*, and tends to read *saw* for *was*, *ton* for *not* and *form* for *from*. Spelling is grossly defective, especially spelling of written words

In writing with the right hand, *rat* becomes *tar* This writing from right to left is called mirror writing. When the left hand is used for writing, mirror writing is often performed consistently In these children there is a failure in development of proper ocular movements from left to right There is slow improvement

Stuttering. Stuttering may be defined as a disturbance in the rhythm of speech characterized by intermittent or irregular spasmodic blockage or repetition of sounds and words Stuttering, as it unfolds itself from its early onset, is an example of a disorder wherein the emotional factors gradually play a greater and greater part and, finally, assume a dominant role Boys are affected more frequently than girls

The cause for stuttering or stammering is unknown There are four theories of the origin of stuttering which are worthy of mention (1) A psychosomatic theory regards stuttering as due to a combination of organic and psychologic factors occurring at approximately the same time, the primary basic factor being a delay in myelinization of the cortical speech areas There is no anatomic proof for this theory. (2) Stuttering is an organic disorder of the language function According to this theory stuttering is considered mainly the result of a conflict between the two cerebral hemispheres caused by a lack of development of a dominant gradient, the disorder is related to left-handedness, in that normally left-handed children (see Handedness, p 221) who are forced to use the right hand may acquire a stutter because of a lack of development of a dominant hemisphere (3) Stuttering is a functional disorder, a psychoneurosis (4) Stuttering is a habit or a behavior that is learned (a "diagnosogenic" and a "semantogenic" disorder) According to this theory stuttering is due to a faulty diagnosis in a semantic environment This theory contrasts sharply with that of psychoneurotic origin. The psychoneurotic theory places the emphasis on the child whereas the diagnosogenic theory places the etiologic emphasis on the parents

The last three theories, like the first, are not supported by objective data.

At the onset the child of about 3 or 4 years may begin to repeat words or sounds There may be only an occasional slight hesitation in speech, and while speaking the child may stop suddenly as if groping for a word. In many cases a period of observation may be required before it can be decided definitely that the child stutters The normal or physiologic period of hesitancy or repetition of words is relatively longer in the child who is a stutterer than in a child who does not stutter Nonstutterers repeat words and phrases The stutterers' speech has a much greater proportion of syllabic repetition, owing to the spasmodic contractions of the muscles concerned with speech The spasm may be tonic, the parts involved remaining tense or showing only a slight quiver until the sound is forced through. In other cases the spasm is clonic, producing explosive repetition of the same sounds

As the stuttering becomes more definite, the parents become concerned, and

; told, "Speak clearly" or "Talk slowly. Think before you speak." The becomes conscious of his speech difficulty, and there is anxiety with nsions and spasmodic movements in other parts of the body such as of the eyes, jerking movements of the head, contortions of the face, of fists and stamping of feet may appear singly or in various combinang these spasms the stutterer frequently tries to speak on inspiration, t resulting in short inspiratory gasping movements until, apparently he forces out the word on expiration. Between the ages of 6 and 12 culties in personality adjustment may gradually develop. The child ensitive to ridicule and may resent correction The resultant loss of and security in speech situations may gradually lower self-esteem.

adolescent or the young adult stutterer, if stuttering is severe, there is ech with resultant difficulties in personality and adjustment. There is a shyness, and usually a sense of inferiority develops. Basically, however, lity of a stutterer as a whole is just as varied as that of the nonstutterer. capacity to lead a normal life by adjusting to the difficulty Usually lears in early adult life

ler adult stutterer is matured physically and emotionally. By trial and tern of speech has developed which has a minimum of stuttering Under otional excitement stuttering may occur, and despite normal intelligence st expert care the disorder may persist throughout life

gnosis of stuttering can be made only when the child stutters when he are no tests by which one can tell which child who begins unduly to to repeat words or sentences will start stuttering and which child will al speech Those who have stuttered during childhood have a great repeat words, phrases and conversation after they have ceased to

roclonus Multiplex (*Friedreich's Myoclonus*). This disease, which may occurs in middle-aged men more frequently than in women There are cklike contractions of the muscles of very brief duration. In the beginctions are fascicular but later the entire muscle or muscles are affected patient may fall to the ground As a rule there is a symmetric involve- proximal muscles of the arms and shoulders, but eventually all the scles are involved The diaphragm may show myoclonus There is no r atrophy The movements are increased by emotional excitement and luring sleep An attempt to elicit the tendon reflexes may induce violent . The violent contractions distort all volitional activity

re no demonstrable changes in the nervous system.

yelitis Optica. This disease occurs in both children and adults As a poradic condition, but McAlpine has described familial cases

verse myelitis and optic neuritis may appear simultaneously or sepa- of vision may appear without any prodromes One or both eyes may The ophthalmologist describes the appearances of the optic disks as pilledema. After a few weeks these changes begin to recede and they use pallor. The loss of vision develops rapidly. The central scotoma, absolute scotoma, enlarges, and in most cases the peripheral fields istricted. Within a few days after the onset the affected eye may be course of optic neuritis of this type is relatively brief, averaging perhaps ks to 2 or 3 months.

elitis may precede the optic neuritis, may occur simultaneously, or may months or years The onset is usually acute and may be attended with process is a disseminated one, but the clinical manifestations usually ransverse lesion of the spinal cord In most instances there is complete with anesthesia and loss of control of the bladder and rectum within the

course of a few days. Paraplegia-in-extension, paraplegia-in-flexion and flaccid paraplegia with loss of tendon reflexes may all occur. The process may become arrested at any stage, and there may be much more improvement than expected. Even complete paralysis may admit of a return of function.

If both optic neuritis and myelitis be present, and if other causes such as the encephalomyelitis of measles and vaccinia can be ruled out, the diagnosis of neuromyelitis optica seems to be justified.

The patient survives the first attack of myelitis and indeed often makes a complete or nearly complete recovery. Even severe optic neuritis admits of substantial recovery of vision. The ultimate prognosis, despite remissions of symptoms, seems to be unfavorable.

Hereditary Tremors. Hereditary tremors are common. They commence early in life and, once established, do not progress until middle life is attained, when progress may be resumed.

The tremor often occurs in members of successive generations. Both men and women may have this condition, and either may transmit it. The tremor affects the hands In some instances the head, tongue and legs may participate. The tremor begins during puberty, is accentuated by emotional reactions and fatigue, and is absent on relaxation The station, gait, and articulation are unaffected

There is never any improvement in the condition once the tremor has developed. If these patients are taught to adapt and adjust themselves, they may suffer minimal handicap from the presence of the tremor (see p 46)

CEREBRAL BIRTH INJURIES

The causes of cerebral birth injury in full term infants are maternal malformed and contracted pelves, often due to rickets, rigid soft parts, precipitate or prolonged labor, abnormal presentations, high forceps deliveries, breech extractions and overlarge fetal heads First babies are most frequently injured Owing to softness of the cranium, cerebral birth injury is perhaps more frequent in the premature babies than in mature infants The congenitally malformed nervous system is more susceptible to birth injuries than normally formed ones

Ford has expressed the belief that cerebral birth injury is the most frequent cause of *congenital hemiplegia* If syphilis, neoplasm and abscess can be etiologically eliminated, the history of birth will decide whether there has been a birth injury or whether there is some prenatal process The presence of convulsions signifies the degree of seriousness of the brain injury.

The mental condition resulting from cerebral birth injury comprises a mild or moderate deficiency in intelligence with little change in personality Some children and adult hemiplegics are so coddled and spoiled that they make a very bad impression, an impression which elaborates their mental deficiency rather than minimizes it.

A common birth injury is tearing of the small tentorial vessels. The blood then collects in a film on the upper surface of the cerebellum or on the upper tentorial surface Likewise injury to the cerebral sinuses and veins may be sustained

The monoplegias are often of crural and brachial distributions The crural monoplegias are more frequent than are brachial ones. In all of these the contralateral limb is often slightly involved Double hemiplegias resemble the congenital diplegias Athetoid movements of mild degree may be associated with either bilateral or unilateral paralysis.

Hemiplegia is the usual type of paralysis due to birth injury. There is underdevelopment of the affected arm, hand, leg and foot When there is considerable spasticity present, the affected hand is deformed to an extreme degree. Much less obvious is the deformity of a foot

Convulsive seizures occur in many of those who have a birth injury The convulsions may be confined to the affected members or may begin on the affected side

and become generalized. The focal attacks may be *jacksonian in type* l spread to involve the other cerebral hemisphere, in which case there is a consciousness. A severe focal convulsion is followed by increased weaknes affected limb which should clear up in a few days If the limb remains we *the presence of a brain tumor is suspected.*

The diagnosis depends chiefly on the history of birth. The chance of ir ment of manifestations, once expressed, is not good. The development of (makes the prognosis less favorable than it would be otherwise, since deter may be associated However, many of these deformed individuals reach (

BACTERIAL AND VIRAL INFECTIONS OF THE NERVOUS SYST

BACTERIAL INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

Neisseria meningitidis (Meningococcus) and Epidemic Meningitis anc brospinal Fever. The *Neisseria meningitidis* is a gram-negative coccus, nc and nonspore-forming The meningococci are classified by bacteriologists in groups The organisms of these groups cause most cases of meningitis It appe: different epidemics may be caused by different types (I, II, III and IV) of mening but mainly by type I

A number of intermediate heterogeneous types of meningococci which are to each other and to the fixed types have been described The virulence of a pa type of meningococci cannot be determined, for these organisms do not dissoci: smooth (S) pathogenic forms and rough (R) nonpathogens

In about 7 of every 10 cases of acute meningitis the meningococcus etiologic agent Two patients in every 10 will have a pneumococcic mening the remaining cases the disease will be due to some other sort of germ or t infection.

Meningitis occurs most commonly in temperate climates during Nov December and January The infection is air borne Sporadic cases of meningo meningitis occur usually among children Negroes seem more susceptible those of other races Individual susceptibility is not predictable; often the and the robust are affected The disease is one that is easily spread when p are crowded close together in sleeping quarters For instance, epidemics are created in army barracks

Meningococcic meningitis seems to be transferred mainly by carriers, for (an epidemic there are many more carriers than there are persons who ha active disease The meningococcus is present in the nose and throat of many h persons The organisms may remain for a long time in the respiratory secreti those who have had the disease. There are three groups of carriers. (1) ch (2) intermittent and (3) transient

The meningococcus invades the body by first establishing a focus or loc infection in the respiratory passages A focus thus established may produce se *disease in the skin, joints, heart, eyes and ears* However, there is a tendenc the germs to be blood borne and to localize in the meninges of the central ne system

Meningococcic Septicemia. The cutaneous lesions of meningococcemi easily observed and accessible for examination (*Daniels*)

The cutaneous lesions of meningococcemia are the result of vascular in which consists of endothelial damage and inflammation of the vessels, often minating in thrombosis and necrosis The meningococci occur in these lesions when they are demonstrated, the specificity of the lesion is thus proved

The symptoms of a meningococcic septicemia are first those of disease of upper part of the respiratory tract After a period of from one to many days manifestations become more acute. There is a sudden chill with gradual or r

rise in temperature. Malaise, extreme weakness, aching of muscles, moderate headache, nausea, vomiting, pains in the joints or actual acute inflammation of joints develops

The cutaneous lesions of meningococcemia appear within 12 to 36 hours after the onset of the disease if they occur at all These lesions are macules, papules, nodules, vesicles, and petechial and purpuric lesions, they are situated over the lower extremities and the trunk. Papules often do not fade on pressure

Examination and observation will reveal that the temperature varies from normal to 105 F (about 40 5 C). The rash may be obvious or it may be so sparse that careful and frequently repeated search is necessary to find it.

A wide variety of forms of rash occurs. The commonest cutaneous lesion is petechial or purpuric eruption, the individual lesions vary from 1 to 15 mm. in diameter. In addition to this type of rash there are ill-defined, faintly pink macules similar to the rose spots of typhoid fever These may be evanescent, and occasionally a few of them may constitute the only cutaneous manifestation.

Maculopapular lesions are often present, and in a few there may be central petechiae. The larger ones are nodular or plaquelike and often tender. When on the extremities these resemble the smaller lesions of erythema nodosum. Petechiae occasionally are present in the conjunctivae and the oral mucous membranes. The macular lesions may recede with fall in temperature, only to reappear as the temperature again rises The rapidity with which the rash may appear makes it necessary to examine the patient at frequent intervals, for the rash may advance from a few indefinite spots to a widespread eruption in a few hours Large ecchymotic lesions may become vesicular and finally ulcerate

Herpes simplex is common, usually occurring about the second day of the illness Herpes zoster involving the ophthalmic and maxillary branches of the fifth cranial nerve has been recorded

It is desirable to diagnose meningococcic septicemia before meningitis develops, for a meningitis may be prevented by appropriate chemotherapy or antibiotic therapy.

The diagnostic value of smears from the purpuric lesions of the skin in meningococcic disease is illustrated by the work of Tompkins, who found positive cutaneous smears in 39 of 48 cases Positive smears may be obtained when blood cultures are negative

Meningococcic Meningitis (Epidemic Meningitis, Cerebrospinal Fever, Spotted Fever) The prodromal period and the meningococcic septicemia have been described.

SYMPTOMS After the prodromal period the onset of the disease is usually acute There are different symptomatic types of the disease· (1) fulminating, (2) the acute common type, (3) subacute or chronic and (4) the abortive

The fulminating type of the disease frequently occurs at the beginning of severe epidemics The symptoms commence with an intense headache, chills and high fever. In some instances the victim falls suddenly without warning as if stricken with apoplexy There is prostration with pallor and cyanosis and coma In those in whom the infection is overwhelming, the temperature may be normal or subnormal. There are petechiae and large purpuric spots in the skin (see Meningococcic Septicemia, p 1140)

The common signs of meningeal irritation are often absent. Hemiplegia and other evidences of focal cerebral lesions may develop as a result of purpuric lesions in the brain An extremely fulminating type of this disease termed the *Waterhouse-Friderichsen syndrome* is associated with hemorrhages into the adrenal glands and diffuse widespread hemorrhages into the skin The pulse is irregular, rapid and

feeble. Respiration is rapid and irregular. The spinal fluid is clear at first but soon there is an excess of leukocytes. The *meningococci are recovered in cultures and* often are found in smears. The entire course averages between 1 and 2 days.

The *acute common type* of meningococcic meningitis is symptomatically characterized by malaise, catarrhal rhinitis, sore throat and cough lasting for a few days to 2 weeks The temperature then rises to 104 F (40 C) within a few hours One or more chills and headache occur. Hyperesthesia, rigidity of the spinal column and often opisthotonos develop. There may be delirium and stupor. The pulse is rapid (120 to 150) and may be irregular. Respiration may be either rapid or slow. Petechiae are common but purpura is unusual

On examination the findings are the same as in the fulminating type of the disease but less severe.

In the most favorable *instances the disease runs a course of from 1 to 2 weeks.* With or without treatment, in a few cases toward the end of the first week the temperature begins to fall, the mental condition improves and the spinal fluid clears Usually the temperature falls by lysis but in some cases termination by crisis has been observed Cervical rigidity usually diminishes as the other symptoms do, but occasionally may persist after the spinal fluid and the temperature become normal.

In the unfavorable instances death is preceded by deepening coma, relaxation of the musculature and hyperpyrexia. Throughout the course meningococci are found in the spinal fluid.

Meningococcic meningitis does not often persist more than 2 weeks When of longer duration, the disease becomes *subacute or chronic.* In such instances the *temperature slowly diminishes until fever is irregular and the meningeal irritation* continues. The patient may recover, but more frequently hydrocephalus ensues which often is fatal In some cases the course of the illness is characterized by remissions and exacerbations.

The chronic type of meningococcic meningitis is observed after epidemics The onset commences with vague symptoms such as fever, anorexia and vomiting The general symptoms are those of an infection The symptoms attributable to the nervous system are those due to an increased intracranial pressure.

Vomiting, headache and deterioration of cerebral function and vision result from intracranial hypertension. Diarrhea and incontinence are frequent and severe in those seriously ill from meningitis

The *abortive type* of meningococcic meningitis is manifested by malaise, headache and perhaps pain in the back There may be fever and a mild chill. Meningococci are found in the nasopharynx but the symptoms disappear within a few hours and no signs of meningeal irritation ever develop

Worster-Drought and Kennedy distinguish between those cases in which the symptoms disappear spontaneously, the true abortive type, and those in which the favorable course is the result of prompt treatment

Examination The nervous system may be destitute of positive findings In some, very soon after the onset, *there is pain in the back and legs. In children,* convulsions may be observed. Very soon the muscles of the neck and back become painful and stiff, with cervical retraction or even opisthotonos There are photophobia, hyperacusis, delirium, followed in severe disease by stupor or coma. Strabismus is frequent. Nystagmus, ptosis, irregularity of the pupils, and facial spasm may be present. Impairment of sight or hearing may be found There are often general cutaneous hyperesthesia, and tenderness along the spinal column, with tremor, and occasional tonic or clonic spasms of the extremities The joints may be red and swollen. Kernig's sign is usually present The spleen may be palpable.

Breathing is rapid, shallow and irregular Pallor and cyanosis may be present from the onset The pulse is rapid and often irregular except in those in whom

increased intracranial pressure causes bradycardia Blood pressure is low. The temperature varies, but may be subnormal until death ensues as the result of a fulminating infection. In all there is fever at some period during the active stage of the disease. The temperature ranges between 100 F (37.8 C) and 105 F (about 40.5 C).

The cutaneous manifestations, as described under meningococcic septicemia, are erythema, labial herpes, petechial hemorrhages and large purpuric lesions

The blood shows a constant leukocytosis, the count averaging between 15,000 and 30,000 per cubic millimeter The polymorphonuclear leukocytes average between 80 and 85 per cent of the white count but may be greater In rare cases leukopenia may prevail. Often results of blood culture are positive on the first day of the illness.

The spinal fluid may be normal on the first day In some there is only a slight increase of cells. In almost all, however, there is a great increase in the cell count which ranges from a few hundred to many thousands. The fluid may be opalescent, cloudy, turgid or purulent, depending on the number of cells it contains Polymorphonuclear leukocytes usually predominate but the lymphocytes also are increased. In those in whom convalescence is slow the lymphocytes become relatively more numerous. The spinal fluid is under increased pressure which may not be evident due to an increased viscosity The globulin is increased The total protein concentrations may reach 500 mg per ml. The fibrin is often increased and a film may form on standing Sugar and chlorides are diminished. Sometimes a spontaneous coagulation of the spinal fluid may have resulted from its increased protein content and obstruction of the spinal canal The meningococci often are difficult to demonstrate in smears of the spinal fluid

Diagnosis The diagnosis of meningococcic meningitis depends on the demonstration of the organism in spinal fluid or in a cutaneous lesion or the joint effusion, or in the blood provided the essential manifestations are present in association with the foregoing findings

The prognosis depends on the virulence of the invading organisms, host resistance and the promptness with which treatment is instituted The presence of hydrocephalus with thick or coagulated spinal fluid (Froin's syndrome) renders the chances for recovery very bad Under unfavorable conditions half of those who have the disease may succumb

Pneumococcic Meningitis. A pneumococcic meningitis may be suspected by the development of signs of meningitis during the course of pneumonia, but is established only by the demonstration of the organisms in the spinal fluid where they are usually abundant The fluid may be clear for a time when the meningitis is circumscribed Signs of meningeal irritation without any change in the spinal fluid may occur at the onset of pneumonia as in any other severe acute infection These are attributed to intoxication rather than to bacterial invasion of the meninges, and the term meningism is often employed to designate this syndrome

The examination of the spinal fluid reveals the presence of pneumococci. This is the only certain diagnostic criterion

The mortality rate was extremely high until the introduction of the sulfonamide series of drugs in therapy.

Meningitis Due to Staphylococci and Streptococci. The pathogenic staphylococci and streptococci cause severe meningitis *Staphylococcus aureus* (*Micrococcus pyogenes* var *aureus*) and *Streptococcus hemolyticus* are the commonest

The diagnosis depends on the presence of the symptoms and findings of meningitis and the identification of the organism in the spinal fluid.

Prognosis has improved since modern antibiotics have been used in therapy of these diseases In the past a few patients survived but this was exceptional The

number of colonies of staphylococci and streptococci grown on culture of the spinal fluid is of some prognostic importance.

"Influenzal" Meningitis. The causative organism, termed Pfeiffer's bacillus or *Bacillus influenzae (Hemophilus influenzae)*, may cause severe meningitis.

The diagnosis depends on the study of the spinal fluid The high cell count establishes the presence of meningitis and the recovery of the organism reveals the nature of the infection

Otitic Meningitis. *Otitic meningitis is due to the entrance into the space within* the subarachnoid by such bacteria as the streptococcus, the pneumococcus or the staphylococcus The infection originates from foci about the middle ear or mastoid cells. The extension of the purulent labyrinthitis occurs through the internal auditory meatus or by necrosis of the bony capsule, by rupture of a petrous apical abscess, by the spread of infection from the lateral sinus thrombosis, by rupture of a brain abscess into the ventricle or the subarachnoid space, or by the accidental opening of the dura during an operative procedure about the mastoid petrosa.

The symptoms and signs of otitic meningitis begin with generalized headache of increasing intensity, a chill and sustained high fever, vomiting, drowsiness, irritability, hyperesthesia of the skin and muscles, changes in mentality, stupor and convulsions

There are stiffness of the neck, a positive reaction to Kernig's turning test, irregular nystagmus, muscle twitching, hyperemia, papilledema of the optic nerve head and paralysis of the cranial nerves, especially the abducens. Later there are widespread flaccid paralysis, incontinence, fast pulse, dilated pupils without reflexes, deep coma and death (see p 99)

The diagnosis is established by examination of the spinal fluid In the purulent form of the disease the fluid contains increased leukocytes, an increased amount of globulin, decreased or absent sugar and decreased chloride

Otitic hydrocephalus is characterized by papilledema, lateral paralysis of the abducens, and the fact that the normal spinal fluid is under extremely high pressure, there are few other symptoms. In this condition recovery usually follows repeated spinal drainage In otitic meningitis the prognosis depends on effective use of chemotherapy

Otitic, suppurative and serous forms of meningitis may resemble tuberculous, meningococcic, influenzal and syphilitic forms of the disease. The differential diagnosis is made from the clinical history, serologic reactions and the results of smears and cultures of the spinal fluid.

Nonsuppurative Encephalitis of Otitic Origin. There is a condition of inflammation or encephalitis which may not be too serious when infection enters the brain from an adjacent focus in the skull It usually occurs in the temporal lobe from mastoiditis or its complications. In this form of encephalitis, which is subacute and localized, there are focal signs of the lesion in the brain adjacent to the suppurative focus in the skull. These signs are changeable, varying with the amount of edema in the portion of the brain surrounding the focus The signs greatly resemble those produced by infection of a temporal sphenoidal lobe or by a cerebellar abscess.

Lateral Sinus Thrombosis. A lateral sinus thrombosis does not always produce symptoms. A nonobstructive and aseptic thrombus is without symptoms other than those of the middle ear disease. When symptoms are present, they are those of infection. There are *chills in the afternoon followed by fever up to 104 F (40 C)* or higher, accompanied by severe headache and vomiting Often the chill is of short duration and is followed by sweating and a rapid descent of the temperature to normal or almost to normal Soon metastatic abscesses in the bones, joints, and lungs or other internal organs appear and portend the seriousness of the illness

In some instances of lateral sinus thrombosis the thrombus descends the internal

jugular vein, producing tender swollen regions around its course in the neck, and may penetrate into the superior petrosal sinus and the cavernous sinus These secondary intracranial complications may terminate the patient's life.

Ophthalmoscopic examination may reveal papilledema if a brain abscess is present The papilledema may be greater on one side than the other, and at times may reach 5 or 6 diopters In the beginning the papilledema may be observed in a patient having at the time minimal clinical symptoms

Tuberculosis of the Nervous System. The following forms of tuberculosis of the nervous system are described (1) tuberculous meningitis, (2) tuberculoma of the brain and spinal cord, (3) tuberculous spondylitis with involvement of the spinal cord, (4) tuberculosis of the bones of the cranium and (5) neuritis associated with tuberculous infection

Here only *tuberculous meningitis* and *tuberculomas* (see Abscess of the Brain, p. 1146) are considered Tuberculous spondylitis and tuberculosis of the bones of the head have been described with diseases of the bones Neuritis associated with tuberculous infections is the sort described under interstitial neuritis

Tuberculous Meningitis. Tuberculous meningitis is almost always due to the human type of organism The disease is most frequent during the second year of life although it may develop at any age It usually occurs during the winter or early spring and frequently follows measles, pertussis or other acute infectious disease.

Tuberculous meningitis may be a part of a generalized meningo-encephalitis or of a generalized meningitis associated with solitary tubercle A localized meningitis, subacute or chronic, may be present occasionally

In the beginning there are lack of energy, anorexia and loss of body weight, headache and vomiting The temperature may reach 101 F (38 3 C) and the pulse is rapid Episodes of irritability and excitability may alternate with apathy, drowsiness and stupor. In some instances the stupor clears and symptomatic improvement follows and lasts for a week or two, at the end of this period the patient sinks into a deep stupor and finally into coma The fever returns and the temperature rises to 105 or 106 F (40 5 or 41 C), the pulse is slow and irregular and the respiration is periodic.

Sixth nerve palsies, localized muscular twitchings and various automatic movements as well as focal and general convulsive seizures are often observed Often early, and always in the late stages, congestion of the retinal veins develops and there is papilledema which may reach a height of several diopters.

There are irregularity and slowing of the pulse. The heart action becomes progressively weaker and with this the pulse rate increases In the early stages of the disease there are narrowing of the pupils and photophobia As the intracranial pressure increases, the pupils dilate and become irregular and there may be conjugate deviation There may be involvement of the third nerve on one side and paralysis of the face, limbs and hypoglossal nerve on the opposite side (Weber's syndrome) Tubercles in the choroid are common.

Tremors, athetoid movements, paralysis and hemiplegia may be present. Facial monoplegias are common, other monoplegias may be present Kernig's sign and plantar extension are sometimes present

The cerebrospinal fluid is but slightly changed in the early stages of the disease. The pressure becomes increased and the fluid is clear or at most slightly opalescent The cell count, chiefly lymphocytic, is relatively low at first but slowly rises to 100 or 200 or more per cubic millimeter. The globulin and total protein are greatly increased Sugar estimations may give results within normal limits at the onset but the values decrease When the fluid is permitted to stand a while, a delicate fibrin film usually forms and this contains tubercle bacilli Inoculation of a guinea pig usually will give positive evidence of the presence of tubercle bacilli.

There is no leukocytosis in the early stages of the infection, but toward the end

the leukocytes may number 30,000 per cubic millimeter of blood Reaction intracutaneous tuberculin test is almost always strongly positive at the onse during the early stages of the illness, but toward the end it may become neg

The diagnosis is based on the presence of the clinical findings as describe the presence of tubercle bacilli in the cerebrospinal fluid. Reaction to the tube skin test, the physical signs of tuberculous disease in the thorax, bones or l nodes, and the history of exposure to infections are diagnostically helpful

When the diagnosis is fully proved, a fatal outcome is expected The diag is fully proved by cultures or obtaining the organisms by guinea pig inocu from the spinal fluid

Subdural Abscess of the Cranium. Subdural abscess of the cranium r from otitis and mastoiditis or from nasal sinusitis. The onset of symptoms is us preceded by evidences of otitis or of nasal sinus infection. There are heada fever, stiff neck, drowsiness, stupor, focal convulsions on the contralateral side aphasia followed by hemiplegia This disease usually runs a rapid course to e death of the patient

A correct diagnosis cannot be made until the skull is trephined and the t studied histologically and tubercle bacilli demonstrated.

Abscess of the Brain. The common causes of acute bacterial meningitis w arise in association with middle ear and mastoid infections are discussed in cor tion with diseases of the middle ear (Chapter 4) It is obvious that some of t infections may reach the brain and originate an abscess therein

Here we shall discuss mainly those brain abscesses which arise *in associa* with chronic otitis media, infection of the nasal sinuses, subacute bacterer septicemias, and abscess which may follow a relatively mild infectious diseas one associated with a staphylococcic infection and osteomyelitis. The streptoc pneumococci, *Escherichia coli* and anaerobic organisms may cause brain absce Staphylococci, streptococci and *Escherichia coli* may be the casuative organism brain abscesses after trauma to the skull

In these less acute abscesses the infection reaches the brain through the bl stream If the symptoms of a blood infection are slight, it is difficult to contemp the nature of the expanding brain lesion

If there should be a history of syphilis and if there is a positive serologic r tion in the blood or cerebrospinal fluid, a *gumma* may be suspected, and the pat should be given the benefit of energetic antisyphilitic treatment for a time If th is a highly malignant glioma present, nothing will be lost by postponement surgical intervention Gummas may resist treatment, and it may be necessary remove a cerebral syphiloma by operation

Tuberculous disease of the basal cranial bones may extend to the meninges brain within, largely by setting up thrombophlebitis in one or other of the g venous sinuses. Thus the cavernous sinus may become thrombosed in *tubercul* of the anterior fossa, while the lateral sinus may become implicated *in disease* the middle or posterior fossa

Tuberculomas of the nervous system are the result of blood-stream invasion the tubercle bacilli. The invasion of the brain by this method is relatively *rare*, si tubercles which simulate neoplasm of the brain comprise a very small percent of all intracranial tumors

In tuberculoma the temperature is often subnormal and irregular, with oc sional rises to 100 F (37.8 C) The blood shows a polymorphonuclear *leukocyto* Finally the abscess bursts, producing a fulminating purulent ventriculitis or me ingitis; the pulse and temperature increase and the patient dies, and then the corr diagnosis is made Or the abscess may evacuate itself spontaneously, usually inco pletely, into the middle ear or accessory air sinus from which the infecti

originated. If there has been an opportunity for parasitic infection, such infection may localize in the brain and cause an expanding lesion, a parasitic cyst.

Tuberculoma is often manifested by signs of focal cortical irritation such as jacksonian fits, but not by paralysis or other physical signs. Increased intracranial pressure develops late and the disease runs a very slow course, sometimes lasting for several years.

The diagnosis of many tuberculomas is made at the time of operation for suspected neoplasm of the brain The presence of signs of multiple lesions or of lesions in the cerebellum or brain stem favors the diagnosis of tuberculomas if Recklinghausen's disease is not present In almost all instances in which the diagnosis is established, death ensues.

Parasitic cysts of the brain comprise two chief varieties, (1) hydatid cyst and (2) *Cysticercus cellulosae*

The hydatid cyst represents the cystic stage in the life history following the ingestion of the ova of *Taenia echinococcus* (see p 939)

Hydatid disease may be suspected as the cause of an expanding tumor of the brain in natives of Iceland, Greece, and Australia The hydatid cyst may be single or multiple. When solitary, it may attain a large size

The complement fixation test on the blood serum with a suitable antigen, the cutaneous reaction to an intradermic inoculation of sterile hydatid fluid, and the presence of eosinophilia of the blood and the cerebrospinal fluid are helpful diagnostically when these cysts of the brain are suspected

Infection with *Cysticercus cellulosae* follows the ingestion of the ova of *Taenia solium*. Multiple cysticercal worms develop and become encysted in the muscles and subcutaneous tissues and in the brain and its meninges or in the vitreous humor of the eye. When in the course of time these cysts undergo calcification, they become visible roentgenographically. In the muscles and brain the roentgenographic shadows are pathognomonic

The symptoms of cerebral cysticercosis depend on the situation of the encysted parasite A convulsive disorder is the common manifestation Eosinophilia of the blood and the cerebrospinal fluid sometimes will be helpful in the initiation of a proper investigation

A brain abscess forms in much the same way as an abscess elsewhere There is first the diffuse localized stage of engorgement, or localized acute encephalitis, in which there appear regions of softening and liquefaction These regions enlarge, coalesce, lose their red color and form pus The surrounding brain tissue reacts by forming about the abscess a definite limiting wall which is composed of a dense fibrous tissue surrounded by a zone of gliosis

SYMPTOMS. If the abscess is originated by a virulent infection, as has been described in diseases of the ear, it may extend rapidly, the fever remains high, the leukocytosis continues and headache, vomiting, drowsiness and finally stupor ensue Death may occur within 2 or 3 weeks

In less virulent infections the course is different Fever, leukocytosis and other signs of infection disappear The temperature often is subnormal If the abscess does not occlude the ventricular system or give rise to focal signs, the patient may appear well The process may stop, but usually increasing pressure within the abscess causes rupture of the inflammatory tissue which confines the abscess, with extension of the infection to the surrounding tissues This is made evident by a recurrence of the fever and by focal signs A meningeal reaction may occur and subside, or a purulent meningitis may ensue. The infection may again become walled off by an inflammatory reaction, and the signs of infection may again disappear Such remissions and exacerbations of symptoms are frequent Eventually death occurs from increased intracranial pressure, extension of the infection into the ventricles or the meninges or throughout the brain. Symptoms from an abscess

which follows a compound fracture of the skull may not occur for months, or years, after the head injury The patient appears healthy; this may be the c in injuries of the brain received in various accidents.

Frontal abscess commonly arises as a result of direct infection from the fro ethmoidal, or sphenoidal air sinuses The significant findings are mental dull deficient control of sphincters, loss of the abdominal reflex on the side opposi the abscess, and the presence of an extensor plantar reflex on this same side. triculograms are often useful in demonstrating deformity or displacement of adjacent lateral ventricle

A *temporal abscess* is easier to recognize when situated superficially in the temporal lobe in right-handed persons, for in right-handed persons lesions of left temporal cortex produce impairment of the auditory memories of spoken wo Hence in a left-sided temporal abscess the patient tends to have dysphasia makes mistakes in naming objects Large frontal abscesses situated in either may press inward toward the corona radiata and cause a facial or faciobrac monoplegia As the result of pressure backward toward the angular gyrus, h anopsia may ensue. Even when the abscess is far forward, it may press on fibers of the optic radiation, causing a visual field defect. Visual defects of this are difficult to verify, owing to the patient's mental dullness Extension downw toward the floor of the skull and the ocular nerves may cause dilatation of pupil, ptosis and impairment of external ocular movements on the side of the absc

A *cerebellar abscess* causes vertigo, hemiataxia and hypotonia of the limbs the side of the abscess, with spontaneous mispointing on Bárány's pointing t conjugate deviation of the eyes to the side away from the abscess, and nystagn A cerebellar abscess may induce acute ventricular hypertension with a rapid incre in pressure causing sudden respiratory paralysis and death unless the abscess be localized and promptly evacuated

Multiple abscesses originate from metastatic blood-borne infections and may situated anywhere in the brain, but are common in the parietal and occipital lo

In *multiple cerebral abscesses* the focal signs depend on their situations. C monly one abscess produces the symptoms, while evidences of the other coexist ones are absent Mental confusion and headache are the common symptoms. M tiple abscesses may cause several widely scattered focal lesions which indic multiple lesions.

Chronic *localized serous arachnoiditis* or *meningitis serosa circumscripta* chronic arachnoiditis) is generally a sequela of chronic otitis media and usuall is situated in one or other pontocerebellar recess This process is often the ca of the condition known as *pseudotumor cerebelli* It consists in a local accumulat of cerebrospinal fluid in a thickened and obstructed lateral cistern, causing obstructive hydrocephalus which often produces intracranial hypertension There usually a permanent unilateral impairment of hearing The impaired hearing a intracranial hypertension are characteristic too of an acoustic neuroma from wh differentiation is made only by an exploratory operation

Pseudotumor cerebri is a term applied to the condition in which the clini signs of brain tumor appear, followed by complete recovery, or in which ventricul grams or necropsy do not reveal a lesion which can account for the symptoms

There are instances of pseudotumor cerebri in which the symptoms arise fro an acute otitic hydrocephalus or serous meningitis of the ventricles which is reliev by puncture of the ventricle.

EXAMINATION. Abscesses of the frontal lobes may give minimal signs of loca zation. When the abscess is on the left, aphasia is common There is a loss mental alertness which may be accompanied by stupid jocularity and motor apath

When the temporal lobe is the site of abscess, homonymous defects in t ... Focal paresis is sometimes present. Alterations

the tendon reflexes with the plantar extensor are often present on the side opposite to the abscess.

Abscess in the cerebellum produces in-co-ordinate equilibratory muscular activity. There may be muscular hypertonus and cerebellar fits; more often, there is a disturbance of postural fixation with atonia of muscles. Nystagmus is horizontal and is most evident when the eyes are deviated toward the side of the lesion Suboccipital tenderness and headache are common symptoms of cerebellar abscesses.

The spinal fluid reveals 20 to 100 cells, chiefly lymphocytes, per cubic millimeter. There are normal sugar and chloride content and elevation of the proteins to between 50 and 150 mg. If the abscess leaks from time to time, there is a preponderance of leukocytes. If the cell count is not high and bacteria cannot be cultivated and if the sugar and chlorides are not diminished, the condition is a meningeal reaction which will subside. Decrease of the concentration of the chlorides and sugar and rapid rise of the polymorphonuclear leukocyte count indicate an impending purulent meningitis.

DIAGNOSIS. The diagnosis of brain abscess usually can be safely made if there are symptoms of a general infection and evidences of an increased intracranial pressure There should be signs of a focal cerebral lesion, the history of some preceding infections such as otitis media or of trauma, and the presence in the spinal fluid of from 20 to 100 cells, chiefly lymphocytes, per cubic millimeter. The diagnosis may be difficult and may require a period of observation or ventriculograms and surgical exploration

THE VIRAL ENCEPHALITIDES

The term neurotropic agent implies the affinity of any disease agent, irrespective of its nature, for the nervous system

The terms encephalitis, encephalomyelitis, polioencephalitis, poliomyelitis and leuko-encephalitis when employed in a general way imply infections of regions or particular tissues of the nervous system. These terms, while not confined to viral infections, are commonly employed thus and some of them are employed almost entirely to designate viral infections, for instance, poliomyelitis usually refers to poliomyelitis of viral origin

A number of endemic and epidemic infectious diseases of the central nervous system are produced by neurotropic viruses, for instance (1) type A, Vienna type, von Economo's or European encephalitis, (2) type B, which includes Japanese B encephalitis, Saint Louis encephalitis, equine encephalitis, (a) western, (b) eastern, and (c) Venezuelan, and Australian X disease, (3) Russian tick-borne encephalitis, (4) poliomyelitis and (5) rabies Poliomyelitis was described in Chapter 6

Infections of the nervous system by filtrable viruses affect chiefly the gray matter of the neuraxis These infections have a selective tendency to certain structures, for instance, epidemic encephalitis injures the substantia nigra, rabies, the bulbar nuclei, and poliomyelitis, the anterior spinal gray matter All may occur in either sporadic or epidemic forms, and there is usually a definite seasonal incidence and a tendency to select individuals of the same age group Epidemic encephalitis is unique in that it is characterized by a chronic phase, known as Parkinson's syndrome, which follows the acute phase after a prolonged remission

Epidemic Encephalitis (Encephalitis Lethargica) This disease is known also as the Vienna type of encephalitis, von Economo's disease, type A encephalitis, epidemic encephalitis, and sleepy or sleeping sickness The disease is a meningoencephalomyelitis The consensus is that the disease is a viral infection, and the virus has been termed virus A.

The brain in the acute phase of the disease is diffusely congested and contains small hemorrhages which are more intense in the basal ganglia and brain stem than in parts of the brain There may be scattered areas of meningitis.

Epidemic encephalitis appears in the winter months It is not trans person to person, for it is unusual for more than one member of a hous affected. The incubation period is not established. No age is exempt, highest incidence of encephalitis is in the second and third decades. You and even infants may be affected. The disease may attain pandemic pro it did in 1918 However, sporadic instances of the disease are common.

On the basis of symptoms three stages of the disease are describe acute stage, after which all symptoms disappear or there is progression the chronic stage, (2) the stage of remission, which may last for years d the patient seems well, and (3) the chronic stage of the disease which is first recognizable manifestation of the disorder Rarely can the first stag nized, and then in retrospect when the third stage is evident The seco the disease is not manifested and therefore not recognizable

Acute Stage of Epidemic Encephalitis The acute form of the disease is as an acute infection of the upper part of the respiratory tract In retrospe may be obtained which implies that during the supposedly respiratory inf were pains of a radicular distribution, myoclonic twitchings, and diplopia however, some patients who have a severe acute onset of symptoms definite, and these definite types are designated as the somnolent-ophth type, the hyperkinetic type, early development of symptoms of the pa syndrome, and the fulminating type

In the somnolent-ophthalmoplegic type of encephalitis the patient li deep sleep The patient may be aroused easily and will then respond but immediately relapses into somnolence, which may deepen to stupor a coma When the patient is aroused, radicular pains, local hyperesthesias a gias may be complained of If fever is present, the temperature is not 103 F (39 4 C)

In the hyperkinetic type of encephalitis the disease is more severe t somnolent-ophthalmoplegic type The onset is abrupt, fever is high There ment, restlessness and insomnia, confusion or disorientation, anxiety, ap and hallucinations. There may be sharp severe pains and myoclonic twitch extremities

Involuntary choreiform movements may be observed which may be a oculomotor palsies The pupils are unequal, and myosis and loss of the ligh frequent The course is often brief, and if the patient survives, the overac for several weeks The mortality rate is high

In the acute parkinsonian syndrome type of encephalitis the patient conscious without expression, change of position or movement for ma When movements are made they are slow and weak, and there may be a tremor initiated by movement The temperature often is normal. These pa begin the manifestations of the chronic parkinsonian syndrome while acute the disease

In the fulminating types of the disease a bulbar palsy develops rapidly cause of death Fever may be absent; if fever is present and of intermittent temperature rarely rises above 103 F (39 4 C) Hyperpyrexia is presen who do not survive the illness

Bulbar palsy is identified by difficulty in swallowing, and weakness o palate and the tongue with occasional fibrillary twitching

A reversal of the hours of sleep may occur in acute encephalitis. I common in chronic encephalitis. Often most of the daylight hours are sleep, but as night approaches the patient becomes active and restless. A the reversal of sleep is a transient phenomenon.

jerks affect the abdominal musculature, the face, shoulders, arms, legs and muscles of respiration Hiccough is common.

Bilateral extra-ocular palsies are incomplete, complete or transient Ptosis of the lids is common, The pupils may be dilated and inactive to light and during accommodation Nystagmus is often present.

Facial palsies are usually incomplete and transient Trismus is mild Paralysis of the extremities, hemiparesis and monoplegias are sometimes present. The tendon reflexes are normal.

The urine may contain albumin and occasionally and transiently sugar The leukocytes range from 15,000 to 30,000 per cubic millimeter with a slight increase in the polymorphonuclear leukocytes. The spinal fluid is normal in the early stages except for a moderate increase in lymphocytes ranging from 20 to 100 and rarely exceeding 200 per cubic millimeter

Chronic Stage of Epidemic Encephalitis (Parkinson's Syndrome) A chronic stage of encephalitis is peculiar to the virus A type of infections Rarely is there a history of an illness which can be said to be the acute phase of the disease and which definitely dates the beginning of the illness. The symptoms of the chronic stage of epidemic encephalitis advance slowly and uniformly without fever or other signs of infection

The *pathologic changes* present in the gray matter of the mesencephalon and diencephalon are degenerative, inflammatory, infiltrative and perivascular

In this syndrome the outstanding *manifestations* are those of extrapyramidal neuron lesions (see Organization of the Motor System, Chapter 6).

The parkinsonian syndrome is characterized by an altered posture with flexion of the trunk and extremities, by hypertonicity of the muscles characterized by a cogwheel phenomenon on extension of the muscles and by slowness of all movements, by expressionless face, rhythmic tremor during rest, and absence of associated movements when walking Repetitive movements are frequent and may persist for years.

The head may be tilted and rotated as in spasmodic torticollis The spinal column may be twisted and curved and the hips and shoulders held in asymmetric postures.

The lack of expression is sometimes replaced by a rigid smile, the jaws are often widely opened, the tongue is protruded and the head retracted The rigidity may become so severe eventually that the patient is virtually paralyzed

There are slow movements of large amplitude which occur at regular intervals (bradykinesia).

Tremors may involve the lips, face, eyelids, jaws and other parts of the body but are commonest in the hands and head In many patients these spasms disappear when the patient relaxes Intention tremors are rare in encephalitis

An *oculogyric crisis* is characterized by a sudden fixed stare followed by the eyes being rolled upward or to one side and fixed in that position The eyes cannot be returned to a normal position during the attack although they may be moved about in the main fixed position The attack is accompanied by severe pain in the eyeballs. Grimaces and rotation of the head and distortion of the trunk may be performed during the attack. Hallucinations, catatonic or trancelike states or anxiety may transpire during the fit The duration of the crisis varies from minutes to hours.

There may be disturbances in respiration characterized by increase in the respiratory excursion until after a few minutes respiration becomes violent. The mouth is widely opened, and the patient is frightened. After minutes or a few hours the disturbance slowly subsides The excessive ventilation may lead to tetany and prolonged

turbed

holding

Ble

When the lids are closed tightly, they cannot be opened by the patient for several seconds, but once they are opened, either by a violent effort or by the fingers, the spasm disappears *Myotonus of the lids* may be present.

Excessive salivation is common Hyperhidrosis, localized edemas, cyanosis and various disturbances of vasomotor innervation occur

The psychic changes in adults are trivial In children the natural inhibitions and fear of consequence may be lacking. Such children may steal, lie, destroy property, commit various offenses, run away from home, and physically mutilate themselves

DIAGNOSIS OF EPIDEMIC ENCEPHALITIS In the acute stage, encephalitis, tuberculous meningitis, lead encephalopathy, encephalomyelitis following acute infectious diseases, poliomyelitis, brain abscess and benign lymphocytic meningitis may be difficult to differentiate The differential diagnosis of these diseases is discussed under poliomyelitis and elsewhere in this text

In the acute stage of encephalitis the spinal fluid is clear, under normal pressure, without coagula, and there may be from 10 to 200 lymphocytes present The protein may be slightly increased, glucose is present in normal concentrations and the fluid is sterile on culture It is evident that these findings are of no diagnostic value.

In the chronic stage of encephalitis diagnosis can be made with confidence if there is present a parkinsonian syndrome (in a patient less than 50 years of age) with oculogyric crises, sleep reversal, disturbances of respiration or typical personality changes In some cases the differentiation from a progressive cerebral degeneration or tumor of the hypothalamus may require prolonged observation in order to establish the diagnosis

The mortality rate during the acute stage cannot be estimated. The development of late symptoms is of very bad prognostic import

Saint Louis Encephalitis (Epidemic Encephalitis Type B, American Encephalitis) The disease caused by the virus of the B group is different from the European form of the disease caused by virus A. In the United States it has occurred in the region of Saint Louis, Missouri

Encephalitis type B includes both the Saint Louis and the Japanese forms of this disease Clinically these types of epidemic encephalitis do not vary despite the detectable differences in the causative viruses

Epidemics and sporadic cases of encephalitis type B begin in July or August and decline rapidly during September and October The manner in which the virus is transmitted from one to another or from whence it came or where it goes is unknown

In comparison with encephalitis type A the process in type B is more severe and more generalized However, in type B there is no tendency to destroy selectively the substantia nigra and the oculomotor nuclei which is characteristic of type A In type B, in addition to the brain involvement, inclusion bodies are often present in the kidneys

The incidence has been most frequent and most severe in elderly residents of suburban and rural districts The incubation period is unknown

For convenience of description the manifestations of this disease, the onset, and the progress have been divided into types and stages These are more artificial than real because there is much overlapping and variation in the types of symptoms and the course of virus B infections

SYMPTOMS In general, there are restlessness and delirium beginning one or two days after the onset of the fever The sensorium is clouded and stupor or coma may ensue

In general the progress of type B infections consists of the prodromal period, which lasts 2 or 3 days, and the period of stupor and delirium, which may be present from 2 to 7 days However, great variations in duration of the symptoms may be observed. There are some cases in which the disease may be characterized by severe chills and coma, and life may be terminated within 24 hours In contrast to these fulminating instances of the disease, a few patients may have fever and stupor for months and eventually may recover. Despite these variations in symptoms and dura-

tion, usually the course of the disease lasts about 3 weeks, and terminates in full recovery without residua.

EXAMINATION. The findings on physical examination are dependent on the severity of the disease and on the duration and the trend of the disease at the time of examination.

On examination there are present intense symptoms Marked meningeal irritation, manifested by cervical rigidity, hypertonicity or often rigid musculature, tremors and fibrillary twitchings are present Trismus and transient cerebral palsies such as hemiplegia, monoplegia or bilateral paralysis may be revealed At this stage of the disease death may ensue from hyperpyrexia, paralysis of respiration and pneumonia. However, in some who have hyperpyrexia the fever declines, to be followed by a clearing of the sensorium, and convalescence ensues

After recovery there are never present more than a mild speech disorder, slight reduction in vision, deafness, gait disorder or slight psychic changes. Usually after recovery the results of examination are negative

During the active phases of the disease the leukocytes range between 10,000 and 35,000 per cubic millimeter, the increase is chiefly in the polymorphonuclear leukocytes; the lymphocytes are decreased

The spinal fluid is usually clear and the pressure is increased There are between 30 and 250 mononuclear cells per cubic millimeter The protein is increased and the globulin reaction is positive

DIAGNOSIS. During an epidemic the diagnosis is easily established by examination of the patient and the spinal fluid In sporadic cases the diagnosis depends on an awareness of the significance of an illness which has acute onset with high fever, delirium and restlessness or stupor, the signs of severe meningeal irritation, muscular rigidity, involuntary movements, and the changes in the blood and spinal fluid

In the Saint Louis epidemic in 1933 the mortality rate was about 20 per cent.

Equine Encephalitis (Epizootic Equine Encephalitis) Equine encephalitis is caused by two similar viruses. The western form of the disease occurs in western United States, and the eastern occurs in the region of the Allegheny Mountains and east to the Atlantic seaboard

Western equine encephalitis is a disease principally of horses and mules. The virus closely resembles that of the Saint Louis encephalitis (virus B).

Eastern encephalitis is a summer disease of equine and avian animals The eastern virus is similar to the western one and to the Saint Louis B virus but with differences known to those who have studied it Despite these differences in the viral characteristics, the diseases caused, irrespective of the particular viral etiology, are essentially the same disease clinically

In equine encephalitis the human and horse infections occur within the same district There is reason to believe that the several varieties of mosquitoes which act as vectors obtain the disease from a reservoir of encephalitis which is present in birds The disease is not necessarily transferred from horse to man, but horse and man get the disease from the same source A large epidemic has occurred in Minnesota and the neighboring western states and to the north in Canada Epidemics of the eastern variety of the disease have occurred in Massachusetts In that epidemic those affected were children and a mortality rate of 65 per cent was recorded

There are prodromata consisting of drowsiness and headache which subside. Several days later headache, vomiting, drowsiness, muscular rigidity, positive Kernig's sign, absent reflexes, plantar extension and high fever ensue. The polymorphonuclear leukocyte count may rise to 50,000 per cubic millimeter The spinal fluid is under increased pressure and the cells vary in numbers from several hundred to 1,000 or more per cubic millimeter

The duration of the disease is short If the patient survives, the symptoms are gone in 10 to 15 days

The diagnosis of equine encephalitis may be suspected whenever acute enceph-

alitis in humans appears in a district in which an epidemic among horses

The mortality rate is high. Residua consist of mental deficiency, speec and hemiparesis

Australian X Disease. The virus of Australian X disease produces le symptoms identical with those of virus type B encephalitis The disease epidemics during the warm season, January to April, in Australia, New Sou Queensland and Victoria. Boys less than 5 years of age are more commonl than other persons though adults may have the disease.

Epidemic Hiccough. Hiccough is a common symptom of epidemic en (type A) Epidemic hiccough may be related to or may be an abortive encephalitis (type A).

Epidemics of hiccough occur in autumn or winter. These epidemics ma or follow epidemic encephalitis (type A). The disease often affects men c age or older It rarely occurs during childhood. It is mildly contagious.

The first symptoms commence with mild coryza, low fever and slow pul a day or two the hiccough begins. The hiccough may last only one day persist for a week Neither complications nor sequelae follow.

Herpes Simplex. Herpes simplex is a common viral disease. The virus mentioned in connection with diseases of the skin, of the mucous memb the genitalia and of the eyes. Here it is considered as a cause of diseas central nervous system.

Pathologic changes occur in the cortex and subcortical white matter. There flattening of the convolutions with petechial hemorrhages in the brain and loc *widespread regions of softening There is considerable loss of ganglion cells, w* replaced by large collections of fat-containing cells and a few leukocytes In th borhood of the necrotic regions there is an increase in glial cells, many of w well as some neurons, contain intranuclear inclusions The meninges are conges

The onset of symptoms is sudden with fever and sometimes chills. Symp *increased intracranial pressure quickly ensue There are evidence of m* irritation and stupor of varying degree

In fatal instances, death has occurred between the eighth and twelfth da onset

On examination there are transient pupillary changes, alterations in paralysis and paresis of muscle groups, and abnormalities of sensation ir taste and smell Convulsions may occur. The cerebrospinal fluid shows a nuclear pleocytosis up to 1,000 cells per cubic millimeter, an elevated protei normal amount of sugar The white blood count reveals leukocytosis with *preponderance of polymorphonuclear cells.*

Herpetic meningo-encephalitis cannot be distinguished clinically from an form of viral meningo-encephalitis It has been diagnosed with certainty isolation from the brain, spinal cord or cerebrospinal fluid of herpes simple

Acute Benign Lymphocytic Meningitis (Virus). Choriomeningitis is mon acute disease which is self-limited and terminates in complete recover

The causative virus of choriomeningitis seems to be endemic in house mice an ... has been recorded in a place of residence free of mice a cor een d

incriminated as important natural vectors of any disease

Acute benign lymphocytic meningitis occurs sporadically and in small ep and most frequently affects children

The illness commences acutely with headache, fever and vomiting, me *irritation, irritability*, insomnia and intense restlessness. As a rule nystagmus, and paraplegia of the cranial nerves do not occur. The temperature ranges 102 or 103 F (38.9 or 39.4 C) and ends by lysis in about a week.

The spinal fluid pressure is increased The fluid is clear. The cell count ranges from 100 to 1,500 per cubic millimeter or higher Early in the course the leukocytes are predominant but later mononuclear cells constitute most of the total count. The sugar and chloride contents are normal, thus aiding in the differential diagnosis It is said that the pleocytosis may persist to some degree for weeks after clinical recovery has occurred, but as a rule the cell count returns to normal during the second or third week.

The diagnosis is based on the predominance of mononuclear cells and the absence of any demonstrable organisms, on the brief course and favorable outcome of the disease and on the absence of otitis, mastoiditis, septic sore throat and other infections. Abortive poliomyelitis may give rise to an identical syndrome

Rabies (Hydrophobia, Lyssa, Rage) Rabies is usually transmitted by the bite of a rabid (mad) dog, skunk, or any other animal infected with rabies

Emulsions of brain tissue from a rabid animal will contain the contagion of rabies after it has passed through a Berkefeld filter Therefore the cause of rabies is placed in the group of filtrable viruses

There are degenerative changes without definite evidences of inflammation in the lenticular nuclei, the thalamus, cerebellum and parts of the spinal cord In cases in which the incubation period is short, but the latent period is prolonged, the process may be almost entirely degenerative The characteristic features of the disease are Negri bodies, which are rounded structures between 4 and 10 microns in diameter, which stain with acid dyes, and are found in the cytoplasm of the nerve cells of the hippocampus, cerebellum, spinal ganglia and cerebral cortex

In only a few of those bitten by a rabid animal will the disease not develop. Whether or not the patient succumbs to the infection depends on the severity as well as on the situation of the bite or bites The infection develops most frequently when there are multiple wounds near the head

The *incubation period* in general is from 3 to 8 or 10 weeks It is shorter when the bite is on or near the head and longer when it is on the leg or foot Multiple bites increase the dose of the virus and thus shorten the incubation period In rare instances the infection remains latent in the nervous system for a year or more before giving rise to active symptoms The name hydrophobia refers to the painful spasms of the pharynx and larynx, which are precipitated by effort to take fluids The rabid dog, tortured by fever and thirst, may be found dead beside a stream where he fell with convulsions on attempting to drink water

Symptoms. The first symptoms are pain and numbness in the region of the bite Soon there are drowsiness, headache and loss of appetite The drowsiness is supplanted by restlessness and irritability In some there is no fever, in others the temperature may reach 105 F (40 5 C) Irrespective of fever, the patient begins to be frightened by noises and bright lights, the stimuli for which are of central origin. These annoyances increase and are supplanted by terror The patient stares and foams at the mouth in much the same way as does the mad dog

Examination Local twitchings followed by convulsions are frequent. Periods of delirium may alternate with periods of lucidity Cervical rigidity is severe and [illegible]

vulsions After 1 to 3 days the paralytic stage sets in It is characterized by coma and may be followed by death within a few hours

The spinal fluid usually shows a few lymphocytes In cases in which the incubation period is brief and the symptoms are acute, there may be several hundred cells in the spinal fluid.

Diagnosis The history of a dog bite or bite by mink, skunk or other carnivora followed by an incubation period of 3 to 10 weeks, and by the characteristic terror,

excitement and hydrophobia is definitely diagnostic. The shorter durations of the incubation period occur when the bites are sustained on the face or hand. The diagnosis of hydrophobia or rabies can and should be established by examination of the brain of the carnivora, if rabies is suspected, as soon as the bite is inflicted In most states examination of the brain of a rabid animal may be had from laboratories of the state department of health

Once the disease is established and symptoms have developed, death is inevitable

Preventive treatment is of the greatest importance. The wound is opened widely and thoroughly cauterized with phenol and alcohol The Pasteur treatment is given as soon as possible thereafter This treatment is the use of antirabies vaccine.

NEUROLOGIC COMPLICATIONS FOLLOWING THE USE OF RABIES VACCINE. The incidence of neuroparalytic accidents complicating the use of rabies vaccine in a world-wide statistical review is 1.5,814 in a series of 1,290,758 treated patients. In those who have adverse reactions there is a mortality rate of 25 *per cent*, an insignificant figure.

Pathologic changes include adventitial infiltration of cerebral vessels with round cells, perivascular microglial reaction and infiltration of the vagus nerve with polymorphonuclear leukocytes

There is the history of previous antirabies treatment, usually in childhood. During the course of prophylactic use of rabies vaccine there may be neuroparalytic disease such as a transverse myelitis or systemic reactions These reactions may occur at any time during or soon after the administration of the vaccine. Either death or recovery may follow

Encephalomyelitis Following Certain Viral Infections (Intoxication). Encephalomyelitis sometimes follows measles, German measles, smallpox, *mumps*, and whooping cough The etiology is essentially the same in all of these diseases, *namely, one or more filtrable viruses producing a series of toxins* which have a similar effect on the myelin

There are diffuse focal perivascular degeneration and demyelination.

SYMPTOMS The following syndromes occur: (1) meningism, symptoms referable to acute diffuse involvement of the cerebrum, (2) cerebellar syndromes, (3) spinal syndromes, (4) optic neuritis and (5) multiple focal and diffuse lesions of the brain or spinal cord It is well to recall that encephalopathies may follow acute and severe infectious diseases such as *diphtheria, pneumonia, septicemia, erysipelas*, scarlet fever, influenza, dysentery and malaria. *In some instances following encephalomyelitis it may well be that the complication of the viral disease by a bacterial* infection was responsible for the syndromes present

Meningism is characterized by a sudden rise in temperature up to 105 F (40.5 C) accompanied by drowsiness, stupor or even coma. There is evidence of meningeal irritation such as cervical rigidity, Kernig's sign and tache cérébrale. Headache, vomiting, dilatation of the pupils, and muscular twitchings appear within a few hours of the onset

The spinal fluid is under increased pressure and there is a moderate increase *in* the lymphocytic cell count The globulin and total protein content are moderately increased The illness is self-limited and quick recovery is the rule

When there is a sudden onset of violent convulsions at the height of the disease, [illegible] may disappear;

[illegible] esia below the

[illegible] oss of all reflexes [illegible] symptoms ap-

[illegible] attack of mumps

[illegible] igns of cerebellar ataxia, including loss

[illegible]

occur during the convalescence from measles or German measles. It most commonly follows varicella though nervous symptoms are rare in this disease. The cranial nerves may be involved and ptosis of the eyelids, squints, optic neuritis, retrobulbar neuritis, facial palsy and palsies of the bulbar muscles are described.

Deafness may represent the only evidence of involvement of the nervous system. Often hearing is suddenly lost without warning and no symptoms of irritation of the eighth nerve are present, but in other cases the onset is marked by tinnitus, vertigo, nystagmus, nausea and vomiting. Deafness may develop in children who have been exposed to mumps, and it is thought that deafness may occur without parotitis It has been estimated that nearly 5 per cent of all deaf mutes owe their condition to an attack of mumps in childhood.

The spinal syndromes have spinal cord manifestations like the acute ascending myelitis of the Landry type which has been mentioned in Chapter 6 The spinal syndrome may be complicated by convulsions and stupor indicating cerebral involvement.

Optic neuritis may occur during measles or German measles or soon thereafter. It at times follows vaccination for smallpox or occurs immediately after the rash subsides In some cases there is reduction of vision and even transient blindness as the result of congestion of the optic nerve.

During mumps the optic nerve may be affected Optic neuritis, neuroretinitis, retrobulbar neuritis, papilledema and optic atrophy have been reported Some of these conditions are the result of increased intracranial pressure.

Multiple and Diffuse Lesions of the Brain or Spinal Cord. There are lesions of this type which cannot be considered separately They occur sporadically in a number of diseases

Diagnosis The diagnosis may be suspected whenever in the course of an acute viral infection the patient becomes stuporous or delirious, and there develop convulsions and muscular rigidity, cerebellar symptoms, a spinal syndrome, optic neuritis or deafness. Meningitis, abscess of the brain and dural sinus thrombosis are the conditions most likely to resemble toxic encephalopathy During convalescence in certain cases ventriculograms will reveal symmetric wasting of the brain

If the neurologic symptoms are of brief duration, the prognosis is favorable for complete recovery If not, the prognosis must be guarded, for the patient may be permanently disabled.

TOXIC AND HEMORRHAGIC ENCEPHALOPATHIES AND THEIR SEQUELAE

Hemorrhagic encephalitis is a secondary process due to various toxins, bacterial and viral, and other poisons Any acute infectious disease may cause hemorrhagic encephalitis, but influenza is the commonest cause. Other infectious diseases also, such as scarlet fever, diphtheria, typhus fever, typhoid fever, malaria, pneumonia, septicemia and measles, may cause hemorrhagic lesions. Certain nonbacterial poisons, such as arsphenamine, carbon monoxide and hydrocyanic acid, may cause hemorrhagic encephalopathy

On examination of the brain there are seen small yellow or red regions which are most numerous in the centrum ovale, internal capsule, corpus callosum, brain stem and cerebellum

The manifestations may not be evident because the condition often occurs in stuporous or comatose patients as a result of the original infection. When it is possible

palsies are frequent

The diagnosis may be suspected but usually is not made clinically.

Cerebral Hemorrhage and Softening as a Sequela of Acute Infections. An infection may be followed by cerebral hemorrhage and softening. Pertussis, scarlet fever, pneumonia, diphtheria, measles, dysentery, influenza, typhoid fever and typhus fevers are among the commonest causes.

The onset commences with convulsions which are followed by hemiplegia, aphasia, hemianopsia or other focal cerebral manifestations. There may be stupor or coma. The spinal fluid is usually normal.

The diagnosis is made at postmortem examination.

SYPHILIS OF THE NERVOUS SYSTEM

The generic term neurosyphilis is employed to designate all forms of involvement of the nervous system by *Treponema pallidum* The term thus used includes all of the various types of neurosyphilis, and is made specifically applicable by an appropriate modifying adjective in each instance, for example, *meningeal*, wherein the various layers, especially the leptomeninges, show the most marked reaction; *parenchymatous*, wherein the brain or the cord is chiefly affected; and *meningo-vascular*, wherein both meninges and vessels are affected. Parenchymatous neurosyphilis is a general term, but through usage it has come to be employed specifically to designate degenerative and inflammatory processes of the substance of the brain and cord. Parenchymatous neurosyphilis finds its most precise meaning when employed for the description of tabes and general paresis and thus distinguishes these from other forms of neurosyphilis.

Meningeal neurosyphilis is manifested within the first, second, and up to the fifth year after infection It is thus a relatively early manifestation of tertiary syphilitic disease. Parenchymatous neurosyphilis, that is, tabes and paresis, is a late manifestation, appearing in from 5 to 15 or more years after the initial infection

Congenital Syphilis. Congenital syphilis is not hereditary, but is acquired in utero from a syphilitic mother The twenty-seventh Annual General Assembly of the International Union Against [illegible] postulates regarding the mode of transmission of [illegible] transmitted from the mother to [illegible] sage of spirochetes across the chorionic villi takes place after the fifth month of pregnancy. (2) Direct infection of the ovum by the sperm is unlikely. (3) The so-called spirochetal granules represent a developmental stage common to all spirochetes The assembly also recommended that the term hereditary syphilis be replaced by the term congenital syphilis

Levaditi and Vaisman, although in agreement with the foregoing postulates, have pointed out that Mayer reported 2 instances in which *Treponema pallidum* was found in the chorionic villi of aborted fetuses, one 4 months and one 3 months old. These, however, appear to be exceptional instances

Congenital syphilis of the central nervous system commences in the meninges and in perivascular spaces at the base of the brain. Acute syphilitic meningitis develops; localized regions of basilar meningitis may be present Infiltration by the infection invades the optic nerves and optic atrophy may ensue There are often endarteritis and infarctions of the brain, and if the subarachnoid spaces are obliterated, hydrocephalus ensues The foci in the meninges may become enlarged and organized and gummas may develop If the parenchyma of the brain is invaded and severely injured, general paresis results, or if the syphilitic process begins in the spinal meninges and affects the spinal nerve roots and the blood vessels and invades the cord, tabes will follow if sufficient destruction is wrought

A great many neurologists and syphilologists regard congenital neurosyphilis as [illegible] with con-

Often the attention of the physician is directed to the disease in either infants or juveniles by a knowledge that the mother has syphilis. In some instances the mother notices that the child is ill with what she thinks is a minor illness of the upper part of the respiratory tract (sniffles).

If the infant does not succumb to a meningitis, there will arise symptoms of various cranial nerve palsies. The seventh, third, fourth and sixth nerves are commonly involved A degree of hydrocephalus is present in about one third of all infants who have syphilitic meningitis Optic atrophy and blindness may follow hydrocephalus and papilledema or may appear spontaneously. Increased intracranial pressure may be present Hemiplegias develop suddenly as a result of thrombosis of the cerebral vessels. Apoplexy may prove to be fatal

In juvenile *paresis* there are dullness, apathy and forgetfulness. The child is untidy and careless of manners and dress. Grandiose trends, euphoria and speech defects develop The gait is clumsy and unsteady.

Juvenile *tabes* is less frequent than juvenile paresis. There may be no symptoms, and the condition is revealed by examination

Deafness beginning at 10 to 15 years is a common manifestation of congenital syphilis It is a nerve type of deafness and is bilateral and complete.

Convulsive disorders are common in the congenital syphilitic patient and may be the only symptoms of cerebral syphilis The convulsive seizures may be general or focal or may resemble the attacks of petit mal and grand mal of epilepsy

The serologic reaction of the blood or the spinal fluid is almost always positive unless the patient has undergone prolonged treatment.

The lesions of the *skin and mucous membranes* consist of rhinitis, bullous cutaneous eruption and abnormalities of the skin and hair

There may be pseudoparalysis as the result of acute osteochondritis. A congenital syphilitic infection may be present as osteitis and periostitis with frontal bossing of the skull, saber shin, scaphoid scapulas, saddle nose, scoliosis and osteomyelitis

In many the *second set of teeth,* the upper central incisors, show the peg shape and central notching described by Hutchinson (Hutchinson's teeth), and the molars may be beset with extra facets

The spleen and liver are sometimes enlarged and jaundice and ascites are present (see Diseases of the Liver, Chapter 13)

Interstitial keratitis may be present in both eyes, or iritis may be found without keratitis

The Argyll Robertson pupil is commonly present in neurosyphilis of all types. The pupils are usually unequal and irregular They do not react to light stimulation but do contract during accommodation. This type of pupil is usually bilateral but may be unilateral Its presence does not indicate active syphilis, for once developed, it is permanent whether the syphilitic process is arrested or not

Diffusely and widely dispersed retinitis and chorioretinitis appearing as small brown and yellow spots scattered over the entire retina are almost diagnostic, and are definitely so if associated with interstitial keratitis

In juvenile paresis the serologic reactions are strongly positive in both blood and spinal fluid The spinal fluid contains an increased number of lymphocytes. Results of globulin tests are positive The gold curve is often of the paretic type

In juvenile tabes the patient is 10 to 15 years of age. On examination Argyll Robertson pupils, optic atrophy, loss of knee and ankle jerks, positive Romberg sign and ataxic gait are present Serologic reaction of the spinal fluid is positive but the cell count may be low

The diagnosis of congenital syphilis may be presumed if there is present a family history of abortions and stillbirths, evidence of congenital syphilis in siblings, and a personal history of infancy with reference to prematurity, bullous cutaneous erup-

tions, rhinitis, bone lesions (roentgenograms), and positive serologic reactions of the blood and spinal fluid.

Acquired Syphilis. The term neurosyphilis is particularly appropriate in acquired syphilis since all of the tissues of the nervous system are affected. At times the infection progresses slowly enough that it becomes manifest in some particular part of the nervous system and thus originates one or more of the syndromes of the central nervous system which characterize neurosyphilis. The predominant affection of certain structures justifies the enumeration of the varieties, for instance, gumma, syphilitic endarteritis, meningo-encephalitis, meningomyelitis and syphilitic neuritis.

The *gumma* is a round, irregular, nodular granulomatous growth, varying in size and numbers. Single gummas, however, do occur in the region of the motor cortex The gumma is hard and frequently caseated in the center. The accumulation of gummas on a blood vessel occasionally obliterates the lumen of the vessel and creates a *syphilitic endarteritis* The artery may rupture and hemorrhage may ensue. When the vessel wall is weakened sufficiently, aneurysmal dilatations occur Partial or complete obliteration of the lumen of a vessel results in localized anemia and secondary softening of the tissues distally in the path of the vessel Gummas obliterate the lumen of a blood vessel by a proliferation of the endothelium of the vessel and replacement of the muscular and elastic fibers The endarteritic or obliterative process may involve only one or a few vessels or be very widespread The circle of Willis is frequently the seat of syphilitic endarteritis The veins (syphilitic phlebitis) reveal somewhat the same process that is observed in the arteries

Syphilitic meningitis may be gummatous and involve the dura mater or the leptomeninges either at the base or at the convexity of the brain All the nerves at the base may become involved, but particularly the optic and oculomotor nerves. Meningitis of the convexity may originate a *meningo-encephalitis* The meningitic process may be grossly circumscribed

Symptoms The symptoms of neurosyphilis may commence slowly or may appear suddenly When the symptoms develop slowly, the patient may complain of mild or severe headache which is possibly worse at night. There is dizziness and occasional vomiting Scattered pains and areas of numbness, or numbness of an entire member, and other subjective sensations are common Often the patient seems to be neurotic because of prevailing irritability, restlessness, anxiety, depression, apathy, dullness, mild or severe memory defects, and alteration of personality With the suddenly developing symptoms there may be attacks of unconsciousness, and epileptic convulsions. The fits may be of the jacksonian type, or may be a generalized convulsive disorder In a middle-aged adult the occurrence for the first time of a fit is suggestive of syphilis of the brain or a brain tumor. In the severest brain involvement mild or high-grade dementia, and varying degrees of stupor up to coma, alternating with delirium, excitement or violence, are present. The symptoms may be those of a suddenly appearing psychosis which has nothing distinctive about it.

Polyuria and polydipsia (diabetes insipidus) may be present, these follow involvement of the floor of the third ventricle and the tuber cinereum

Paralytic symptoms, as the direct result of cerebral softening from a syphilitic process, generally come on in early middle age. The absence of cardiac lesions, antecedent infections, or other diseases of the brain in young persons frequently points to the syphilitic character of the hemiplegia While the onset and progress may simulate hemiplegia of atherosclerotic origin, the mentality or higher cerebral functions are frequently intact in syphilitic hemiplegia.

Examination. Owing to the fact that the syphilitic process is most marked at the base of the brain, *cranial nerve palsies* are very commonly present Involvement of the optic and ocular nerves, especially the oculomotor nerve, is the commonest manifestation of syphilitic encephalitis. The ocular palsies are generally lower motor

neuron palsies As such the oculomotor nerve is severely involved, giving ptosis and external strabismus with diplopia and convergence The pupillary reaction to light is lost. A fixed rather than an Argyll Robertson pupil is characteristic of meningovascular neurosyphilis. The pupils are frequently irregular, dilated and unequal. The paralysis of the fourth and sixth nerves results in palsies of the superior oblique and external rectus muscles. The ocular palsies are generally unilateral and often are permanent.

Often there is a neuritis of the optic nerve which is most commonly unilateral in the beginning. Transient amaurosis, impaired vision, scotoma, contracted fields, hemianopsia and blindness, the results of syphilitic optic neuritis, are often present.

Anosmia, trigeminal neuralgia, neuroparalytic keratitis, facial paralysis, deafness, and paralyses, when present, of the palate, pharynx, larynx, sternocleidomastoid and trapezius muscles and the tongue are manifestations of an involvement of the cranial nerves or nerve

The physical findings of syphilitic hemiplegia differ in no wise from the signs of hemiplegia from any other cause.

The spinal fluid usually shows an increase in the number of cells, from 10 or 20 up to many hundreds, an increase of globulin, and positive serologic reactions. The colloidal gold test gives an ascending or luetic curve.

DIAGNOSIS The diagnosis of neurosyphilis can generally be based on the history, on the multiplicity and dissemination of the signs and symptoms, on the presence of pupillary signs, on the positive serologic reactions, and on the results of therapeutic tests.

General Paresis (Parenchymatous Neurosyphilis) General paresis is a chronic syphilitic meningo-encephalitis characterized by atrophy of the convolutions of the brain in the frontal, parietal and insular regions. There is a deepening of the sulci and flattening of the gyri Despite an increased vascularization, the cortex atrophies and there are both an internal and an external hydrocephalus The dura and the piarachnoid are thickened and adherent. There are a generalized proliferative glial reaction and disappearance of the ganglion cells. The inflammatory reaction and perivascular cellular infiltration extend into the substance of the brain Regions of softening secondary to periarteritic and endarteritic changes are scattered through the brain. Degenerative changes occur in the basal ganglia, in the brain-stem nuclei, especially those of the oculomotor nerves, and in the cerebellum The lateral and posterior columns of the cord are frequently degenerated Degeneration of the optic nerves and involvement of the posterior columns, when present, link general paresis with tabes and frequently constitute the basis for the presence of symptoms referable to both the spinal cord and the brain

SYMPTOMS The patient is more frequently irritable than euphoric, shows bad temper, lacks power of concentration, and is easily fatigued. There may be anxiety, insomnia and hypochondriacal complaints Loss of interest is common

There is often loss of appreciation of the correct ethical, moral and esthetic standards. A previously honest person may commit petty thefts, a hitherto sober person may indulge in excessive amounts of alcohol, or a moral person may become immoral. There is carelessness of personal hygiene. The manners deteriorate, the conduct becomes lax, and there are loss of interest in business and neglect of the usual responsibilities As the memory defect increases, details are overlooked and mistakes are forgotten Changes in temperament and often an unwarranted feeling of well-being develop

A general euphoria consisting of a sense of well-being, elation and exuberant phantasy may prevail. There is a meaningless incoherence in association of ideas. Interspersed among all of these feelings of grandeur are irritability and insomnia Manic outbreaks occur during which the patient may commit personal violence and

destruction or may destroy the property of others. The psychosis may simulate the Korsakoff variety, that is, with much chatter and then delirium. In some there is a depressive type of psychosis characterized by hypochondriacal ideas or delusions The depressed paretic expresses self-accusatory ideas and feelings of insufficiency. Often when there is sufficient destruction of the cerebral cortices, the patient becomes quiet, harmless, and demented and thus lives for a long time.

A convulsive disorder and apoplectiform paralytic attacks are two of the most characteristic manifestations of paresis The convulsion may be partial and may occur in any part of the body The face is most commonly affected by such a convulsion Localized twitchings, tremors, or other abnormal involuntary movements may persist for days or even weeks A rise in temperature may accompany the fits. The fits are sudden, are mild or severe, and may last from a few minutes to half an hour They may come on singly or be repeated and may pass over into status epilepticus and end in death

The apoplectiform attacks, of fleeting time interval, may give rise to partial or complete paralysis or to hemiplegia Paretic hemiplegias usually, at least the first ones, disappear in a few hours or days but in time the paralytic attacks leave permanent residua

The course of general paresis as a rule progresses slowly, with or without remissions The disease may begin suddenly, however, with a manic attack or epileptiform convulsion, and progress rapidly Generally all signs and symptoms become aggravated, and mental and physical deterioration progresses Speech is difficult and unintelligible; walking becomes awkward and finally impossible, the patient takes to the bed; incontinence of urine and feces sets in; complete dementia supervenes; and finally death occurs *but not soon enough*.

EXAMINATION. On examination the patient appears and acts silly The presence of pupillary changes is a most important finding The Argyll Robertson pupil is common in paresis, being present in about half of those who have this disease. As the disease advances, almost all have pupillary disturbances, and finally the pupil may be fixed and *respond to neither light nor convergence* A *completely normal* pupil, however, may be present in paresis Ocular palsies and optic atrophy with transient blindness are sometimes present.

Soon there is impairment of memory for recent events which is a part of a defect of the general mental processes Characteristic of this sort of intellectual defect is failure to appreciate ethical, moral and esthetic standards.

The speech is tremulous and dysarthric, an explosive sort of utterance emitted with a shower of slobbers There is slurring of letters and syllables Test phrases, such as "round the rugged rock the ragged rascal ran" are poorly repeated, or forgotten before they can be repeated. A fine tremor is present on the lips, tongue and eyelids, and there is a coarser tremor of the fingers *The handwriting is tremulous* and inaccurate. The deep reflexes are generally increased, frequently unequally. Spinal cord changes are indicated by signs of involvement of the posterior columns, and the clinical syndrome then becomes one of *taboparesis* In taboparesis the knee jerks and ankle jerks are absent There is swaying in the Romberg position Finally urinary incontinence ensues

The serologic reactions of the blood and spinal fluid are positive in practically all instances of the disease. In the blood the reactions may be negative early in the course of the disease or after "adequate treatment," so that negative serologic reac[illegible] do not exclude paresis The spinal fluid generally shows an increase [illegible] an increase in globulin. [illegible] "paretic" curve. [illegible] nbination of symptoms [illegible] tive serologic reactions of the blood and spinal fluid or the spinal fluid alone, permits of the diagnosis of

general paresis in most instances The diagnosis of general paresis can rarely be made in the absence of positive serologic reactions.

Spontaneous recoveries or remissions have been reported The average duration of the disease is about 3 years The disease is always fatal in the advanced stages.

INFECTIONS OF THE NERVOUS SYSTEM BY HIGHER PLANT ORGANISMS

Various members of the higher plant organisms which cause disease of men and animals may reach the nervous system during the course of the infection and thus originate disease. The organism *Torula* (*Cryptococcus neoformans*) is the only one expressing special tropism for the nervous system.

Torulosis (Cryptococcosis). The organism *Torula* (*Cryptococcus neoformans*) of a genus of yeastlike fungi, reproduces by budding Several types are recognized which are differentiated by their morphologic differences The organism enters the body through the upper part of the respiratory system and thence passes to the nervous system

The brain shows at necropsy a granulomatous meningitis most severe at the base and very similar to tuberculous meningitis The fluid in the subarachnoid spaces is turbid and gelatinous, and contains the organisms in large numbers. In the cortex are found cysts and granulomas The organisms penetrate along the perivascular spaces into the cortex from the subarachnoid space They then proliferate, distending the tissues and forming small cystic structures filled with a gelatinous material composed of the organisms and their capsules There is practically no reaction by glial and nerve cells. Lesions may be found deep in the cortex and basal ganglia which seem to have arisen as a result of embolism.

Evidences of the disease outside of the nervous system are rare. Involvement of the lungs is sometimes seen. The lymph nodes may be enlarged. In generalized torula infection the organisms may be found in the blood and urine, and the liver and spleen may be enlarged Torulae have been found in pus withdrawn from the liver and in cultures from the pharynx, tonsils and nasal sinuses A torula infection may be associated with or resemble tuberculosis, and during life it may be very difficult to distinguish the two processes

Torula infection may occur at any age or in either sex Symptoms commence with vomiting and drowsiness In children the head may enlarge slowly as a result of hydrocephalus In some instances there is low-grade fever. In others the disease progresses without signs of infection or systemic symptoms but a slow failure of health ensues.

Cervical rigidity and Kernig's sign are present but they are not so severe as in purulent meningitis. Hemiplegia or hemiparesis and other evidences of focal cerebral lesions may be evident on examination Papilledema is usually present and may eventually lead to optical atrophy and reduction of vision The sixth nerves are frequently paralyzed and the other cranial nerves are sometimes involved. Anemia may be absent but sometimes develops in profoundly cachectic patients. A slight increase in the leukocyte count may be present.

The spinal fluid shows a cell count from 50 to 1,000 per cubic millimeter. Mononuclear cells predominate but leukocytes may be present. Many torulae usually are present and are recognized by their refractile capsules Cultures are usually obtained on Sabouraud's medium Torulae may be absent from the spinal fluid or may fail to grow on Sabouraud's culture media

The diagnosis cannot be established without demonstration by culture of the organism in the spinal fluid The disease clinically resembles tuberculous meningitis. If the intracranial tension is high, sarcomatosis of the meninges or brain abscess may be present. Effective treatment is not known.

DISEASES OF THE BRAIN DUE TO TRAUMA

In head injuries there are: (1) the element of shock or concussion, (2) the signs of increased intracranial pressure and (3) the evidences of destructive lesions in the brain. As time passes, the signs and symptoms of such sequelae as abscess of *the brain, meningitis, subdural hematoma*, effusions into the subdural or subarachnoid spaces, delayed hemorrhage and pneumocephaly are recognized if they arise.

A history of a fall and head injury in a patient who has fits or headache or both and who is first examined long after the injury occurred is difficult to evaluate, for all patients have had degrees of head injuries in the past In the stoic person it is safe to assume there was injury to the brain if the patient was unconscious for an hour or more immediately after the accident. A history of vomiting, convulsions, paralysis, bleeding from the ears and roentgenologic evidence of fracture of the skull are often conclusive

Extradural Hemorrhage. Hemorrhage between the skull and the dura is termed an extradural hemorrhage The significant manifestations of an extradural hemorrhage are a history of head injury with or without loss of consciousness, followed by a period of time during which the sensorium was clear, and then rapidly increasing signs of intracranial pressure. If focal signs such as dilatation of the homolateral pupil and hemiplegia or muscular twitchings on the opposite side are present, localization of the hemorrhage is largely accomplished. Roentgenologic examination of the head is diagnostic in many instances

The prognosis is unfavorable if operation is not performed at once. In the severely injured patient a life may be saved by operation but the patient may not be grateful because of the limitations the injury imposed on locomotion

Subdural Hematoma. This hematoma is considered in all cases of unexplained cerebral symptoms following injuries of the head, particularly if there is increased intracranial pressure, unless some other cause is apparent. The conditions which resemble subdural hematoma are brain tumor, cerebral abscess, hydrocephalus and subarachnoid hemorrhage. *If subdural hematoma is suspected, puncture of the subdural space* will usually either establish or disprove the diagnosis If a hematoma is present blood will be obtained from the exploratory needle.

Chronic Subdural Hematoma. Chronic subdural hematoma is often caused by trauma. It can occur spontaneously. Trauma on forehead or occiput without indications of concussion may lead to rupture of cortical veins. From this rupture blood leaks into the subdural space and forms a collection in this space, over the convexity of the brain, and often bilaterally

Chronic subdural hematoma was formerly believed to be an inflammatory process known as chronic pachymeningitis hemorrhagica, found in demented, epileptic, tabetic and alcoholic persons. It is now known to be traumatic, and it occurs in the types of patients enumerated because they fall down and injure their heads, and they are less able to give a history of trauma

There is a latent period after the injury of days to months before symptoms appear Headache develops and increases in frequency and severity. Intermittently there may be drowsiness, forgetfulness and at times confusion which may progress to stupor, or even to coma The pulse rate tends to become slower, falling to 60 or even 50

In all cases of rapidly developing intracranial pressure, without clear localizing [illegible] slowness and confu-
[illegible] story of *head injury*
[illegible] without a history of
head injury of some degree

Pneumocephaly and Cerebrospinal Rhinorrhea. The terms pneumoventricle, pneumocranium, intracranial aerocele and pneumatocele refer to the *accumulation of air within the cranial cavity*. This occurs in a patient who has sustained a fracture at the base of the anterior fossa of the skull. A fissure in the bone extending through the frontal sinus may be palpated. Some weeks after what was considered to be a minor injury headache, vomiting and other signs of increased intracranial hypertension ensue. The signs of intracranial hypertension may commence and persist soon after the head injury.

The flow of fluid from the nose is characteristic of this condition. The fluid is clear, blood-stained or even yellow. Sometimes large amounts of fluid are discharged at intervals but in other cases there is a constant drip.

The demonstration of air within the cranium by roentgenologic examination is conclusive The diagnosis may be suspected if head injury has been followed by discharge of fluid from the nose and increasing manifestations of increased intracranial pressure

The outlook depends on the degree of injury and on the outcome of prompt, skilful surgical treatment.

Spontaneous cerebrospinal rhinorrhea may occur in which there is no evidence or history of trauma to the head. Such rhinorrheas are due usually to imperfections in the bony structures at the base of the brain.

DISEASES OF THE BRAIN DUE TO CIRCULATORY DISTURBANCES

The circle of Willis gives origin at the base of the brain to vessels which pass through small perforations in the occipital bone to enter the brain substance, and to larger vessels which pass from the main trunk (basilar and posterior cerebrals) of the circle to continue their course over various surfaces of the brain within the pia mater, branching and being progressively dispersed into smaller vessels which disappear within the sulci, enter the superficial gray cortex and continue into the white matter. The internal carotid arteries and their branches supply the rest of the brain.

The vessels of the dura mater and pia mater, the intracerebral vessels, and the choroid plexus are supplied with vasomotor nerves. The vessels of the brain act anatomically and physiologically as vessels act elsewhere in the body. Stimulation of the cervical sympathetic trunk results in contraction of the pial vessels Stimulating the vagus dilates the capillary bed

The caliber of the intracranial arterioles is influenced by chemical substances (carbon dioxide, chlorides and epinephrine) in the blood stream and vasomotor nerves and by variations of venous pressure and pressure of the cerebrospinal fluid.

The rise in pressure within the veins causes stasis of blood. If the rise in pressure is slow and not too great, vasodilatation results, thereby overcoming the venous stasis caused by increased venous pressure If the rise in cerebrospinal fluid pressure is sudden and great, a rise in systemic arterial pressure is necessary to overcome the venous stasis (see Intracranial Tumors, p. 1181). This rise of systemic arterial pressure subsequent to increased intracranial tension is accompanied by slowing of the pulse and respiratory rates If the intracranial tension becomes too great, paroxysmal irregularities of respiration ensue.

Cerebral Anemia. Cerebral anemia may occur acutely or chronically in myocardial weakness and decompensation, or in acute dilatation of the heart and in severe degrees of general anemia

Acute cerebral anemia results from sudden pressure on the vessels of the neck (carotid sinus syndrome), rapid loss of blood, and sudden dilatation of the splanchnic circulation which may follow withdrawal of large amounts of ascitic fluid or pleural effusions.

The symptoms of acute anemia of the brain are apprehension, scotomas, giddiness, weakness and faintness, and often syncope. Sudden loss of large quantities of

blood, as from postpartum hemorrhage, rupture of tubal pregnancy and a bleed peptic ulcer, has resulted in complete and permanent cerebral deterioration a blindness due to ischemia of the ganglion cells of the retina, and subsequent atrop of the nerve fibers.

Chronic cerebral anemia is often due to a chronic anemia caused by a gr reduction of erythrocytes In cerebral arteriosclerosis intermittent transient peric of local or general anemia appear when posture is suddenly changed. In those w have orthostatic hypotension the general circulatory apparatus and the local vasc lar bed can no longer compensate for the sudden effects of gravity during postu changes Cerebral anemia may be incident to sudden changes of position by one wl has been long confined to bed.

The symptoms of chronic cerebral anemia may be headaches, dizziness an faintness, especially severe on sudden shift of position of the head. There may be deficiency of memory and increase in irritability.

On examination usually there are no local focal cerebral signs The diagnos is made because of the presence of generalized and retinal arteriosclerosis

Cerebral Hyperemia. Cerebral hyperemia is a part of all acute inflammato and toxic encephalitides, failure of the right side of the heart, polycythemia, mali nant hypertension and partial obstructions of the dural sinuses, jugular veins superior vena cava When a patient who has pulmonary emphysema with increase venous pressure lies down or bends forward there may be cerebral hyperemia Whe a person who has atherosclerosis or arteriosclerosis bends forward or lies down th vessels lack the ability to make the normal adjustments, and therefore there ar transient giddiness, general tingling, suffusion of the face, and headache In malig nant hypertension an increased intracranial tension may be permanently increase because of cerebral edema with multiple small hemorrhages and softenings, an constant headaches and choking of the optic disks develop This condition of hyper tensive encephalopathy, which often occurs in malignant hypertension, of Wagene and Keith, is distinguished with difficulty from that caused by intracranial tumor if multiple focal signs, due to arteriosclerotic softenings, are not present.

Edema of the Brain. A generalized cerebral edema is often a part of a anasarca as in congestive heart failure or edema caused by decreased concentration of serum proteins, starvation and generalized sepsis Focalized cerebral edema sur rounds abscesses, hemorrhages and tumors. At necropsy the brain is large and pale

The symptoms of cerebral edema consist of mental and motor apathy, menta confusion and, perhaps, focal or generalized convulsions The pulse is slow and the respirations are irregular and often periodic in character. The systolic blood pressure is usually raised above its usual level (160 to 170 mm of mercury). The stupor may increase and coma and death may ensue

Arrest of Cerebral Circulation. Arrests of cerebral circulation from cardiac arrests cause anoxia and neuronal damage Successful cardiac massage performed by surgeons for cardiac arrest during surgical procedures has been limited to cases in which the critical time limit of 5 minutes has not been exceeded. Premortem and postmortem studies of cases in which the heart has restarted after periods longer than 5 minutes are scarce.

Three British investigators, Howkins, McLaughlin and Daniel, reported an instance in which total duration of cardiac arrest was computed at 10 to 11 minutes until re-establishment of the heart beat by massage Six hours postoperatively abnormal neurologic responses were present and at 10 hours the patient's condition resembled somewhat that of decerebrate rigidity, but the patient survived 26 days. During this period the coma remained at the same depth, the patient responding only to strong painful stimuli The deep reflexes and the degree of hypertonia varied from day to day. Features of clinical interest included (1) a coma which was pe- ... in that the brain stem was rather active although higher cerebral activities

were depressed, (2) "seizures" occurring 8 days after operation, (3) absence of reaction to menace despite the presence of pupillary reflexes and spontaneous ocular movements, (4) failure to respond to auditory stimuli, (5) atrophy of the small muscles of the hand indicating considerable change in the anterior horn cells, (6) normal results in examination of spinal fluid and (7) almost straight lines in electroencephalograms with complete absence of any alternating potential difference. The patient died 26 days after operation of pneumonia and infection of the urinary tract.

Necropsy revealed excess fluid in the subarachnoid space. The sulci of the brain were widened Section of the brain revealed a moderate generalized ventricular dilatation, outer pallor and a slight generalized diminution of the thickness of the cortex and irregular areas of pallor of the basal ganglia. Microscopic examination revealed the disappearance of the majority of the pyramidal cells of the cerebral cortex and an increase of astrocytes and microglial proliferation, especially in the occipital cortex. The destruction of the occipital (visual) cortex and the superior temporal gyrus was severe.

Arterial Malformations and Aneurysms. Arteriovenous aneurysms and saccular aneurysms occur in association with the arteries of the circle of Willis (posterior group) and the carotid arteries (anterior group). These lesions are often of millimeter dimensions and produce symptoms only if they enlarge, leak, or rupture.

Aneurysms of congenital origin of the cerebral vessels occur between the ages of 30 and 50 years Aneurysms of atheromatous origin occur in persons more than 50 years of age Cerebral aneurysms occur in young or middle-aged adults although children may be affected Women are more frequently affected than men

Congenital arteriovenous aneurysms are often situated on the lateral surfaces of the hemisphere in the distribution of the middle cerebral artery but may occur in any location The walls of the dilated vessels are often partially calcified and degenerated, and thrombosis is common

The available information on 150 instances of subarachnoid hemorrhage, almost all in members of the armed services, has been recently reviewed by Magee He could not find any reliable premonitory sign of aneurysm or its rupture There was no evidence that physical strain was a cause for rupture In most cases the symptoms appear suddenly and the victim becomes stricken without premonitory warning

In the majority of those who have subarachnoid hemorrhage violent headache is the most important presenting symptom This usually is accompanied by moderate pyrexia, vomiting and rigidity of the neck which in many instances lead to the suspicion that meningitis is present In Magee's series vascular hypertension rarely was found; positive serologic reactions for syphilis were not obtained in any cases

The gravity of subarachnoid hemorrhage is well illustrated in Magee's series in which the mortality rate was 56 per cent Of his 150 patients 105 either died or were seriously crippled by paralytic sequelae (hemiplegia), incapacitating headache or vertigo. A second hemorrhage occurred in 50 of the 150 patients, and this represents an even graver prognosis when it is realized that 52 of the 150 died in the primary attack. The 50 recurrences therefore occurred among the 98 survivors of the first attack The prospects of good recovery diminished with advancing years; few of those examined subsequently to an attack were entirely free from symptoms Necropsy in 58 of the 84 fatal instances of the disease disclosed 43 ruptured aneurysms, these were commoner in the anterior half of the circle than in the posterior half and on the right side than on the left. The latter observation is the reverse of that commonly found in intracerebral hemorrhage of other varieties, the cause is obscure.

The cerebral aneurysms of atheromatous origin cannot be differentiated from the congenital ones prior to necropsy

Cerebral aneurysms may arise from causes other than congenital malformations or arteriosclerosis Syphilis, mycotic aneurysms and those of periarteritis nodosa

as well as those arising from penetration of the vessel wall by infections occur, but these causes are not common.

Often cerebral aneurysms are accidentally discovered at necropsy when there had been no recognized symptoms during life In some the aneurysm is manifested only on rupture with massive, often fatal, ventricular or subarachnoid hemorrhage. In still others there may be a history suggestive of small ruptures or leaks The patients recover from the apoplectic effects, but the subsequent course is associated with further ruptures until a large hemorrhage ends fatally.

In some instances the enlargement or leakage of the aneurysm will produce focal or general convulsions. There is a sudden onset of severe headache, vomiting, loss of consciousness, slow pulse, periodic breathing, and often convulsions If there is a moderate hemorrhage, the patient may remain unconscious until death a few days later During this period the head may be retracted, the legs and the arms fully extended, the legs adducted and the forearms pronated Convulsive twitchings of the entire body, irregularity of respiration and vomiting are frequent Kernig's sign, photophobia, hyperesthesia and herpes zoster are often present. Some patients survive and, after the acute symptoms are over, usually show mental deterioration

There is usually fever, the temperature rising to 104 F (40 C) In some instances the patient complains of a noise in the head. Each seizure is followed by transient weakness or paralysis of the extremity in which the convulsion begins. However, in those who have these early symptoms, complete recovery occurs until a persistent hemiplegia ensues With the motor symptoms there are hemianopsia, aphasia and other cerebral symptoms.

Leukocytosis is present. The cerebrospinal fluid contains blood Clotting does not occur on standing The color is pink or red during the first day but soon begins to turn yellow, brown or orange The diagnosis cannot be made until there has been some leakage of blood into the cerebrospinal fluid

Leakage of an intracranial aneurysm is compatible with life Some of these patients have a permanent hemiplegia after one or more leakages have occurred

Rupture of an intracranial aneurysm is fatal almost at once

Arteriovenous Aneurysm of the Carotid Artery. Arteriovenous aneurysm of the carotid artery in the *cavernous sinus* may be due to traumatic communication between these two structures, often as the result of a skull fracture However, these lesions, like those in the region of the circle of Willis, may be of congenital origin and occur in the same age groups of patients as do lesions of the circle of Willis. Occasionally the condition may develop as a result of atherosclerosis in persons beyond middle age.

Immediately after traumatic injury there is an audible bruit within the cranium which often can be heard without the aid of the stethoscope The orbital tissues become edematous and the veins about the orbit, distended The eyeball protrudes and there is palpable and visible pulsation synchronous with the heart beat

The diagnosis is made on the basis of a history of trauma, exophthalmos and pulsation of the eyeball. Defects in the superior orbital plate will cause pulsating exophthalmos. Various types of congenital aneurysm and hemangiomas will give rise to the same symptoms These conditions are distinguished by the absence of trauma Thrombosis of the cavernous sinus causes exophthalmos but not pulsation or an audible bruit. Pressure on the affected artery in the neck will stop the bruit and reveal the side of the lesion

Ligation of the internal carotid artery is recommended and usually results in great improvement, if not in cure, of the condition

Intracranial aneurysm of the carotid artery occurs at all ages but most commonly in young and middle-aged women.

Aneurysms of the nontraumatic type may be either fusiform or pedunculated. These aneurysms invariably are filled with blood clots, and there are adhesions

around the lesion where leakage or rupture has occurred. Staining of the subarachnoid and a subdural space with blood pigment is almost constantly observed. Subdural hematomas may be present.

Ocular signs and headache are constantly observed in those lesions affecting that part of the carotid artery which is inside the skull before it divides into the middle and anterior cerebral arteries. Within an anatomic radius of about 1 inch (2 5 cm) around this part of the carotid artery lie the optic, oculomotor, trochlear, abducens and trigeminal nerves, which may be injured by these aneurysms

In instances of aneurysms of congenital and arteriosclerotic origins increase in size of the expanding segment of the carotid artery is attended by prodromes of the impending disaster. These prodromes consist of headache and vertigo. When the aneurysm ruptures, the patient has a sudden sharp headache and pain in the eye, hears loud noises, and falls unconscious Slowly the eye begins to protrude, pulsating synchronously with the heart beat. Pulsation may not begin, however, for some months after the onset of exophthalmos. The exophthalmos is exaggerated by increase of intracranial pressure. The ocular veins are dilated and edema of the soft tissues about the orbit ensues.

The eye is observed to be forced laterally and rotated outward and down but it can be easily pushed back into the socket, a procedure which causes pain. The eyeball may recede into the orbit if compression is exerted on the carotid artery. Dilatation of the facial veins which drain into the ophthalmic vein may be present Auscultation over the eye or over the head will disclose a bruit which is discontinued by carotid pressure.

The prodromes consisting of headache and vertigo do not always immediately end in disaster. In such instances the oculomotor nerve is the most commonly damaged, and hence an early oculomotor palsy is often present. Pressure or irritation in this region causes pain in the ipsilateral eye, eye socket, and forehead and often along the side of the nose and inner canthus

The upper lid is observed to be ptosed and covers the pupil so as to obscure vision, the eye turns outward, and the pupil is dilated and does not react to light or convergence or consensually. A slight ptosis of the upper lid, with only an appreciable dilatation of the pupil, is the minimal sign of dysfunction. Occasionally the pupil on the involved side will be smaller than the pupil on the opposite side. Extraocular paralysis may occasionally be present Sometimes an episodic type of paralysis occurs which suggests multiple sclerosis or perhaps myasthenia gravis An associated involvement of the fourth and sixth cranial nerves is often observed.

Papilledema may be caused by direct irritation of the tissues about the optic nerve or it may arise from increased intracranial pressure.

If there is bleeding into the subarachnoid space, the symptoms of spontaneous subarachnoid hemorrhage occur, such as meningismus, mental confusion, or long-continued stupor. Vomiting may be an early symptom.

Immediately after the onset of symptoms there are often fever and leukocytosis Roentgenograms of the skull or orbits may reveal calcification situated under the bones or deep in the substance of the brain when intracranial aneurysms are present.

Ligation of the internal carotid artery has been successful in treatment in some of these patients.

Cerebral Arteriography. Arteriography may be used in cerebral vascular syndromes as an aid in the differential diagnosis of hemorrhage from thrombotic softening Arteriography will facilitate the decision of whether or not surgical intervention should be performed in cases of hemorrhage. It is barely possible that occasionally arteriography would make possible treatment with vasodilators in partial or complete thrombosis of the cerebral artery occurring at its termination or, more frequently, at the carotid bifurcation.

This procedure in the diagnosis of cerebral aneurysms and angiomas is safe in

experienced, trained hands, and should be practiced whenever aneurysms or angiomas are suspected It is a guide for the neurosurgeon and an aid in deciding whether surgical intervention should or should not be performed. Arteriography of cerebral tumors is limited to the cases in which the symptoms suggest vascular tumor (meningioma) and to cases of temporal tumor in which ventriculography is not feasible or its interpretation is difficult because of displacement of the ventricular system In cranial trauma arteriography is less indicated than ventriculography

Arteriosclerosis of Cerebral Arteries. The two main varieties of cerebral arterial disease are atherosclerosis or atheroma and arteriosclerosis. These have been described under vascular diseases.

Atherosclerosis and Arteriosclerosis. *Atherosclerosis* in the arteries of the brain is a process identical with that which occurs in the large arteries of the heart. It consists of a patchy and nodular process, distorting the vessel and perhaps narrowing or occluding its lumen The essential lesion arises in the intima and consists in deposition of fat, followed by sclerotic changes. These may cause narrowing of the lumen or aneurysmal dilatation and even rupture of the vessel

Arteriosclerosis comprises the changes in the smaller vessels, the arterioles, found in association with hypertension. The response is first spasm and later medial hypertrophy and hyaline change and thickening of the intima of the vessels.

Atherosclerosis occurs in the older age groups, whereas arteriosclerosis or arteriolar sclerosis occurs in younger patients. In the brain this is the same disease as essential hypertension

The softening of the brain which ensues on atherosclerosis of the larger arteries is the result of an occlusion of an artery already narrowed by blood clot, a true thrombosis The softening which ensues on the sclerosis of arterioles is probably the result of intimal changes.

In the presence of either atherosclerosis or arteriosclerosis, if cardiac weakness supervenes in a person who has cerebral arterial disease, serious consequences may result, impeding the cerebral circulation

Hypertensive Encephalopathy (*Cerebral Crises*). Hypertensive encephalopathy may occur in those who have essential hypertension or in those who have glomerulonephritis or other renal ailment accompanied by hypertension.

In *acute hypertension*, attacks of severe headache occur which are followed by vomiting, drowsiness, bradycardia, convulsions and perhaps coma These attacks may be preceded or followed by focal symptoms and signs which clear up without residua. These symptoms are similar to those present in acutely raised intracranial pressure However, mental deterioration may ensue. The patient can recall remote events, but new impressions and concepts are grasped with difficulty and thought processes and comprehension are confused and slowed Emotional instability, crying and laughing excessively are common. If life should be sufficiently prolonged, dementia may ensue

On ophthalmoscopic examination retinal changes indicative of severe hypertension are often present In these patients often there is spasm of the retinal arteries [illegible] result- [illegible] ever, [illegible] ts of when widespread foci of destruction are present, [illegible] the attack may not follow There is frequently present papilledema of a magnitude of several diopters

In *chronic hypertension* of a severe grade in an elderly patient, there may occur headaches and vertigo, transitory amaurosis, hemianopsia, aphasia, monoplegia and hemiplegia, and in some instances fits As soon as the spastic artery or arteries relax and there is a restoration of the lumen so that blood can flow through, the ischemic brain recovers and the paralysis or other disturbance disappears.

The larger arteries of the arm or leg may participate in such spastic episodes

which are manifested by paresthesias and color changes in the involved extremities. In the extremities the pulse is diminished or lost and the extremity is cold.

On examination the larger arteries, for instance, the radial arteries, are hardened, and palpable nodules may be present. When the arm is flexed, the artery appears to be too long for the arm and it pulsates in two planes. Often the pulsations in the dorsalis pedis and posterior tibial arteries are decreased in volume. The blood pressure is characterized by an increased pulse pressure, for instance an average reading is 180 systolic and 70 or 80 diastolic. Retinal atherosclerosis is evidenced by narrow nodular arteries giving a wide light reflex and depression in the veins where the arteries cross them.

The diagnosis is obvious from the foregoing description. However, caution is exercised before atherosclerosis is assigned the main etiologic role in production of the symptoms from which the patient suffers because these patients may have an expanding intracranial lesion which may require time to enable a certain diagnosis to be made.

Apoplexy. Apoplexy is an acute condition caused by hemorrhage, thrombosis or embolism in the brain, and characterized by coma followed by paralysis or death (see Chapter 6)

The physician may not make a definite diagnosis immediately after observing and examining a patient during an apoplectic fit Generally, however, if the patient has severe essential hypertension or is aged, a cerebral vascular disease is the cause of the convulsion.

The differential diagnosis between cerebral hemorrhage, embolism or thrombosis cannot be made with certainty Hemorrhage comes on more suddenly than cerebral embolism or cerebral thrombosis, may be preceded by sudden severe headache, and is associated with more severe general shock and unconsciousness than are present in apoplexy due to other causes. Blood in the cerebrospinal fluid is the only certain criterion of hemorrhage

Some brain tumors give rise to thrombosis of neighboring cerebral vessels and thus lead to diagnostic difficulties. Some cystic gliomas of the cerebral hemispheres *of adults are particularly likely to bleed. The first manifestation of such a tumor may* be an apoplectic seizure which differs in no way from that seen with atherosclerosis. As with a thrombosis due purely to vascular disease, the patient's condition may then improve, but soon extension of the lesion becomes apparent from the spreading manifestations and the developing intracranial hypertension (see p. 338).

Apoplexy Without Focal Findings. Apoplexy without focal findings is commonly observed The patient falls to the ground unconscious, with changes in color, respiration, and coma. Examination during the fit or in the stage of recovery discloses absence of focal symptoms. Following the attack there is usually cerebral dysfunction Succeeding attacks will occur with less fortunate recoveries and with more definite manifestations

Focal Findings Without Apoplexy. Frequently a patient who has atherosclerosis will be found to have focal weakness or palsies of the face or perhaps of a hand Often the muscular palsies, if one half of the face is involved, will be considered to be a Bell's palsy However, in the beginning there may have been also ataxia and difficulty in swallowing, a combination of manifestations obviously not due to a single lesion. These widespread manifestations are due to multiple focal vascular lesions. The diagnosis of focal vascular lesions is supported if the patient has had an angina pectoris or a coronary occlusion.

When widely dispersed cerebral symptoms are present in a patient who has a malignant tumor in the breast or elsewhere in the body, the possible diagnosis of metastatic malignancy of the brain is considered

Pseudobulbar Palsy. Pseudobulbar palsy is commonly caused by atherosclerosis of the cerebral blood vessels with multiple sites of softening Such processes also

may follow syphilitic vascular disease, general paresis, and infections. Ther disorders of speech, swallowing and chewing.

There is a nasal, explosive voice. The pronunciation of consonants is avc The volume of the voice is diminished, often to a whisper. These patient: aphonic but not anarthric. Mastication and deglutition are affected so that accumulates in the cheeks and above the gums. The swallowing is poorly perfo and the patient frequently chokes on food. The face is sad and inexpressive. S taneous laughing and crying are frequent and cannot be voluntarily stopped D ing of saliva is present However, with good nursing care these patients often for many years, and spontaneous improvement is common. Death usually oc from inanition or bronchopneumonia caused by aspiration of food.

Subarachnoid and Subdural Hemorrhage and Hematomas. Most forn cerebral hemorrhage occur in the later years of life or in persons whose cer blood vessels have been damaged by sclerosis, tumors or intercurrent infection. condition commonly called spontaneous subarachnoid hemorrhage, however, pears frequently in youth and in early middle age, often due to congenital malfo tions resulting in aneurysms or in arteriovenous fistulas of the vessels.

Subdural spontaneous nontraumatic hematomas may be manifested as an a cerebrovascular accident or as a slowly expanding intracranial lesion

The differentiation of subdural hematoma and subarachnoid hemorrhag based on the recovery of blood from the subdural space while the spinal fluid is cl When blood-stained fluid is obtained from both punctures, the origin of the blee is obscure The history, however, offers some aid, for subarachnoid hemorrha usually due to rupture of an aneurysm of the circle of Willis. The ventriculog shows normal or dilated ventricles in subarachnoid hemorrhage and compre ventricles in subdural hematomas.

The neurosurgeon may find a subdural hematoma at the time of operation stead of a suspected brain tumor.

Vascular Disorders of the Cerebellum (*Arterial Hemorrhage and Oc sions*) Occlusion of a cerebellar artery usually does not produce symptoms. Beca of the intimate anastomoses of the cortical branches, hemorrhage into the wl matter produces definite symptoms. Sudden death may ensue because blood rupt into the fourth ventricle, or the bulging cerebellar roof of the fourth ventricle r compress the medulla oblongata

If recovery from the stroke occurs there are present the syndromes produced interference with the blood supply of the cerebellum including that of the supe cerebellar artery and the posterior inferior artery (see Chapter 6)

When circulation to the cerebellum is interfered with by occlusion of the *super cerebellar artery*, there is a disturbance of skilled voluntary movements There ipsilateral in-co-ordination of skilled voluntary movements with loss of sense of p and temperature of the opposite half of the face and body. The onset is genera sudden, and there is gradual improvement. A disturbance of postural fixation a muscle tone is permanent.

... result from invol

intention tremor. In addition there is present the cerebellar gait consisting of staggering. The characteristic signs of medullary involvement include ipsilateral lo of corneal reflex and pain and temperature sensation to the face associated wi contralateral pain and temperature loss of the body. Cranial nerve signs inclu vertigo, nystagmus, Horner's syndrome, difficulty in swallowing and hoarsenes The cause is usually thrombosis, and the prognosis is good for satisfactory fun tional recovery.

Air Embolism of the Nervous System. Air embolism occurs as the result of the liberation of nitrogen in the blood stream due to sudden reduction of atmospheric pressure and from the accidental introduction of air or other gases into the vascular system during therapeutic procedures.

The common therapeutic procedures which are known to have caused air embolism to the nervous system are: a large intravenous needle accidentally left open while in a vein, antrum irrigations and injections of air into the pleural cavity.

The patient suddenly collapses and unconsciousness and convulsions usually occur If the patient does not die at once, there are usually fever, cyanosis and dyspnea for some hours. Hemiplegia often is observed. Transient blindness is characteristic evidence of air embolism. Generally improvement begins within 1 or 2 days and full recovery ensues Permanent symptoms of disability may result.

Fat Embolism of the Brain. Fat embolism results from (1) fracture of one or more bones, (2) extensive bruising of fat deposits or (3) surgical operations on obese patients.

Within a few hours to a few days after an injury or a surgical operation, symptoms develop with rapid respiration, rapid, feeble pulse, cough, cyanosis, blood-tinged sputum and fever. Some hours later the emboli pass through the capillaries of the lungs and begin to reach the brain and other organs. The patient becomes restless, delirious, stuporous and finally comatose Convulsions often occur. Focal signs such as strabismus, hemiparesis and localized twitchings may occur. Many petechiae are distributed over the thorax and other parts of the body and in the conjunctivae and mucous membranes. Fat globules may be present in the urine and sputum Death almost always results when the symptoms are severe.

Venous Disorders. In the congenital angiomas which involve the brain the veins as well as the arteries may participate in the anomaly When there is a direct connection between artery and vein, without any intervening capillary bed, there is a rapid flow of blood from a high pressure to a low pressure system and as a result a noise or bruit develops. Such noises and bruits are synchronous with the heart beat.

Venous Angiomas. Venous angiomas are associated with malformations of the brain and occur in the meninges and the cortex and deep in the brain tissue. They may be manifested by focal epilepsy.

The diagnosis of venous angioma of the brain may be suggested by the known presence of the angiomas in other parts of the body when there is a history of focal convulsions beginning early in life and associated with transient or persistent hemiplegia or other focal signs (see p 315).

Telangiectases. The roentgenographic appearance of the calcification of intracranial telangiectases is characteristic Such a calcification most frequently is situated in the region of the occipital lobe of the brain in an individual who has facial nevi, focal convulsions, hemiplegia and mental deficiency. Other members of the family may be similarly affected

THE CONVULSIVE STATES

Epilepsy. The manifestations of epilepsy are generally a combination of sensory, mental and motor disturbances

The abnormal sensory disturbances are characterized by the aura Abnormal sensations may originate in either the superficial or the deep sensory nerves, or the special senses, especially vision, hearing or taste may be affected. Thus the aura may be described by its association with any of these senses

The mental symptoms too are varied The mind is likely to be profoundly af-

are characterized by the epileptic fit. The true major epileptic fit never occurs without loss of consciousness. The loss of consciousness may be transient and manifested only by cessation of motor activities in petit mal or minor epilepsy. The motor activity may respond as the Jackson type of fit, which is transient in nature, but this too, if due to epilepsy, is accompanied with loss of consciousness In the jacksonian fit, if the consciousness is lost, the disturbance has spread to both hemispheres in the course of progressive cerebral involvement When the fit is generalized, there is a widespread disturbance of cerebral functions

Those epilepsies produced by a discoverable disease process are termed *symptomatic*, those not directly due to any demonstrable organic brain disease, reflex irritation or other abnormal somatic conditions, are termed *idiopathic*.

Heredity plays a definite etiologic role in epilepsy. Occasionally a patient is encountered whose mother or father and all the brothers and sisters suffer from epilepsy. Rarely are both parents affected. In other instances neither parent has convulsions nor is there a known family history. No one would encourage two epileptic patients to marry each other. If they should wed, children should not be contemplated The same warnings are given to two persons in whose families there was a high incidence of convulsions However, some physicians are liberal enough in their views to condone the marriage of a person who has had convulsions, but in whom the convulsions are entirely controlled, and who has a negative family history for convulsions. Such a person may enter parenthood provided the marital partner and the partner's family are free from convulsive disorders, and provided there is a reasonable assurance of financial security.

The immediate causes for the epileptic attacks are difficult to evaluate Certain physiologic conditions such as occur during the first year of life, pubescence, pregnancy, and the puerperium are often associated with the first attacks. Psychic disturbances, such as shock, fear, other emotions and mental overwork, seem to precipitate a fit. Illness such as tonsillitis and scarlet fever may be associated with the initial attack. The onset of any of the acute infectious diseases in children may be associated with a generalized convulsion. In most instances such a convulsion must be regarded as a manifestation of the acute infection, for these children will not have convulsions later in life However, the incidence of convulsions in association with acute infections is somewhat higher in those children who are later to suffer from epilepsy than in others Various organic brain diseases, trauma, and disorders referable to the ears, eyes, nose and alimentary tract, when associated with epilepsy, have given rise to the term reflex epilepsy A reflex epilepsy therefore seems to arise from an abnormal sensory impulse originating in a diseased organ Alcohol, in susceptible persons, is a precipitating agent of great significance

The age of onset is difficult to determine, because minor attacks may not be recognized, and a nocturnal occurrence of the major attacks may obscure their recognition, they have been interpreted as nightmares or as being dead asleep—sleep paralysis The first-born seem more likely to be affected than other members of the family.

The course of epilepsy is exceedingly variable The first attack may be major and of severe intensity, and this may be repeated several times within 24 hours Thereafter a certain degree of rhythm may characterize the course of the affection. Frequently the major attacks may occur only at night as the so-called nocturnal epilepsy. Later they may appear during the daytime

Some epileptic patients have a rapid succession of several major attacks in each period of disability. This condition is not status epilepticus, for in status epilepticus a person who has been suffering from major attacks undergoes a succession of severe fits with extremely short intervals between them, becomes profoundly exhausted, and lapses into a stupor or coma with hyperpyrexia. In some cases the status ends in death, probably owing to exhaustion of the cerebral centers or to

cardiac failure. Status epilepticus usually is precipitated by the patient indulging in alcoholic beverages and forgetting medications.

The varied pathologic changes of idiopathic epilepsy are interpreted as a result of trauma sustained during the attacks and not as the cause of epilepsy. If there are any changes present at all in the brain these may be described as an increase of glia of the first and second layers of the cortex The glial fibrillary groundwork is diffusely thickened around the blood vessels The ganglion cells show various stages of ischemic degeneration and, in many places, they completely disappear. Certain regions of acute change, comprising complete or incomplete softenings, are found along the blood vessels. This change in the blood vessels and thus the blood supply of certain portions of the brain is not associated with organic occlusions of the blood vessels. It is likely, therefore, that the vascular disturbances are concomitants of convulsions.

Dilated, abnormally placed ventricles, dilated subarachnoid spaces, subdural hematomas, and cerebral edema have been observed in epileptic brains.

The trauma incurred by the epileptic patient during spells is rarely of a serious nature unless the patient falls from a height, into water, or in the way of a moving vehicle, or strikes the head against an object, giving rise to a subdural hematoma.

The attacks, fits or seizures of epilepsy are classed in three groups: (1) minor seizures or petit mal, (2) more violent seizures, mainly with progressive motor manifestations, the so-called jacksonian type of epilepsy and (3) the major seizures or grand mal Except for the grand mal seizures these groups overlap and often are not distinctive.

Petit Mal (*Minor Epilepsy*). The petit mal or minor attacks are extremely variable in character, and when they occur without major attacks, their relation to epilepsy may not be suspected by the patient. In fact, some seizures of minor epilepsy may be difficult of detection except by the experienced physician. The minor seizures may consist of transient dizziness, faintness, indescribable sensations, dazed states, hot flushes, pallor, vomiting, belching, or temper tantrums The minor attack leaves no memory that loss of consciousness has occurred. Suddenly the musculature is relaxed and what is being held in the hand is dropped, or there is a cessation of conversation for a moment and then speech is resumed by continuing with the conversation If a complete loss of consciousness does not occur, the patient may be aware of the occurrence of a spell When some consciousness persists, only the patient may be aware of the spell

Minor attacks may take the form of sudden sensory phenomena related to the visual, auditory, or gustatory sensations. There may be peculiar rushing sensations through the body or sudden jerks and starts The minor spells sometimes take the *form of an aura, which precedes the usual major attacks, as if the attack were* incomplete

Grand Mal (*Major Epilepsy*). Prodromal symptoms usually precede the major attacks [illegible]
may con[illegible]
of giddi[illegible]
one or all extremities. Sudden but transient abdominal pain, feelings of oppression or choking, and hiccough or pounding of the heart are common prodromes. Prickly sensations or numbness may appear in an extremity or up the back.

During a day or two preceding an attack the patient may be irritable, lethargic, or euphoric, or may have feelings of impending disaster.

The *aura* commonly arises in the epigastrium, but frequently it appears in an extremity, and auras do arise in any part of the body or viscera.

Auras may be situated in an arm or a leg or in one side of the face as sensations of numbness, tingling or pain. Frequently, one half of the tongue tingles, and the jaw may deviate or the face may be drawn to one side. Spasm and twitching of an arm associated with numbness, tingling, or a sensation of pins and needles may precede the attack. Muscular movements may involve the arm, the head, the trunk

are characterized by the epileptic fit. The true major epileptic fit never occurs without loss of consciousness The loss of consciousness may be transient and manifested only by cessation of motor activities in petit mal or minor epilepsy. The motor activity may respond as the Jackson type of fit, which is transient in nature, but this too, if due to epilepsy, is accompanied with loss of consciousness. In the jacksonian fit, if the consciousness is lost, the disturbance has spread to both hemispheres in the course of progressive cerebral involvement. When the fit is generalized, there is a widespread disturbance of cerebral functions

Those epilepsies produced by a discoverable disease process are termed *symptomatic*, those not directly due to any demonstrable organic brain disease, reflex irritation or other abnormal somatic conditions, are termed *idiopathic*.

Heredity plays a definite etiologic role in epilepsy Occasionally a patient is encountered whose mother or father and all the brothers and sisters suffer from epilepsy. Rarely are both parents affected. In other instances neither parent has convulsions nor is there a known family history. No one would encourage two epileptic patients to marry each other. If they should wed, children should not be contemplated The same warnings are given to two persons in whose families there was a high incidence of convulsions. However, some physicians are liberal enough in their views to condone the marriage of a person who has had convulsions, but in whom the convulsions are entirely controlled, and who has a negative family history for convulsions Such a person may enter parenthood provided the marital partner and the partner's family are free from convulsive disorders, and provided there is a reasonable assurance of financial security

The immediate causes for the epileptic attacks are difficult to evaluate Certain physiologic conditions such as occur during the first year of life, pubescence, pregnancy, and the puerperium are often associated with the first attacks. Psychic disturbances, such as shock, fear, other emotions and mental overwork, seem to precipitate a fit Illness such as tonsillitis and scarlet fever may be associated with the initial attack The onset of any of the acute infectious diseases in children may be associated with a generalized convulsion In most instances such a convulsion must be regarded as a manifestation of the acute infection, for these children will not have convulsions later in life. However, the incidence of convulsions in association with acute infections is somewhat higher in those children who are later to suffer from epilepsy than in others Various organic brain diseases, trauma, and disorders referable to the ears, eyes, nose and alimentary tract, when associated with epilepsy, have given rise to the term reflex epilepsy A reflex epilepsy therefore seems to arise from an abnormal sensory impulse originating in a diseased organ. Alcohol, in susceptible persons, is a precipitating agent of great significance

The age of onset is difficult to determine, because minor attacks may not be recognized, and a nocturnal occurrence of the major attacks may obscure their recognition, they have been interpreted as nightmares or as being dead asleep—sleep paralysis The first-born seem more likely to be affected than other members of the family.

The course of epilepsy is exceedingly variable The first attack may be major and of severe intensity, and this may be repeated several times within 24 hours. Thereafter a certain degree of rhythm may characterize the course of the affection Frequently the major attacks may occur only at night as the so-called nocturnal epilepsy. Later they may appear during the daytime

Some epileptic patients have a rapid succession of several major attacks in each period of disability. This condition is not status epilepticus, for in status epilepticus a person who has been suffering from major attacks undergoes a succession of severe fits with extremely short intervals between them, becomes profoundly exhausted, and lapses into a stupor or coma with hyperpyrexia. In some cases the status ends in death, probably owing to exhaustion of the cerebral centers or to

automatism occurs The patient wanders away, talking when necessary, but completely amnesic for his normal personality. Many of these psychomotor attacks have much in common with the dreamy states which occur with lesions of the temporal lobes.

Status epilepticus is a serious condition in which the patient has one generalized convulsion after another in rapid succession. Usually consciousness is not recovered between attacks. Death may result. Status epilepticus may occur in an epileptic person when therapy is improper or inadequate or when satisfactory medical management is suddenly discontinued, often during an alcoholic bout. However, status epilepticus may occur in those who have never had any treatment.

EXAMINATION IN EPILEPSY During the major attacks, the pupils are usually dilated and rarely react to light The reflexes, including the corneal, are usually abolished Changes in respiration and increase in pulse rate and blood pressure may precede changes in muscular tone and thus suggest a medullary origin of the fits.

After a severe generalized fit deep reflexes may be absent and an extensor plantar response present for some hours; the patient may be unable to understand spoken words, temporary bilateral facial weakness and irregular coarse ocular nystagmus may be present for some time after the seizure.

Injury may be present which was incurred by the physical impact of the limbs, injury of the blood vessels may occur Corneal and subcutaneous hemorrhages appear frequently

In the chronic epileptic patient, owing to vascular lesions which are the results of the fits, there may be present a modification of tonus resembling an extrapyramidal type of rigidity and posture. Other neurologic signs may be those of a slowly progressive, bilateral degeneration of the pyramidal system or a progressive pseudobulbar palsy with contractions in flexor attitudes. Neurologic signs are rare in all except those who have severe forms of the disease.

During the period between attacks a leukopenia and a relative eosinophilia may be present Immediately after an attack often there is leukocytosis associated with a rise in temperature During the attack the blood pressure and the cerebrospinal fluid pressure are increased. Frequent casts and variable quantities of albumin occur in the urine after an attack.

Electro-encephalograms of patients who have epilepsy, and of their relatives, often reveal cerebral dysrhythmias all of the same type The cerebral dysrhythmia seems therefore to be inherited and constitutional It can be demonstrated in twins and nonepileptic persons in the same family However, cerebral dysrhythmias are not synonymous with epilepsy Many apparently normal persons have some abnormality in their electro-encephalogram The full significance of these facts has yet to be determined

DIAGNOSIS OF EPILEPSY The most difficult part of the diagnosis in epilepsy is the separation of symptomatic from idiopathic forms of the disease. Numerous conditions of an organic nature, especially brain tumors, are associated with epileptiform fits

The convulsive seizures themselves are to be differentiated from hysteria and malingering. The hysterical fit does not show the progression of tonicity, there is not the deep unconsciousness, and the convulsions are not orderly. There is a peculiar grotesque excitability during which the patient is never completely unconscious The convulsions usually occur after some emotional disturbance, and lack the periodicity of the epileptic, and finally, the hysterical personality is present. The spells usually occur in the presence of other persons, and the patient rarely injures himself

The malingerer has usually an obvious cause for his procedures and performs his convulsions in front of people, never alone. He rarely hurts himself when

or the leg before loss of consciousness. Twitching of the thumb and index finger, and movements of the same side of the face often appear simultaneously. Bilateral and generalized auras are but increased distributions of the numbness, tingling, or pains and twitching, jerking in the limbs, and tremor of the localized auras. However, shivering and faintness are truly generalized auras.

Auras involving the special senses may be manifested by gustatory or olfactory sensations and smacking of the lips. Such auras are comparable to those which accompany uncinate fits. Visual auras consisting of flashes of light, of color, and of hallucinations of movement may appear Auditory auras of hissing, ringing and other noises are frequent

Major attacks of epilepsy often commence with a wild, harsh, screaming sound produced by expelling or sucking air through the glottis. The cry occurs at the time of loss of consciousness.

The first part of the convulsion is a tonic muscular spasm. The head and eyes may be rotated to one side The facial muscles are in strong contraction, the fingers flexed at the metacarpophalangeal joints and extended at the others. The thumb is adducted into the palm, the elbow joint is flexed to about a right angle. The legs are extended and the feet inverted. The muscular contractions are bilaterally equal. Respiratory movements are arrested until deep cyanosis and engorgement ensue. Occasionally, the tonic spasm may be so violent that a shoulder, hip or mandible may be dislocated. Sometimes fractures of bones occur, including fractures of the jaw and compression fractures of the vertebrae.

When the patient is almost asphyxiated, the tonic muscular spasm changes to a clonic one As the remissions become greater, the contractions become stronger. Finally, as the remissions become longer, the spasms cease.

Saliva mixed with air bubbles is spit and spattered from the mouth by the *forcible clonic movements causing the so-called foaming at the mouth* The patient frequently bites the tongue or the cheek. A tooth may be dislodged. Loss of control of the urinary and anal sphincters and the involuntary passage of urine and feces is common and diagnostically suggestive

The convulsion may consist only of loss of consciousness and tonic spasm end*ing without the appearance of clonic intermissions.* These sudden collapses and loss of consciousness resemble a benign syncope of circulatory origin

After an attack the patient may pass directly into a heavy sleep, often lasting for hours, or he may awaken from unconsciousness for a brief period and then lapse into a deep sleep. The days immediately following an attack are associated with generalized muscular soreness, lethargy, and hebetude. There may be a persistent weakness in an arm or a leg for a few days after the attack. If such weakness does not recede within a few days, a brain tumor is suspected.

A type of major attack, the *cerebellar fit,* begins with stiffening of the entire musculature. The patient becomes rigid in extension, the back is arched and the head extended in opisthotonos Extreme cyanosis occurs as a result of rigidity of the thoracic musculature Gradually, with relaxation, the apnea gives way to shallow irregular respiration; then respiration becomes normal and consciousness returns. These attacks are often followed by changes in the sensorium.

In an *akinetic fit* the patient falls unconscious without an aura Consciousness is quickly recovered The upright posture is maintained without subsequent disability.

A rare type of attack is the so-called *inhibitory epilepsy*. Instead of a local motor seizure, a transient focal paralysis occurs [illegible] temporary

Epilepsy consisting of periods of depression or derangement attain the s[illegible] homicidal. There are spells in which a peculiar [illegible]

and by transient periods of muscular weakness. Either characteristic may be produced by sudden emotional stimuli, of which amusement with laughter is the one most commonly operative

Unless the physician is cognizant of this syndrome and if it is not clearly described by the patient, it is likely to be interpreted as an epileptic seizure. In the accesses of cataplexy, there is no diminution of consciousness. When present, these symptoms are of daily occurrence

The Fainting Attack (Vasovagal Syncope). The faint is a characteristic manifestation of sudden and transient cerebral anemia, and though most frequently seen in the child or the adolescent, it may occur in the adult also. The factors which give rise to it are the fasting state, fatigue, unpleasant emotions, the debility that may follow illness, and confinement in a hot and ill-ventilated room. In weakly subjects the sudden assumption of the erect posture may suffice to induce a faint. A faint rarely occurs when the subject is leaning forward or is lying down. The fall in blood pressure and the attendant loss of consciousness indicate splanchnic dilatation from vasomotor failure (see Chapter 5)

The family and the patient may dismiss a minor or a major attack of epilepsy as a faint The physician is careful not to sanction such a home-made diagnosis until he can be sure about it, lest he become involved in the mistake In epilepsy there is no slowing, weakening or irregularity of the pulse.

In the majority of instances the circumstances leading to the attack and the general emotional status of the patient render diagnosis simple In the faint there is no tongue-biting or loss of urine or feces during the attack

The Faint and the Valsalva Maneuver. In the "mess trick" (played in a mess or at a party) the uninformed person is persuaded to hyperventilate for about a minute and then his chest is suddenly compressed by someone standing behind him He usually loses consciousness for a few seconds. The hyperventilation leads to dilatation of blood vessels of the muscles and constriction of blood vessels of the brain. Compression of the chest causes the victim to perform an involuntary Valsalva maneuver, which in the presence of peripheral dilatation is sufficient to reduce effective blood pressure and consequently cerebral blood flow to levels that cause unconsciousness

In the "fainting lark" the uninformed person squats and takes 20 deep breaths, then rises quickly to his feet, closes his nostrils with his fingers and blows hard. He then drops to the ground and "passes out" for a period of about half a minute. The mechanism in the fainting lark is essentially the same as in the mess trick, except that a voluntary Valsalva maneuver replaces the involuntary response to chest compression with the added factor of the fall in blood pressure produced by rising from the squatting posture.

COMMENTS ON CONVULSIVE DISORDERS

The commonest of convulsive disorders is the epileptic fit The epileptic fit affects but few of the general population and it is largely confined to younger individuals The commonest fit occurring in older persons is of vascular origin, a hemiplegia, monoplegia or paraplegia. Brain tumors are uncommon causes of fits Likewise a fit as a manifestation of neurosyphilis is rare

A sudden convulsive seizure in the presence of gross cerebral symptoms in a patient who has previously enjoyed good health is suggestive of *hemorrhage*, either in a glioma or from an aneurysm, gliomas being, from their loose texture and high vascularity, particularly liable to spontaneous hemorrhages Aneurysms, especially nonsyphilitic congenital aneurysms, run their course at first without symptoms, they are prone to recurrent leakages of blood into the subdural and subarachnoid spaces In the latter event, there is sudden intense headache with rigidity at the back of the neck, Kernig's sign being positive.

allowed to fall. He presents none of the vegetative signs, and can be aroused from his supposed stupor by the production of pain or a dash of cold water in the face. The production of pain or dashing cold water on a patient are both undesirable procedures in the practice of medicine. Of the two procedures it is much more effective to dash cold water on the malingerer's face. A definitely abnormal electroencephalogram practically excludes hysteria as the sole cause of the convulsions. It does not exclude the possible presence and importance of functional emotional disturbances

The biting of the tongue and the loss of sphincteral control are indicative only of a complete loss of consciousness during a fit and have no further diagnostic importance.

In the absence of focal or general neurologic signs, and when the foredescribed conditions are accordingly fulfilled, the diagnosis of major or minor epilepsy may be made If there be doubt, observation for varying periods, with the proper administration of anticonvulsants, may be required before a diagnosis can be made

Idiopathic epilepsy does not present a hopeless outlook. Some of those who have this condition can be completely relieved of their attacks by proper treatment; many of the others can have the frequency and severity of their attacks materially reduced A few who have the disease deteriorate rapidly and require domiciliary care and treatment

Pyknolepsy is a minor or petit mal-like epilepsy which occurs most frequently in girls and young women and in young children Major seizures are not usually associated. The spells consist of some mannerism and an extremely short lapse in consciousness There may be smacking of the lips and twisting of the fingers and occasionally flushing or paleness of the face. Consciousness is lost so suddenly that there is no time for auras The patient does not fall if standing or change posture if in bed After the spell, the patient may resume conversation where it was interrupted. Occasionally urinary incontinence has occurred during an attack. The spells may come with great frequency, occurring 30, 40 or more times per day. Curiously, these attacks often cease at puberty or in girls at the onset of menstruation. The presence of many minor spells, without major attacks, unaffected by medicaments indicates a good prognosis. Usually this type of convulsive disorder (pyknolepsy) ceases spontaneously without physical or mental deterioration Cessation of the attacks, in former days, was observed after the shock of administration of vermifuges such as pumpkin seeds The administration of pumpkin seeds is heroic treatment for either epilepsy or worms.

Jacksonian Epilepsy. Epilepsy without loss of consciousness which spreads from the beginning of involuntary clonic contractions in a hand and successively involves the forearm, arm and shoulder is jacksonian epilepsy. Consciousness may be lost if the second hemisphere is involved These attacks are indicative of irritation of the motor projection system in the brain If this irritation should be from a tumor or an injury, the lesion may be in the motor cortex or below in the frontal, parietal, or peduncular structures.

The Hysterical Fit. In the hysterical fit there is no ordered sequence of events, there is no true loss of consciousness, there are no changes in the reflexes, there is no incontinence or tongue-biting, and the patient (of either sex) does not sustain injuries in falling, nor fall in a dangerous place. The eyes are not passively closed as in true coma, but shut, and the attempt to open them with the finger is usually met with a tightening of the lids The convulsion is not a matter of tonic and clonic stages but of struggling which is aggravated by attemps at restraint The hysterical fit may appear to last for hours, phases of apparent unconscious intermitting with phases of activity.

Narcolepsy. Narcolepsy may resemble minor epilepsy. Narcolepsy is characterized by excessive, uncontrollable drowsiness relieved by a short period of sleep,

characterized by zigzag courses across the visual field to which they are limited Vision is possible only between the scotomas. Such scotomas may occur without a succeeding headache.

The attacks of headache are periodic and have no definite time of the day at which they may begin or end. Mild attacks may be of less than an hour's duration. Many patients find that if they lie down and sleep for a short time or if they even relax completely for an hour or more, the pain will cease. Severe attacks may continue for 2 or 3 days.

The first attack of migraine comes usually during puberty. The attacks may be so mild that they are passed unobserved until later in life. It is the onset of severe migraine headaches in later life, particularly at the time of the menopause, that resembles the beginning of headache due to intracranial hypertension

INTRACRANIAL TUMORS

(Brain Tumors)

Brain tumors arise from the neuroglia of the brain The time of onset and the nature of the symptoms, whether general or focal, usually depend on the expansile characteristic of the tumor. Infiltration of the brain by malignant neuroglia (glioma) may delay either general or focal symptoms until the tumor has infiltrated widely and gives focal symptoms or expands enough to produce the symptoms of intracranial hypertension. The infiltrating anaplastic cells pass between the functional units of the brain and find new places to grow without disturbances of the functional units until they are compressed by an abundant or localized growth of the anaplastic cells There is no definite relationship between the size of the tumor and the symptoms which it produces, nor between the symptoms and the amount of invasion of the brain which may be present The relationship lies in the localized growth of the cells in or near the vital centers and to the circulatory disturbances it can produce.

The expansion of the lesion causes an expulsion of cerebrospinal fluid from the cranial cavity. This fluid passes into the venous blood The total volume of the veins is great and rarely is there obvious venous congestion In some cases, however, transient cyanosis, facial edema and sometimes slight generalized edema may be present Facial edema is the commonest of these manifestations. During the periods of rapid increases in intracranial tension the arterial tension may be slightly increased (160 to 170 mm. of mercury). Except for these transient increases the arterial tension remains normal

Venous congestion leads to an increased secretion of cerebrospinal fluid from the choroid plexuses, and to a diminished reabsorption of this fluid into the dural venous sinuses. The volume of cerebrospinal fluid therefore begins to rise, and since the cranial and spinal dural sac is relatively fixed in volume, pressure within it rises. This leads to still further venous compression and thus a vicious cycle is established However, during the course of establishment of the vicious cycle or soon thereafter the outflow of cerebrospinal fluid from the ventricular system may be obstructed The ventricles then distend, compressing the surrounding portions of the brain.

There are four types of cells contained in the supporting structures in the normal brain and spinal cord. astrocytes, ependymal cells, oligodendroglial cells and nerve cells All of these cells may originate malignant tumors. Of these four types of cells the astrocyte is most prone to form a malignant tumor Less frequently do ependymal cells, and still less frequently do oligodendroglial cells, and rarely do nerve cells form neoplasms The general term used to designate the malignant tumors arising from these cells of the supporting structures (the neurogliocytes) is glioma.

Gliomas. A glioma is a malignant tumor composed of tissue (as noted in the immediately foregoing discussion) which represents neuroglia in any one of its stages

Unruptured *aneurysm* of the intracranial portion of the internal carotid artery produces a characteristic sphenoidal fissure syndrome, comprising unilateral ocular palsy, supra-orbital pain, retinal hyperemia and even chemosis. Sometimes the adjacent optic foramen is affected, causing unilateral visual impairment and optic atrophy. If, in addition to the foregoing, there is roentgenologic evidence of erosion of the sella turcica on the side of the lesion, with or without linear streaks of calcification in the aneurysmal wall, supplemented by filling the aneurysm with thorotrast, the diagnosis is complete

A convulsive seizure occurring in a middle aged adult who has enjoyed good health prior to and after the fit requires a differentiation among epilepsy, neurosyphilis and intracranial hemorrhage, tumor or aneurysm.

MIGRAINE

Migraine is a periodic, recurrent, headache which affects several members of a family. It is due to some inherited constitutional defect. The disorder has in common with epilepsy and some headaches due to brain tumor sensory and motor phenomena. The sensory phenomena consist of visual and psychic disturbances *which precede or accompany the cephalalgia.*

Psychic disturbances such as a subjective feeling of difficulty in thinking, of inability to find the proper word, and a consciousness of slowing of all mental processes are commonly present in migraine but not etiologic. Numbness and thickness of the lips and tongue occur in association with difficulty in speech States of confusion, of excitement and of delirium are described which accompany or replace the headaches.

Owing to variations in manifestations, different types of migraine have been described. Most attacks of true migraine are preceded by visual disturbances, but when such disturbance is a special definite feature, amblyopia, the headache is termed ophthalmic migraine. When the attack is followed by ophthalmoplegia, it is ophthalmoplegic migraine Some patients have abdominal pain, "abdominal migraine," during each attack of migraine, or the abdominal pain may occur apart from the headache as a migrainous equivalent.

Ophthalmic migraine frequently is accompanied by some degree of nausea when the headache is most severe Often if vomiting follows, a great deal of relief is afforded, although vomiting may be present for several days without relief. The cause of the vomiting is not evident It may be an expression of an intracranial disturbance, perhaps vagal stimulation. Accompanying the nausea and vomiting there may be vertigo and occasionally bradycardia.

The term ophthalmoplegic migraine is applied to certain recurrent unilateral headaches which are associated with transient palsies of the extra-ocular muscles. The palsy disappears within a few days or weeks, but it is said that it may eventually become permanent

The most characteristic type of migraine is the hemicrania which begins over one eye and extends backward over the whole side of the head or begins in the occiput and moves forward. The pain may commence locally but eventually becomes general. It may move from one side to the other. The pain is frequently felt in the eyeballs and spreads downward into the cheek. There may be tenderness of the scalp which persists after the head pain has ceased. Often successive attacks of migraine are images of preceding attacks in regard to the place of origin and the progression of the pain.

Descriptions of the onset of the headache beginning with scintillating scotomas limited in distribution to that of an homonymous hemianopsia, and variations of the visual defect to the point of quadrantanopsia, can be given by many patients The margins or the whole of some scotomas are described as *resembling* strips of tinsel in a gleaming light being blown by the wind. The visual disturbances are

It was intimated in the introductory paragraphs on brain tumors that the symptoms of brain tumor arise from an expansion of the tumor. An expanding mass in a closed rigid container like the skull will give rise to two kinds of symptoms, namely, general symptoms, from the increased intracranial pressure, and local symptoms, referable to the seat or origin of the tumor.

General Symptoms of Brain Tumors. The general symptoms are characterized by a progressive change in cerebral function without a febrile illness or evidence of vascular disease at the beginning of the symptoms, nor is fever a part of the illness thereafter. If fever has not been present and if there are no evidences of vascular hypertension, for instance, the so-called malignant hypertension of Keith and Wagener, or encephalitis arising during the course of chronic lead poisoning, and the patient is an adult without evidence of hydrocephalus, the presence of headache, papilledema and vomiting is positive evidence of increased intracranial pressure, caused by an expanding lesion of the brain.

MENTAL CHANGE Early in the course of an expanding lesion of the brain, mental changes are present but they are likely to be difficult if not impossible to interpret. In all instances of increased tension within the skull a gradual blunting of alertness, of memory, and of power of attention develops. Episodic irresponsible moods, tantrums of temper, and poor judgment are common

HEADACHE. Headache is a common symptom of increased intracranial pressure. The origin of the headache is regarded by some as being due to stretching of the dural partitions and by others as being due to abnormal tension in the walls of the cerebral blood vessels However, a general rise of intracranial tension may develop without there being a headache. It is well known too that a headache may be produced or increased by a lumbar puncture which lowers intraspinal and intracranial pressure (see Complaint, Chapter 2).

The evaluation of the symptom of headache is difficult since headache is among the commonest of all subjective symptoms Most headaches result from fatigue or have as a basic etiology a psychoneurosis. Migraine headaches may present many features which resemble headache due to intracranial lesions.

The headache of the psychoneurotic is continuous with slight variations over weeks, months, or even years Despite the descriptions of the severity of the headache by the psychoneurotic, cross-examination without comment usually reveals that the complaint of headache is in reality not a cephalalgia at all but sensations of weight, pressure, or constriction in the head. The hysterical patient is pleased to have an opportunity to relate the great suffering that is bestowed by the constant headache The anxious neurotic patient is despondent on being urged to describe the headache However, both the hysteric and the neurotic patients are anxious to convince their friends and the physician of the truthfulness of their suffering.

In contrast to the behavior of the psychoneurotic and the migrainous individual is the behavior of a patient who has a headache of intracranial origin. Such a patient is quietly preoccupied with the cephalalgia. There is economy of movement and of speech Questions or physical examination when the cephalalgia is present are unwanted. The headache is intermittent, not continuous. When the patient is free from pain, the relief is cheerfully admitted During the interval of freedom from pain the patient returns or attempts to return to normal life in the hope and faith of a child that the pain will not recur. Only with recurrence of the headache do these patients become despondent

The headache due to brain tumor is of a sickening throbbing character and it is increased by physical exertion, coughing, sneezing or stooping It has a tendency to develop during the night, awaking the patient in the early morning During its early course the headache often ceases as soon as the patient is awake and has food or drink. Relief may be obtained by propping up in bed In the beginning the pain is intermittent. The paroxysms then become more frequent and more severe,

of development. These stages of development are represented by the progressive development of astrocytes, ependymal cells, oligodendroglial cells and nerve cells. Kernohan and associates have expressed the belief that the term astrocytoma should be used to designate all tumors arising from these cells

Kernohan is of the opinion that there is a clear-cut correlation between the grade of malignancy, the life history of each tumor (the astrocytoma) and the postoperative survival period. The grade of malignancy of these tumors increases with the age of the patients in whom they grow.

On the basis of anaplasia of each of the four adult types of cells in the central nervous system, with the sole exception of the medulloblastoma, which is in a class by itself, Kernohan has offered a new classification of gliomas. The grade of malignancy is designated as 1, 2, 3 or 4 depending on the degree of anaplasia present Grade 1 of astrocytoma represents a typical slow-growing astrocytoma, grade 2 a more cellular, rapidly growing tumor formerly designated astroblastoma, and grade 3 or 4 the astrocytoma, formerly designated glioblastoma multiforme, with low (grade 3) or high (grade 4) degree of malignancy.

Gliomas of the ependymoma group are likewise classified on the basis of four grades of malignancy

The oligodendrogliomas have not been classified according to different grades of malignancy However, the consensus is that most oligodendrogliomas are very slowly growing gliomas It is also well known that there are some which are highly malignant and rapidly growing and these have been referred to as oligodendroblastomas

Tumors composed exclusively or even predominantly of nerve cells are infrequently found in the central nervous system. The majority of such tumors are a mixture of adult nerve cells and astrocytes or dedifferentiated cells of either or both types. These tumors could be graded 1 to 4 depending on the dominance of the anaplastic cells in the growth, and the term neuro-astrocytoma, grade 1, 2, 3 or 4, could be used. The group of tumors described as spongioneuroblastomas would thus be designated neuro-astrocytomas, grade 2 to 4, depending on the degree of anaplasia present in the tumors

Medulloblastomas usually occur in the midline of the cerebellum of children and occasionally in young adults, and only rarely in other parts of the central nervous system Because of the relatively constant and characteristic structure of this type of glioma no attempt to grade its malignancy has been made

Kernohan's suggested modification of the classification of gliomas is given in Table 15-1

Table 15-1. Suggested Modification of Classification of Gliomas

New	Old with New in Parenthesis
Astrocytoma, grade 1 to 4	Astrocytoma (astrocytoma, grade 1) Astroblastoma (astrocytoma, grade 2) Polar spongioblastoma (obsolete) Glioblastoma multiforme (astrocytoma, grades 3 and 4)
Ependymoma, grade 1 to 4	Ependymoma (ependymoma, grade 1) Ependymoblastoma (ependymoma, grade 2 to 4) Neuro-epithelioma (obsolete) Medullo-epithelioma (ependymoma, grade 4)
Oligodendroglioma, grade 1 to 4	Oligodendroglioma (oligodendroglioma, grade 1) Oligodendroblastoma (oligodendroblastoma, grade 2 to 4)
Neuro-astrocytoma, grade 1 to 4	Neurocytoma Ganglioneuroma (neuro-astrocytoma, grade 1) Gangliocytoma Ganglioglioma Neuroblastoma Spongioneuroblastoma (neuro-astrocytoma, grade 2 to 4) *Glioneuroblastoma* And others
Medulloblastoma	Medulloblastoma

From Adson, A W, and Svien, H J, Brain Tumors Diagnosis and Treatment, Rocky Mountain M J, 45 962, 1948

It was intimated in the introductory paragraphs on brain tumors that the symptoms of brain tumor arise from an expansion of the tumor. An expanding mass in a closed rigid container like the skull will give rise to two kinds of symptoms, namely, general symptoms, from the increased intracranial pressure, and local symptoms, referable to the seat or origin of the tumor.

General Symptoms of Brain Tumors. The general symptoms are characterized by a progressive change in cerebral function without a febrile illness or evidence of vascular disease at the beginning of the symptoms, nor is fever a part of the illness thereafter. If fever has not been present and if there are no evidences of vascular hypertension, for instance, the so-called malignant hypertension of Keith and Wagener, or encephalitis arising during the course of chronic lead poisoning, and the patient is an adult without evidence of hydrocephalus, the presence of headache, papilledema and vomiting is positive evidence of increased intracranial pressure, caused by an expanding lesion of the brain.

MENTAL CHANGE. Early in the course of an expanding lesion of the brain, mental changes are present but they are likely to be difficult if not impossible to interpret. In all instances of increased tension within the skull a gradual blunting of alertness, of memory, and of power of attention develops. Episodic irresponsible moods, tantrums of temper, and poor judgment are common.

HEADACHE. Headache is a common symptom of increased intracranial pressure. The origin of the headache is regarded by some as being due to stretching of the dural partitions and by others as being due to abnormal tension in the walls of the cerebral blood vessels. However, a general rise of intracranial tension may develop without there being a headache It is well known too that a headache may be produced or increased by a lumbar puncture which lowers intraspinal and intracranial pressure (see Complaint, Chapter 2).

The evaluation of the symptom of headache is difficult since headache is among the commonest of all subjective symptoms. Most headaches result from fatigue or have as a basic etiology a psychoneurosis Migraine headaches may present many features which resemble headache due to intracranial lesions

The headache of the psychoneurotic is continuous with slight variations over weeks, months, or even years. Despite the descriptions of the severity of the headache by the psychoneurotic, cross-examination without comment usually reveals that the complaint of headache is in reality not a cephalalgia at all but sensations of weight, pressure, or constriction in the head. The hysterical patient is pleased to have an opportunity to relate the great suffering that is bestowed by the constant headache The anxious neurotic patient is despondent on being urged to describe the headache However, both the hysteric and the neurotic patients are anxious to convince their friends and the physician of the truthfulness of their suffering

In contrast to the behavior of the psychoneurotic and the migrainous individual is the behavior of a patient who has a headache of intracranial origin. Such a patient is quietly preoccupied with the cephalalgia. There is economy of movement and of speech Questions or physical examination when the cephalalgia is present are unwanted The headache is intermittent, not continuous. When the patient is free from pain, the relief is cheerfully admitted During the interval of freedom from pain the patient returns or attempts to return to normal life in the hope and faith of a child that the pain will not recur. Only with recurrence of the headache do these patients become despondent.

The headache due to brain tumor is of a sickening throbbing character and it is increased by physical exertion, coughing, sneezing or stooping. It has a tendency to develop during the night, awaking the patient in the early morning During its early course the headache often ceases as soon as the patient is awake and has food or drink. Relief may be obtained by propping up in bed. In the beginning the pain is intermittent. The paroxysms then become more frequent and more severe,

and are at times accompanied by vomiting, the effort of which intensifies the headache. In great increases of tension within the cranium the paroxysms often are terrifying in their intensity. The patient may hold the hand above the head but is fearful to touch the head lest the presence of the hand further intensify the pain. The intervals of freedom from pain shorten, the sensorium is dulled, the voice weakens, and the patient may pass into coma for several hours at a time but will arouse and be weak but free of pain. When periods of coma supervene, the last part of the downward course is at hand, although the duration may spread over months.

During the progression of the headache there is an added sickness, consisting of apathy, drowsiness, blurring of vision, double vision, and defects in memory and attention. The patient may seem to be profoundly preoccupied.

A patient who has an expanding lesion of the brain may have migraine. If so, during the early course of brain tumor there are no definite differential diagnostic criteria. Migraine has the tendency to increase or decrease periodically in intensity and is often accompanied by vomiting just as is the headache of intracranial hypertension.

Vomiting. Vomiting is not a constant feature of intracranial hypertension. When vomiting is associated with increased intracranial tension, it is of a retching, persistent type. It is, as classically described, projectile in type only when the stomach is full. This sort of vomiting is characterized by not being preceded by nausea. It is prone to occur in the early morning, it may or may not be accompanied by a headache. It is less likely than the headache to be precipitated by exertion or by stooping. Transient unconsciousness may be added to the vomiting and during this occasionally the lips or tongue may be bitten. Terminally the gastric contents may be regurgitated but not vomited, and appear in the nasopharynx as an irritating phlegm causing coughs, choking and respiratory embarrassment, pneumonia and death.

Papilledema. The increased pressure of cerebrospinal fluid within the subarachnoid space is communicated to the fluid within the sheath of the optic nerve. This is recognized ophthalmoscopically as papilledema (see Diseases of the Eye, Chapter 4). Papilledema develops slowly in some and rapidly in others. Papilledema is the most definite diagnostic sign of an expanding intracranial lesion when malignant hypertension is not present. The headaches and papilledema which occur during the course of malignant hypertension may be of the same intensity and appearance as those which occur in an expanding lesion of the brain.

Disturbances of visual acuity or double vision often do not correlate with ophthalmoscopic appearances. Vision may fade gradually, transient blurring occurring during physical exertion, or it may be lost suddenly. If the raised intracranial pressure be not relieved, papilledema proceeds to atrophy of the optic nerve.

Slowing of the Pulse Rate. Slowing of the pulse rate is common in head injuries associated with raised intracranial tension, in some cases of subarachnoid hemorrhage, in abscess and subdural hematoma, and in tumors which cause general signs of raised intracranial tension quickly. In instances of more gradual development, intracranial tension may be greatly increased without any slowing of the pulse, or the pulse rate may fall to 50 or even less, such a fall being of grave import.

Warning. When there are clinical indications of raised intracranial pressure, lumbar puncture or the withdrawal of cerebrospinal fluid should never be performed except for some precise and compelling reason. The fatal issue of lumbar [illegible]

Convulsions. The convulsive seizures of brain tumor [illegible] and indistinguishable from those of idiopathic epilepsy. A convulsion may be the first manifestation, occurring when physical examination of the patient does not [illegible] abnormal physical findings. A convulsion occurring for the first time after

maturity or later requires a consideration of neurosyphilis or brain tumor. These generalized fits have no localizing value, nor do they indicate raised intracranial tension.

Localizing Symptoms of Tumor of the Cerebral Hemispheres. The origin of local symptoms is due to interference with blood supply or to destruction of tissue by the lesion itself If localized pressure from a localized lesion predominates at the outset, the first symptoms may be those of a progressive local lesion of the brain, without signs of a general rise of intracranial tension If the increased pressure is generalized, as often occurs in an infiltrating lesion, the symptomatology is wholly that of intracranial tension and there may be no clue to the situation of the original expanding lesion The absence of early clinical manifestations in many of those who have intracranial tumor depends largely on the plausible explanation that at first malignant cells may be dispersed between the axons and dendrites in a way which will not interfere with their function, and thus there is at least a reasonable cause for the absence of localizing symptoms and signs in the early clinical stages of highly malignant gliomas.

MOTOR SYMPTOMS. Tumors or lesions of the *motor cortex* of the frontal lobes produce irritative and paralytic phenomena

The irritative phenomena consist of unilateral convulsions consisting of spasmodic deviation of the head and eyes to the side opposite from the lesion. These convulsions may occasionally be of the jacksonian type, which commences on the side opposite to the tumor in the face, tongue, arm, or leg, according to the part of the motor cortex which is chiefly implicated In a jacksonian fit the local convulsion, which usually consists of tonic spasm followed by coarse clonic jerks, may be definitely localized to the same group of muscles, or it may spread from them to other groups of muscles, and always in a regular order Jacksonian convulsion differs from ordinary epilepsy in that the patient usually retains consciousness all the time and he may observe the progression of the fit If the convulsion spreads across the middle line, however, and becomes bilateral, consciousness is lost

The paralytic phenomena, in tumors of the motor region, consist in monoplegic weakness of the convulsed muscles during the interparoxysmal periods

A *subcortical growth,* involving the pyramidal fibers, is usually indicated by an initial monoplegia followed later by jacksonian convulsions Convulsions may not be repeated until weeks or months later The deeper the growth, the less tendency is there for the convulsions to localize Tumors of the precentral or motor cortex, if extending across the fissure of Rolando to the postcentral convolution, are usually associated with a sensory aura in the affected limb at the beginning of the motor convulsion

Tumors occurring in the *postfrontal area* may cause unilateral fits with a spasmodic deviation of the head and eyes to the side away from the lesion In left-sided tumors in right-handed patients motor aphasias are common and often persistent. In some left-sided postfrontal tumors aphasia is absent when the individual is right-handed, if the handedness is determinable (see Handedness, Chapter 6).

Tumors on the *orbital surface of the frontal lobe* occurring in the brain or in the meninges may be associated with unilateral diminution of vision, and early and persistent anosmia on the side of the lesion In these there are the same psychic alterations as those which accompany prefrontal lesions.

MENTAL SYMPTOMS Tumors situated on either side of the cortex may or may not give mental symptoms If there are mental symptoms, they appear before the symptoms of intracranial hypertension The mental symptoms consist of alterations in temperament A cheerful person may become depressed and lose power of initiative Yawning and failure of memory ensue Intellectual dullness may be expressed by simple jocularity, together with euphoria and absence of anxiety and concern about the illness. There is a deficiency of attention and often there is a profound

and are at times accompanied by vomiting, the effort of which intensifies the headache *In great increases of tension within the cranium the paroxysms often are terrifying in their intensity.* The patient may hold the hand above the head but is fearful to touch the head lest the presence of the hand further intensify the pain The intervals of freedom from pain shorten, the sensorium is dulled, the voice weakens, and the patient may pass into coma for several hours at a time but will arouse and be weak but free of pain When periods of coma supervene, the last part of the downward course is at hand, although the duration may spread over months.

During the progression of the headache there is an added sickness, consisting of apathy, drowsiness, blurring of vision, double vision, and defects in memory and attention The *patient may seem to be profoundly preoccupied.*

A patient who has an expanding lesion of the brain may have migraine. If so, during the early course of brain tumor there are no definite differential diagnostic criteria. Migraine has the tendency to increase or decrease periodically in intensity and is often accompanied by vomiting just as is the headache of intracranial hypertension

Vomiting Vomiting is not a constant feature of intracranial hypertension *When vomiting is associated with increased intracranial tension, it is of a retching, persistent type* It is, as classically described, projectile in type only when the stomach is full This sort of vomiting is characterized by not being preceded by nausea It is prone to occur in the early morning, it may or may not be accompanied by a headache It is less likely than the headache to be precipitated by exertion or by stooping. Transient unconsciousness may be added to the vomiting and during this occasionally the lips or tongue may be bitten Terminally the gastric contents *may be regurgitated but not vomited, and appear in the nasopharynx* as an irritating phlegm causing coughs, choking and respiratory embarrassment, pneumonia and death.

Papilledema. The increased pressure of cerebrospinal fluid within the subarachnoid space is communicated to the fluid within the sheath of the optic nerve. This is recognized ophthalmoscopically as papilledema (see *Diseases of the Eye,* Chapter 4) Papilledema develops slowly in some and rapidly in others Papilledema is the most definite diagnostic sign of an expanding intracranial lesion when malignant hypertension is not present The headaches and papilledema which occur during the course of malignant hypertension may be of the same intensity and appearance as those which occur in an expanding lesion of the brain

Disturbances of visual acuity or double vision often do not correlate with *ophthalmoscopic appearances Vision may fade gradually, transient* blurring occurring during physical exertion, or it may be lost suddenly. If the raised intracranial pressure be not relieved, papilledema proceeds to atrophy of the optic nerve.

Slowing of the Pulse Rate. Slowing of the pulse rate is common in head injuries associated with raised intracranial tension, in some cases of subarachnoid hemorrhage, in abscess and subdural hematoma, and in tumors which cause general signs of raised intracranial tension quickly. In instances of more gradual development, intracranial tension may be greatly increased without any slowing of the pulse, or the pulse rate may fall to 50 or even less, such a fall being of grave import.

Warning. When there are clinical indications of raised intracranial pressure, lumbar puncture or the withdrawal of cerebrospinal fluid *should never be performed except for some precise and compelling reason* The fatal issue of lumbar puncture *is due to* the displacement of the brain that follows the escape of fluid from the subarachnoid space

Convulsions. The convulsive seizures of brain tumor are usually generalized and indistinguishable from those of idiopathic epilepsy. *A convulsion may be the first manifestation,* occurring when physical examination of the patient does not reveal abnormal *physical findings.* A convulsion occurring for the first time after

maturity or later requires a consideration of neurosyphilis or brain tumor These generalized fits have no localizing value, nor do they indicate raised intracranial tension.

Localizing Symptoms of Tumor of the Cerebral Hemispheres. The origin of local symptoms is due to interference with blood supply or to destruction of tissue by the lesion itself If localized pressure from a localized lesion predominates at the outset, the first symptoms may be those of a progressive local lesion of the brain, without signs of a general rise of intracranial tension. If the increased pressure is generalized, as often occurs in an infiltrating lesion, the symptomatology is wholly that of intracranial tension and there may be no clue to the situation of the original expanding lesion The absence of early clinical manifestations in many of those who have intracranial tumor depends largely on the plausible explanation that at first malignant cells may be dispersed between the axons and dendrites in a way which will not interfere with their function, and thus there is at least a reasonable cause for the absence of localizing symptoms and signs in the early clinical stages of highly malignant gliomas.

MOTOR SYMPTOMS. Tumors or lesions of the *motor cortex* of the frontal lobes produce irritative and paralytic phenomena.

The irritative phenomena consist of unilateral convulsions consisting of spasmodic deviation of the head and eyes to the side opposite from the lesion These convulsions may occasionally be of the jacksonian type, which commences on the side opposite to the tumor in the face, tongue, arm, or leg, according to the part of the motor cortex which is chiefly implicated In a jacksonian fit the local convulsion, which usually consists of tonic spasm followed by coarse clonic jerks, may be definitely localized to the same group of muscles, or it may spread from them to other groups of muscles, and always in a regular order. Jacksonian convulsion differs from ordinary epilepsy in that the patient usually retains consciousness all the time and he may observe the progression of the fit If the convulsion spreads across the middle line, however, and becomes bilateral, consciousness is lost

The paralytic phenomena, in tumors of the motor region, consist in monoplegic weakness of the convulsed muscles during the interparoxysmal periods.

A *subcortical growth,* involving the pyramidal fibers, is usually indicated by an initial monoplegia followed later by jacksonian convulsions. Convulsions may not be repeated until weeks or months later. The deeper the growth, the less tendency is there for the convulsions to localize Tumors of the precentral or motor cortex, if extending across the fissure of Rolando to the postcentral convolution, are usually associated with a sensory aura in the affected limb at the beginning of the motor convulsion

Tumors occurring in the *postfrontal area* may cause unilateral fits with a spasmodic deviation of the head and eyes to the side away from the lesion. In left-sided tumors in right-handed patients motor aphasias are common and often persistent. In some left-sided postfrontal tumors aphasia is absent when the individual is right-handed, if the handedness is determinable (see Handedness, Chapter 6).

Tumors on the *orbital surface of the frontal lobe* occurring in the brain or in the meninges may be associated with unilateral diminution of vision, and early and persistent anosmia on the side of the lesion. In these there are the same psychic alterations as those which accompany prefrontal lesions.

MENTAL SYMPTOMS. Tumors situated on either side of the cortex may or may not give mental symptoms. If there are mental symptoms, they appear before the symptoms of intracranial hypertension The mental symptoms consist of alterations in temperament A cheerful person may become depressed and lose power of initiative Yawning and failure of memory ensue Intellectual dullness may be expressed by simple jocularity, together with euphoria and absence of anxiety and concern about the illness. There is a deficiency of attention and often there is a profound

motor apathy. Late in the course of these lesions defecation and urination may occur during sleep. A motor apathy may be the first symptom of prefrontal tumors.

In instances of astrocytomas, the commonest intracranial tumor of middle-aged persons, the symptoms develop slowly. Weeks or even months pass during which time the patient appears to be and generally is in good physical health. During this time there is a gradual loss of energy and mental alertness In women of the menopausal age the symptoms are those often attributed to the climacteric. There are irritability and apathy If the patient is subject to migraine headaches, these increase in frequency. For a considerable period of time the headache and the vomiting of intracranial hypertension cannot be separated from the same symptoms characteristic of migraine Perhaps the first recognizable symptom characteristic of intracranial hypertension and not characteristic of migraine or the climacteric is drowsiness. The patient sleeps excessively when free from the headache and vomiting

There are those with rapidly growing intracranial tumors who have no detectable change in mental health and no localizing symptoms until the onset of dimness of vision (papilledema) or double vision or a convulsion.

Edema tends to develop around the rapidly growing tumors The edema may cause serious disturbances which end life in a short period of time However, these acute episodes of symptoms are likely to subside, to be repeated several times before death. The immediate cause of death is a rapidly rising fever (temperature 105 to 107 F) and respiratory failure.

On general *examination* of some patients who have frontal lobe tumor there may be no detectable physical or mental aberrations. In others there may be a condition characterized by motor and emotional apathy. In these there may be present an insensibility to what ordinarily rouses feelings of interest, and a hypersensibility to insignificant words or actions There often prevails a dull indifference to the cognitive, conative and affective mental components There may be indifference to, and lack of interest in, pursuits previously vigorously sought and a total disregard of the nature of the illness.

A frontal lobe tumor which exerts pressure backward on the adjacent motor area or pyramidal tract may cause exaggerated tendon jerks with plantar extension in the foot on the side opposite the lesion In lesions of the posterior aspect of the prefrontal region there may be present on stimulation the groping and grasping reflex consisting of a compulsive grasping motion of the fingers or of the toes, on the opposite side from the tumor This reflex occurs only when the patient is psychically confused but not stuporous.

In an occasional patient local cranial tenderness and alteration of percussion note may be present.

Ataxia from a frontal lobe lesion is a unilateral unsteadiness of the foot and leg opposite the lesion, whereas in cerebellar disease the ataxia is in the foot and leg on the same side as the lesion Frontal ataxia may be associated with a tendency to make short backward steps (retropulsion), as if to maintain the stance This aberration of station and gait, if not accompanied by signs of voluntary motor paralysis, on walking may amount to an apraxia of gait

Papilledema, which is late in onset in frontal lobe tumors, tends to be greater on the side of the tumor than on the opposite side, but it is always bilateral. Papilledema on the side of the tumor may result in unilateral optic atrophy However, an optic atrophy may be due to a temporal arteritis or to a retrobulbar neuritis.

Ventriculograms in frontal tumors reveal collapse of the anterior horn of the ventricle on the side of the lesion and if the tumor is large displacement of both anterior horns of the ventricles away from the tumor

Tumors of a *temporal lobe*, situated in the region of the uncinate gyrus, are often attended by convulsive seizures (uncinate fits) commencing with hallucina-

tion of smell or taste, followed by a short period during which there is a feeling of unreality and detachment from the environment The commencement of an uncinate fit may be heralded by noises, such as of bells, heard and vividly described by the patient. An uncinate convulsion usually leaves the feeling that all of the hallucinatory experiences during the fit have been undergone. These beliefs by the patient contrast sharply with the general descriptions of feelings of unreality.

These convulsions may be accompanied by sniffling of the nose, smacking or spitting movements of the lips, and chewing movements of the jaw. In the interim between attacks these patients may complain of feeling as though there were cotton on the tongue and lips. Hemianoptic visual hallucinations are projected to the blind half of the visual fields, which is away from the lesion. These visual hallucinations are complex, elaborate and systematized in contrast to the unorganized scotomas present in lesions of the occipital lobes.

A tumor situated in the *posterolateral part of the temporal lobe* is localized by the ophthalmologist He will observe incomplete visual defects in the contralateral *halves of the visual fields, and as the lesion progresses, he will report that the* hemianopsia has become complete.

Tumors situated in the *postcentral gyrus of the temporal lobe* cause sensory aura and if they extend forward by invasion or by pressure, cause motor symptoms in the corresponding parts which have sensory affections Convulsions are common, they commence with a sensory aura of tingling or of pain, which is present in a lateral half of the face, arm or leg on the opposite side from the tumor. If motor symptoms are present, they consist of muscular spasms. Astereognosis in the hand on the opposite side from the lesion may be present. Anesthesia, monoplegic or hemiplegic, may develop.

If the tumor is *situated on the left side* and the angular gyrus is injured, word blindness occurs which is transient at first but later permanent

If the tumor is situated in or extends deep into the *supramarginal and angular convolutions,* the optic radiations are eventually destroyed Hemianopsia in both visual fields, often attended with hemianesthesia and hemianalgesia on the side opposite to the lesion, ensue

Visual disturbances are significant manifestations of tumors of the occipital region of the hemispheres Tumors in the occipital region produce half-blindness on the opposite side from the lesion

is affected Central vision usually escapes

Tumors of the occipital lobes situated near the cerebellum may extend downward to the cerebellum, and thus cerebellar manifestations may be the presenting symptoms

Large tumors situated deep within the cerebral hemisphere cannot be localized symptomatically

Tumors of the Thalamus. Tumors may be situated in the *thalamus* without producing any definite focal symptoms Involvement of the thalamus produces a degree of hemianesthesia; involvement of the striatopallidal nuclei gives rise to parkinsonian syndrome, on the side opposite to the lesion, accompanied by hemianopsia

Affections of the optic thalamus may cause subjective sensations of pain, heat, and cold on the side of the body opposite to the lesion Often a thalamic tumor fails to give any sensory impairment.

Tumors of the thalamus and corpus striatum may be difficult or impossible to distinguish from chronic epidemic encephalitis. Encephalograms are essential in diagnosis.

Tumors of the Corpus Callosum. Tumors in the anterior part of the *corpus callosum* usually cause mental confusion, deficient memory and attention, and emotional excitability These symptoms are similar to those arising from late neurosyphilis and tumors of the frontal lobes of the hemispheres. Ventriculograms are essential to the diagnosis of a growth involving the corpus callosum.

Tumors of the Corpora Quadrigemina. Tumors in the corpora quadrigemina regions are localized by the presence of a combination of bilateral ptosis with weakness of vertical movements of both eyes and of convergence. The pupils may be dilated and excentric, with loss of the light reflex. *Bilateral deafness, without* vestibular disorder, may result from implication of the posterior corpora quadrigemina Affection of the superior cerebellar peduncle causes cerebellar asynergia simulating a cerebellar tumor

Tumors of the Cerebellum. Tumors of the cerebellum are the commonest tumors of the brain.

The commonest tumors of the cerebellum are the astrocytoma, which is a slow-growing glioma, and the medulloblastoma, which is extremely malignant and which often extends into the meninges In children the commonest tumor of the cerebellum is the medulloblastoma

Extracerebellar tumors which produce pressure symptoms on the cerebellum are commonly situated in the cerebellopontine angle of the posterior fossa of the skull. These tumors may arise from the meninges over the cerebellum (*meningiomas*) or from the sheaths of the cranial nerves, notably the auditory nerve. Tumors of the sheath of the auditory nerve are fibroblastomas, which may be either benign or malignant.

When a tumor or degenerative cerebellar disease is situated in the *anterior lobe* of the cerebellum, the postural reflexes and walking synergies are disturbed. These patients walk with a wide base and stagger or deviate to both sides The gait tends to be stiff-legged owing to exaggerated positive supporting reaction. On occasion it is possible to demonstrate an extensor thrust reflex. If flat pressure is placed against the sole to spread the toes, the leg gives a reflex extensor thrust against the hand

If tumor or degenerative cerebellar disease involves the *posterior cerebellar lobe* there is an interference with the performance of skilled movements, while gait and static equilibrium are maintained. Postural fixation of the extremities is defective, and errors in rate, range, direction and force of voluntary movements occur. On examination, the ipsilateral arm may display hypotonia, which is demonstrated by a tendency for the arm to drift downward and laterally when it is laterally extended Co-ordination tests such as finger-nose and heel-knee show errors in rate, range, direction and force of movements. The movements are slow and jerky, deviate from a direct line, are irregular in force and tend to overreach or underreach the mark

When the *dentate nucleus* also is involved by tumor, combined sclerosis, chronic encephalitis or atrophy, tremor is added to the abnormalities of movements. On walking, the ipsilateral arm lacks the associated swing with the arm contralateral to the tumor There is a tendency to deviate toward the side of the lesion. There is coarse nystagmus on looking toward the lesion, and fine nystagmus on looking away from the lesion The head may be rotated either toward or away from the lesion. On the affected side the tendon reflexes tend to be hypoactive and the knee jerks pendular.

When both of the *posterior lobes* of the cerebellum are involved, there are bilaterally disturbed skilled voluntary movements. Because of bilateral involvement, the gait is more severely involved and dysarthria tends to be severe.

If the tumor is situated in the *cerebellopontile angle* the cerebellar signs develop early, probably owing to pressure on one posterior lobe and the dentate nucleus. There is varying involvement of the eighth, seventh, sixth, fifth, ninth and tenth

cranial nerves as well as brain-stem structures In addition to the cerebellar signs, including nystagmus, there are tinnitus, deafness and loss of labyrinthine function. Diminished corneal reflex and hyperesthesia of the face appear next As the tumor enlarges, facial paralysis followed by paresis of the external rectus muscle of the eye occurs Difficulty in swallowing, hoarseness, hiccough, vomiting and headache are late occurrences

Diagnosis of tumor of the cerebellum or of the cerebellopontile angle is based largely on the presence of a progressive cerebellar ataxia.

Papilledema or other signs of increased intracranial pressure usually are present, and there may be evidence of involvement of the cranial nerves in the posterior fossa or of pressure on the brain stem Vomiting is often the first sign of such lesions and may recur from time to time over a period of months before other symptoms develop

In children a slowly progressive cerebellar ataxia is observed in association with a tuberculoma or with tuberculous meningitis The examination of the cerebrospinal fluid obtained by lumbar puncture, if there is no evidence of increased intracranial pressure, reveals in tuberculous meningitis a lymphocytosis, a diminished concentration of chlorides (normal values 625 to 720 mg. per 100 ml in children and 720 to 760 mg. per 100 ml in adults) and of glucose (fasting normal values in children 70 to 90 mg per 100 ml., in adults 40 to 70 mg per 100 ml.). Tubercle bacilli may be cultured from the spinal fluid. The spinal fluid is clear in the presence of tumors

There is the possibility of the presence of vascular thrombosis or hemorrhage and disseminated sclerosis which symptomatically may simulate tumors of the cerebellum during their early development.

Some of the juvenile cerebromacular degenerations may give rise to cerebellar ataxia among the first symptoms, although disturbances of vision and mental defect are usually present by the time the ataxia is manifested There are also a number of closely related hereditary ataxias which include the familial type of Friedreich. In Friedreich's ataxia there are three components: cerebellar ataxia, posterior column ataxia and pyramidal tract signs.

Tumors of the Cranial Base. Tumors of the cranial base are often sarcomas and metastatic carcinomas Owing to pressure on the cranial nerves before they leave the skull, the symptoms are those of multiple and often bilateral palsies of the ocular, trigeminal and glossopharyngeal nerves Roentgenographically there are sometimes observed defects in the cranial bones where the tumor has invaded the bone and passed on into the cranium Ventriculograms may reveal upward displacement of the third and fourth ventricles

Intraventricular Neoplasms. Tumors within the ventricles give rise to symptoms of increased intracranial pressure When the tumor is movable within the ventricle, the intracranial pressure is not constantly elevated but varies within wide limits The headache may be relieved by placing the head in certain positions In the same way, stooping, straining, sudden movements and certain positions may cause paroxysmal headaches and vomiting

Tumors of the lateral ventricles, when they force their way into the hemispheres, may cause hemiplegia, hemianesthesia or hemianopsia Such tumors may invade the adjacent structures, producing symptoms characteristic of disease of the hypothalamus and infundibulum, optic thalami and lenticular nuclei and the pineal syndrome

Tumors of the fourth ventricle may cause focal signs early. Vomiting often develops before there is definite papilledema Subsequently signs and symptoms indicative of involvement of the cerebellum and pons appear.

Ependymomas. Ependymomas may occur in the lateral, third or fourth ventricles but seem to be slightly more frequent in the fourth ventricle They may occur too in the central canal of the spinal cord

These tumors grow slowly but there is nothing which differentiates them from any other intraventricular tumor Ependymomas often are encapsulated and if successfully localized, they may be removed.

Papillomas of the Choroid Plexus. There is nothing in the course of symptoms of these tumors to distinguish them from any other intraventricular tumors before operation. Treatment consists of localization by ventriculography and operative removal.

Colloid Cysts of the Third Ventricle. Colloid cysts are found only in the anterior part of the third ventricle, attached to the choroid plexus, and are of rare occurrence. Recurrent and periodic headaches may be precipitated by flexing the neck, by straining or by stooping More serious manifestations are slow feeble pulse and low blood pressure accompanying the headaches In a later stage of the process the patient may become stuporous or even unconscious for short periods. The face may flush during the headaches

Meningiomas. The meningioma arises as a proliferation of the cells of the arachnoid villi It grows slowly, does not invade the brain, and never metastasizes to distant organs It may be associated with Recklinghausen's disease, and several members of a family may be affected

The presence of increased intracranial pressure is often the sole indication of a meningioma. A meningioma occurring over the convex surface of the brain gives minimal signs until it has attained considerable size unless it is situated over some structure, injury of which will give recognizable signs early. For instance, if situated on the floor of the anterior or middle fossa, a meningioma may reveal its presence by the appearance of cranial nerve palsies. A meningioma growing from the ethmoidal plate of the frontal bone will compress one optic nerve, giving rise to progressive failure of vision in one eye and unilateral loss of the sense of smell on the same side A tumor on the floor of the middle fossa will produce diplopia, squint, and ptosis from progressive paralysis of the third, fourth and sixth cranial nerves Increased intracranial pressure develops slowly and is of late occurrence.

The course is usually a slow one. The brain is compressed rather than invaded and thus focal signs are inconspicuous The diagnosis prior to operation is made only when there is cranial change which can be detected on roentgenologic examination.

The *auditory fibroma,* or auditory nerve tumor, is often a part (a form fruste) of a generalized neurofibromatosis (Recklinghausen's disease) A single benign neurofibroma may compress and stretch the eighth nerve and cause tinnitus, deafness and vertigo If the fifth nerve is compressed, there are loss of corneal reflex and numbness of the face Compression of the seventh nerve produces Bell's palsy. This is a slowly growing tumor, and deafness with tinnitus may be the only symptom It rarely gives a rapidly developing intracranial hypertension as do intracerebellar tumors, nor is there a well-developed cerebellar ataxia.

Metastatic Neoplasms of the Brain. Metastatic tumors of the brain, especially carcinomas, are frequent Intracranial lesions which cannot be explained on the basis of one tumor are always suggestive of metastasis

Tumors of the nose, throat, eyes and thyroid gland, malignant melanomas and carcinomas of the stomach, colon and the pancreas are likely to metastasize to the brain However, any blood-borne tumor cell may take up abode inside the brain. Malignant tumors may extend into the subarachnoid spaces and produce signs of meningeal irritation and pleocytosis in the spinal fluid (tumor meningitis). Increased intracranial tension is a late event in the course of metastatic tumors of the brain

Roentgenograms of the skull will often reveal multiple regions of absorption of bone which may be sharply defined or indistinct in appearance.

Ventriculograms may offer some difficulties of interpretation. There may be evidences of only one large tumor or the deposits may be so numerous and so small that the ventricular system is symmetric.

Diagnosis of Brain Tumor. The diagnosis of brain tumor is almost always a difficult one to make and rarely is it made early. The diagnosis depends on (1) a progressive loss of neurologic functions; (2) increase in intracranial tension resulting in headache, papilledema, vomiting and stupor; (3) focalizing symptoms, which may be present and diagnostically helpful, and (4) convulsions, which occur in about one half of all those who have brain tumors, for a long time convulsions may be the only symptom

The ophthalmologist often finds the most conclusive evidence of increased intracranial pressure by observing the presence, and measuring the degree, of papilledema Before the presence of papilledema the ophthalmologist may observe visual field defects which are of precise localizing diagnostic value.

In the final analysis it must be remembered that a vascular disease of the brain, accompanied by arterial hypertension, such as the malignant hypertension of Keith and Wagener, or a vascular disease without excessive hypertension, may present all the subjective symptoms and objective findings of a brain tumor and may not be definitely differentiated in some instances except by ventriculography.

The plain roentgenogram of the skull will reveal destruction of the posterior clinoid processes and evidence of intracranial pressure if the pituitary tumor has been present for some time If a meningioma has invaded the skull and has produced thickening and alteration in texture of the bone in the affected region, this is evident on the roentgenogram A tumor may contain calcareous material which casts a shadow and thus reveals both the presence and the site of the growth In and after middle age the normal pineal gland often contains such material, and if a tumor be present in one cerebral hemisphere, the shadow cast by the pineal gland may be displaced laterally A pituitary adenoma or a stalk tumor may produce enlargement and deformity of the sella turcica

The commonest of all intracranial tumors, the glioma and the secondary carcinoma, very rarely give any indication of their presence in the roentgenogram.

If the ventricles are filled with air, the resulting roentgenograms (ventriculogram, encephalogram) may reveal deformity or displacement of the ventricles and thus indicate the situation of a new growth. These tests are best performed by a surgeon capable and trained to undertake any operation that may prove necessary, in case immediate operation should become necessary from a sudden increase of symptoms which may ensue after the introduction of air into the cranium

An intracranial growth that cannot be removed is fatal The malignant glioma and the secondary carcinoma comprise one half of all intracranial tumors and these are not surgically curable Palliative decompression, as a rule, serves to prolong for weeks or months a life of increasing disability and distress.

Cerebral Angiography Recently Craig and associates reported 100 cerebral angiograms made by them at the Mayo Clinic on 77 patients The dye was injected into the common carotid artery In 31 patients suspected of having brain tumor, 16 lesions were identified by cerebral angiography. In 17 of 36 patients suspected of having subarachnoid hemorrhage, a vascular lesion was demonstrated by angiography. In 6 instances the angiograms did not indicate brain tumor, the presence of which was later verified In 2 instances the angiograms were interpreted as indicating brain tumor, but the diagnosis could not be verified at operation Unsatisfactory angiograms were obtained in 10 per cent of the cases owing to technical difficulties.

Cerebral angiography is a helpful diagnostic aid in the localization of intracranial lesions but carries a certain risk to the patient

Radioactive Diiodofluorescein. In the experience of the neurosurgeons of the Mayo Clinic the use of radioactive diiodofluorescein in the localization of brain tumors is valuable in only one half of total cases In those instances in which the dye can be used, this method of localization has given results which are precise enough to be of use to the surgeon in about 4 of every 5 of the cases This experience seems to closely parallel that of Moore and associates, whose technic of testing was, in the greater part,

adhered to in performing the test. Tumors less than 3 cm. in diameter, unaccompanied by a halo of edematous tissue, were sometimes missed, and tumors of the posterior fossa and parasellar region were difficult to localize by this technic.

THE ELECTRO-ENCEPHALOGRAPH. When the brain cells are injured, waves slower than 18 per second with high voltage are present in the electro-encephalogram. Combinations of slow and fast waves are present in those who have petit mal In certain brain conditions abnormal waves are best elicited during hyperventilation.

The dysrhythmias, abnormally slow delta waves, are present when there is an area of abnormal cortex

The electro-encephalograph is employed as an adjunct diagnostic procedure. The apparatus is rarely available and the electro-encephalograms must be interpreted by experts

Part Three

The Body as a Whole

16

THE CONSTITUTION

In the preceding parts of this book the regional and systemic diseases have been separately discussed It is now proposed to describe some normal and some abnormal conditions which demand consideration of the biology of the individual (body as a whole). In the past, diseases of this nature have been termed constitutional diseases. A constitutional disease may be due to inherent imperfections in the constitution or it may arise secondarily from the progress of regional or systemic diseases.

The constitution of an individual comprises the inheritable, invisible structural components These were formerly adequately described as disposition, diathesis, dyscrasias, character, constitution and individuality Some of these terms may still have descriptive value In a broad sense these structural components were present in the primordial protoplasm of mankind or have been added by the progenitors of man and by man himself during the hundreds of millions of years which have been spent in attaining his present constitution.

The constitution of an individual is individual to himself though subject to constant change by environmental influences and experiences from the time of maturation and fertilization of the ovum

Constitutional stamina is manifest in the morphologic and functional characteristics, external form, performance capacity and resistance to, and in the mode of reaction to, pathogenic influences.

There is an intellectual heritage of all animals at least from the fowl onward by which they recognize those that are sick or injured and avoid or often attempt to destroy them. In man the sorting of the sick individuals from the healthy ones and of the healthy ones of varying capabilities one from another requires extensive information and skill In practice the information on any one individual never can be complete and therefore great caution is exercised and the critical sense is employed to the utmost before arriving at decisions concerning how much of the disability is at the time of study dependent upon a person's constitution and how much is dependent on the immediate externalities. Healthy individuals have their dispositional or premorbid individuality which is so varied that a feeling of well-being and physical capability to one may seem to be a state of incapacity to another Moreover these variables are carried by the individual from health into disease and these may cause great difficulty in the separation of a healthy constitution from a sick one

EXTERNAL CONSTITUTIONAL DIFFERENCES

There are, as is well known, both visible and invisible characteristics of men, women and children. These characteristics form the bases for separation into racial stocks Within a racial stock are races separable by certain methods employed by the physical anthropologist. These methods include descriptions and classifications of color of skin, of hair on head and body, eyes, form of internal eye folds, form of noses and a number of anthropometric measurements. Given a race, within it

will occur certain numbers of individuals who have similar morphologic and physiologic characteristics which set them apart from others in types.

It is realized that millennia have been required to evince the changes in anatomic structures observed in different races of men living in different parts of the world. These changes, in part, may be related to climate, environment, health and food

Climate, Environment and Health (Geomedicine). Genera, species, or races may arise as the result of alteration of function in response to climate and environment These alterations in function may require a change in somatic type.

Coon seems to believe that the peoples of the Mediterranean littoral and the Middle Eastern mountains from Palestine to Northern India and particularly those who live in the moist heat of the forests in these regions probably have deviated less from the original human habitus than any others.

ALTITUDE. Coon believes that the peoples who migrated from the Mediterranean littoral or from Palestine and southern India to inhabit the mountain zone to the north were the first to reveal the evolutionary influence which results from habitation in higher altitudes The influence of altitude is manifested in the increase in size of the thorax and in the surefootedness which are characteristic of the Alpines. The physician is not aware of the work and thought which the anthropologist has expended in order to arrive at these conclusions In clinical diagnosis and in prognosis of pulmonary infections such as tuberculosis the physician is aware that the size and shape of lungs may be related to selection and survival Tuberculosis, for instance, is more disastrous in persons who have long lungs in long narrow chests than in those who have shorter lungs in shorter broader chests.

HEAT AND COLD In contrast to the evolution of big chests and compact bodies as the result of higher altitudes Coon calls attention to the evolution of broad flat chests and gaunt bodies of inhabitants of the hot desert countries The gaunt, flat-chested desert folk have long arms and legs, short, shallow bodies, and narrow hands and feet Their surface area is great in proportion to their volume and weight, thus permitting optimal cooling through radiation and evaporation

In the course of migration northward the progenitors of the natives around the Arctic Sea underwent various regional influences On arrival in the Arctic Zone they had the thick wide chests gained from living at high altitudes, and in time they developed short thick arms, legs, hands, fingers and toes and the thick protective layer of subcutaneous fat that conserves body heat

LIGHT AND CUTANEOUS PIGMENTATION In its effect on the human organism light is more important than heat in maintaining health or in causing disease. Light and heat influence racial variations in the amount of cutaneous pigment and thus color of the skin. However, the skin of the original men in the Middle East was brown Human skin darkens when exposed to ultraviolet light of summer, and it fades to a lighter color in the winter

The principal function of pigment in the skin is to protect the skin and the tissues below it from excesses of ultraviolet light, particularly from the narrow but harmful part of the spectrum. Individual human beings vary greatly in the concentration of cutaneous pigment (melanin) which originates in the germinative layer and moves into the granular layer of the epidermis White peoples have varying quantities of melanin, while the lower layers of the epidermis in Negroes and some Negritoes are packed with it The amount of pigment deposited is inherited, but not as a single factor (see Skin, Chapter 8).

SKIN COLOR AND COLOR AND TYPES OF HAIR Coon postulates that when the ice sheet withdrew to the north over the Baltic States, it withdrew gradually and the great humidity in the warming air filled the skies heavily with clouds. In the Baltic States still the clouds gather by October and remain solidly until April

This phenomenon of fog and darkness affected three parts of the body, the skin, eyes, and hair, of inhabitants of the region The *skin* became blond An extremely

blond skin deviates from the normal or ordinary light brown human skin by having fewer and smaller granules of pigment in the pigmented layers. A person who has a truly blond skin may be incapable of tanning when exposed to wind and sun. The skin becomes red and edematous and, on continued exposure, sloughs. Under the Baltic climatic conditions blondism reached a high level of frequency which has remained high because it has not been disadvantageous there and in the climates where these people have migrated. However, a common skin in a dark cloudy region is pale with little pigment. These pale skins may tan in summer and bleach in winter, and get along without trouble in other environments.

Blond persons usually have blue eyes due to an absence of pigment in the outer layer of the iris (see Eye Color, Chapter 4), and it is the inner pigment shining through the radial and circular muscle tissues that makes the iris look blue.

Two factors at least are involved in *hair color*, melanin, as in the skin and eyes, and a red pigment. The size and number of melanin granules determine hair color, from ash blond to what appears to be black. The lightness or darkness of the hair is due both to the concentration of pigment and to the thickness of the hair shaft. Light hair is not confined to northwestern Europe nor has it ever been.

"Red" hair and brown hair are commonest among the blue-eyed, florid-skinned peoples of northwestern Europe and the British Isles. Ash blond hair is commonest among the pale-skinned, gray-eyed peoples of Central Europe from the Baltic eastward and southward.

Color of the skin, including color of the eyes (see Eyes, Chapter 4) and helical and spiral hair are not recent modifications acquired from environmental influences Helical and spiral hair is the tightly curled hair characteristic of Negroes, Pygmies, and Melanesians, but by no means is it limited to them.

Garn distinguished three basic types of curved hair: (1) *Wavy hair*, which forms a two-dimensional figure. This varies in the linear distance between the crests of the waves. (2) *Helical hair*, which forms a three-dimensional figure. Its loops are of a constant diameter as far as each hair is concerned. These diameters vary individually and racially. Helical hair is usually found among Europeans and European-like populations in other continents, and among Melanesians In Europe the oldest, most marginal population, consisting of the southern Irish, the Welsh, some of the Norwegians and Finns, and the Alpines of Bavaria and adjacent mountain regions, has every kind of hair form, including the helical. (3) *Spiral hair*, which is also three dimensional. The loops diminish in diameter outward from the scalp. In the extreme form of spiral hair the loops are narrow, and intertwine in clusters or rows, leaving patches or swaths of skin bare. This is called peppercorn hair.

Environmental Elements and Food. The elements in the natural environment which stimulate and influence somatic responses and finally racial characteristics are the same ones in which aberrations in the supply may produce health or disease These elements include the various rays from the sun, radiation from outer space as controlled by the angle of incidence of the rays of the sun, by the prevailing presence or the absence of clouds in the sky, the density of the air at different altitudes, and the concentration of solutions of minerals, ingested and assimilated through food and drink These mineral solutions are most important in regard to the size of the individual. For instance, calcium and phosphorus are necessary for bone building, iron is necessary for oxidation in the lungs, iodine for the production of the thyroid hormone, and sodium and chloride are essential for the maintenance and regulation of fluid balance and body temperature The trace elements, manganese, copper, zinc, and cobalt, have necessary and relatively significant functions.

The importance of the innate ability of individual members, or most of them, of a race to live on short rations, and of some to grow fat on short rations, is explained on the basis of selection only. This kind of selection seems to have caused a genetic change in some members in all races so that there are unmeasurable changes in their nutritional requirements. Thus, on the same caloric intake, some are lean while

will occur certain numbers of individuals who have similar morphologic and physiologic characteristics which set them apart from others in types.

It is realized that millennia have been required to evince the changes in anatomic structures observed in different races of men living in different parts of the world. These changes, in part, may be related to climate, environment, health and food.

Climate, Environment and Health (Geomedicine). Genera, species, or races may arise as the result of alteration of function in response to climate and environment. These alterations in function may require a change in somatic type.

Coon seems to believe that the peoples of the Mediterranean littoral and the Middle Eastern mountains from Palestine to Northern India and particularly those who live in the moist heat of the forests in these regions probably have deviated less from the original human habitus than any others.

ALTITUDE. Coon believes that the peoples who migrated from the Mediterranean littoral or from Palestine and southern India to inhabit the mountain zone to the north were the first to reveal the evolutionary influence which results from habitation in higher altitudes. The influence of altitude is manifested in the increase in size of the thorax and in the surefootedness which are characteristic of the Alpines The physician is not aware of the work and thought which the anthropologist has expended in order to arrive at these conclusions In clinical diagnosis and in prognosis of pulmonary infections such as tuberculosis the physician is aware that the size and shape of lungs may be related to selection and survival. Tuberculosis, for instance, is more disastrous in persons who have long lungs in long narrow chests than in those who have shorter lungs in shorter broader chests

HEAT AND COLD In contrast to the evolution of big chests and compact bodies as the result of higher altitudes Coon calls attention to the evolution of broad flat chests and gaunt bodies of inhabitants of the hot desert countries. The gaunt, flat-chested desert folk have long arms and legs, short, shallow bodies, and narrow hands and feet Their surface area is great in proportion to their volume and weight, thus permitting optimal cooling through radiation and evaporation.

In the course of migration northward the progenitors of the natives around the Arctic Sea underwent various regional influences On arrival in the Arctic Zone they had the thick wide chests gained from living at high altitudes, and in time they developed short thick arms, legs, hands, fingers and toes and the thick protective layer of subcutaneous fat that conserves body heat.

LIGHT AND CUTANEOUS PIGMENTATION In its effect on the human organism *light is more important than heat in maintaining* health or in causing disease. Light and heat influence racial variations in the amount of cutaneous pigment and thus color of the skin. However, the skin of the original men in the Middle East was brown. Human skin darkens when exposed to ultraviolet light of summer, and it fades to a lighter color in the winter

The principal function of pigment in the skin is to protect the skin and the tissues below it from excesses of ultraviolet light, particularly from the narrow but harmful part of the spectrum Individual human beings vary greatly in the concentration of cutaneous pigment (melanin) which originates in the germinative layer and moves into the granular layer of the epidermis White peoples have varying quantities of melanin, while the lower layers of the epidermis in Negroes and some Negritoes are packed with it. The amount of pigment deposited is inherited, but not as a single factor (see Skin, Chapter 8).

SKIN COLOR AND COLOR AND TYPES OF HAIR Coon postulates that when the ice sheet withdrew to the north over the Baltic States, it withdrew gradually and the great humidity in the warming air filled the skies heavily with clouds. In the Baltic States still the clouds gather by October and remain solidly until April

This phenomenon of fog and darkness affected three parts of the body, the skin, eyes, and hair, of inhabitants of the region The *skin* became *blond* An extremely

blond skin deviates from the normal or ordinary light brown human skin by having fewer and smaller granules of pigment in the pigmented layers. A person who has a truly blond skin may be incapable of tanning when exposed to wind and sun. The skin becomes red and edematous and, on continued exposure, sloughs Under the Baltic climatic conditions blondism reached a high level of frequency which has remained high because it has not been disadvantageous there and in the climates where these people have migrated However, a common skin in a dark cloudy region is pale with little pigment. These pale skins may tan in summer and bleach in winter, and get along without trouble in other environments.

Blond persons usually have blue eyes due to an absence of pigment in the outer layer of the iris (see Eye Color, Chapter 4), and it is the inner pigment shining through the radial and circular muscle tissues that makes the iris look blue.

Two factors at least are involved in *hair color:* melanin, as in the skin and eyes, and a red pigment. The size and number of melanin granules determine hair color, from ash blond to what appears to be black. The lightness or darkness of the hair is due both to the concentration of pigment and to the thickness of the hair shaft. Light hair is not confined to northwestern Europe nor has it ever been.

"Red" hair and brown hair are commonest among the blue-eyed, florid-skinned peoples of northwestern Europe and the British Isles. Ash blond hair is commonest among the pale-skinned, gray-eyed peoples of Central Europe from the Baltic eastward and southward.

Color of the skin, including color of the eyes (see Eyes, Chapter 4) and helical and spiral hair are not recent modifications acquired from environmental influences. Helical and spiral hair is the tightly curled hair characteristic of Negroes, Pygmies, and Melanesians, but by no means is it limited to them.

Garn distinguished three basic types of curved hair: (1) *Wavy hair,* which forms a two-dimensional figure. This varies in the linear distance between the crests of the waves. (2) *Helical hair,* which forms a three-dimensional figure Its loops are of a constant diameter as far as each hair is concerned These diameters vary individually and racially. Helical hair is usually found among Europeans and European-like populations in other continents, and among Melanesians In Europe the oldest, most marginal population, consisting of the southern Irish, the Welsh, some of the Norwegians and Finns, and the Alpines of Bavaria and adjacent mountain regions, has every kind of hair form, including the helical (3) *Spiral hair,* which is also three dimensional The loops diminish in diameter outward from the scalp In the extreme form of spiral hair the loops are narrow, and intertwine in clusters or rows, leaving patches or swaths of skin bare This is called peppercorn hair

Environmental Elements and Food. The elements in the natural environment which stimulate and influence somatic responses and finally racial characteristics are the same ones in which aberrations in the supply may produce health or disease These elements include the various rays from the sun, radiation from outer space as controlled by the angle of incidence of the rays of the sun, by the prevailing presence or the absence of clouds in the sky, the density of the air at different altitudes, and the concentration of solutions of minerals, ingested and assimilated through food and drink. These mineral solutions are most important in regard to the size of the individual. For instance, calcium and phosphorus are necessary for bone building, iron is necessary for oxidation in the lungs, iodine for the production of the thyroid hormone, and sodium and chloride are essential for the maintenance and regulation of fluid balance and body temperature The trace elements, manganese, copper, zinc, and cobalt, have necessary and relatively significant functions.

The importance of the innate ability of individual members, or most of them, of [illegible]

[illegible] nutritional requirements. Thus, on the same caloric intake, some are lean while

others are fat. Likewise, because of better nutrition, the well fed are taller than the less favored individuals.

Somatic Types. The range of human physical, physiologic and psychologic normality varies through wide limits The range of normal contours and sizes of the human body is so great that the physician's attention is attracted only when these limits pass beyond the ones he is accustomed to seeing. It is for those reasons that on general physical examination the body size is simply recorded as the height and weight of the individual patient On a more detailed inspection of the patient it is realized that body size depends on a relationship of constants between its component parts

The physical anthropologists have a system of constants for a number of diameters of the body, such as span, shoulder breadth, thoracic breadth and depth, sitting height, pelvic breadth, and the lengths and breadths of the extremities, and many diameters of the head and face These constants and diameters of the body have been employed by Sheldon, Stevens and Tucker, Hooton, and others for the classification of human beings into somatotypes on the basis of their observations of standard photographs in combination with a number of measurements made thereon The classification of various individuals into somatotypes by this method depends on the recognition that human bodies are a composite of the three primary germ layers, namely, (1) the entoderm, (2) the mesoderm and (3) the ectoderm The types of body build in which these components respectively predominate are termed endomorphy, mesomorphy, and ectomorphy

The three components all exist to some degree in every individual, irrespective of race In a human being it is recognized that in toto a blend of the three components is present but that parts of the body may express different qualitative combinations Accordingly, the body is studied in regions the head, face and neck; thoracic trunk, arms, shoulders and hands, abdominal trunk, thighs, calves and feet. The total of these regional assessments gives an average of the entire body

In *endomorphy* emphasis is placed on rounded soft contours The anteroposterior and transverse diameters tend to be equal In mass the abdomen and the thorax predominate over the extremities, the abdomen predominates over the thorax, and the proximal limb segments, over the distal segments. The head is large and spherical. The face is broad, with upper and lower widths equal The neck is short, the limbs are short and tapering, the hands and feet are small The trunk is long, with the thorax wide at its base The maximal transverse diameter of the body is near the iliac crest The skin is soft, smooth and velvety The external genitalia tend to be hypoplastic

In *mesomorphy* emphasis is on the squared, rugged, hard contours The transverse diameter of the body tends to exceed the anteroposterior diameter The mass is concentrated in the trunk, but not unduly so The thorax predominates over the abdomen, the proximal and distal segments tend to be equal in mass The head is variable in size, but muscular ridges are emphasized The face is relatively large and is long, broad, bony and massive The neck is long, length of the limbs is variable, the hands and feet are large and broad, the long trunk has a thorax wide at its apex, the waist is slender and the shoulders are broad The pelvis is sturdy, and the hips are broad. The skin is thick and coarse with large pores The connective tissue is dense, with good turgor. The external genitalia are well developed

In *ectomorphy* the emphasis is on linearity and on fragility and delicacy of the contours The transverse and anteroposterior diameters are small and usually about equal The mass is decentralized, the abdomen is flat and short with a relatively long thorax The limb segments tend to be equal in mass The head is large and long with slight muscle ridges. The face is small, fragile, and tends to be triangular with its apex at the chin The neck is long and slender, the limbs are long, especially in the distal segments, the hands and feet are long and narrow The trunk is narrow and relatively short, and the shoulders are drooping rather than square The skin is thin and dry and has an early tendency to fine wrinkles The connective tissue is thin; turgor is poor. The external genitalia are elongate and relatively hypotrophic.

The data on *somatic body types in children* are incomplete. Any index of body build changes with age; for example, for males Quetelet's index (W/H) is 10 4 at birth, 17.0 at 5 years, 20 8 at 10 years, 30 0 at 15 years; Röhrer's index (W/H) is 2.30 at birth, 1.60 at 5 years, 1.30 at 10 years, 1.38 at 15 years Body build or body type as a morphologic entity is established fairly early. Sheldon and Wetzel agree that it is firmly entrenched by 6 to 8 years of age or possibly earlier There is no doubt that body build is inherited and too is a reflection of the familioracial background

The foregoing somatotyping has so far not proved to be of great value, for the work [illegible] d.

[illegible] based principally on observation, is [illegible] d three main constitutional types and suggested for these types the following descriptive terms, which now are in commonly accepted use: asthenic, athletic, and pyknic; dysplastic applies to mixed constitutional types

The human being of *asthenic type* has a small, short and low head of average breadth The body is narrow but of average length. Subcutaneous fat is lacking, bones are small, and muscles are underdeveloped; slight anemia is characteristic. The chest is flat, the ribs are prominent, and the angles of ribs with sternum are sharp. The weight is very low for the height, and the thoracic circumference is less than the hip circumference The asthenic type is associated with the dysgenital groups, infantilism, feminism and eunuchoidism As an adolescent the asthenic individual grows rapidly without adding bulk Because of slow development of muscles the asthenic individual finds muscular work difficult and has to learn to do it, but when he has achieved muscular development, he can do moderate labor efficiently, although he never becomes muscular in appearance. Senility or the appearance of senility occurs early At from 30 to 40 years of age he begins to lose his hair, the face wrinkles and sinks, and often early in life arcus senilis develops The female of the asthenic type is an accentuation of the male to the point where she not only is asthenic but may be asthenic-hypoplastic

The male of the *athletic type* has a strong skeleton with strong ligaments and muscular support The height is average to tall. The thorax is muscular and well developed, the abdomen is muscular and not protuberant The hips and legs, as compared with the chest and shoulders, seem slender and long. The upper extremities, like the legs, are rather long. All circumferences of the head, neck and thorax are increased by the musculature and the subadjacent bones The bones of the face are prominent and in relief, and the clavicles, wrists, ankles and hands have prominent bone structure The thick skin has good elastic turgor, with relatively little fat in the subcutaneous connective tissue Dysgenic traits, especially traces of eunuchoidism and feminism, may occur. The muscles of the athletic type develop rapidly during adolescence

The female athletic type has a tendency toward masculine facial traits These undesirable features are offset by increase in adipose tissue, giving rounded feminine contours In some of these women there are masculine features of face and body It is the occurrence of the latter that may make the athletic type of woman seem abnormal, the accentuated traits in her are normal for the man.

The *pyknic type* is characterized by average height, broad figure, flabby broad face, and a short thick neck, so short that often the head seems to be placed between the shoulders The abdomen apparently protrudes from the short, deep, arched thorax The extremities are small and rounded with small, fairly well-developed muscles. The hands are small, short and broad, the wrists and the clavicles are small, the shoulders are narrower than in the athletic type, and are rounded and high and appear to approximate the jaw line, owing to the short thick neck The stoutness of the pyknic type is found in the trunk and the protuberant abdomen The abdomen in reality is not excessively fat, as may occur in the asthenic and the athletic types in later life, the fat of the pyknic type is likely to be in the face, hips and calves, forearms, hands and the acromial ends of the shoulders, whereas the legs may remain relatively thin throughout life. In old age, however, the abdominal fat may become greatly increased Both men and women of the pyknic type have excessive amounts of fat in the breasts and about the hips

The criterion for somatic typing, whether it be that employed by the anthropologist or some less precise but clinically more usable method, as advocated by

Kretschmer, will apply to all racial stocks. A somatic type that might be difficult to classify in one racial stock might be well within the limits of normal within another racial stock.

VISCEROPTOSIS. In all of the racial stocks represented in the United States of America there is one somatic type, the visceroptotic, of common occurrence, which has caused much speculation in regard to diseases which have been considered incident to it

An understanding of visceroptosis can be had by reviewing the anatomy of the skeleton in relation to its contained viscera and the normal visceral supports The small centrally situated heart in the long thoracic cage is considered in diseases of the heart The position of abdominal viscera depends normally on peritoneal attachments and on those conditions which influence intra-abdominal pressure. The diaphragm is an important structure in visceral support The efficiency and support of the diaphragm are in turn dependent on a vacuum in the thorax and on the cervical fascia The latter in its continuation through the pericardium is the supporting ligament of the diaphragm A continuation of the support to the abdominal viscera given by the diaphragm is the transversus abdominis muscle In reality, the transversus abdominis muscle is the chief factor in regulating the piston action of the diaphragm

Failure of visceral attachments and the abnormalities in position and mobility due to lack of normal fusion of viscera to the posterior peritoneum may permit ptosis A normal lordosis with the thick psoas muscle forms a shelflike support for the kidneys and narrows the lower portion of the abdominal cavity. Retroperitoneal mesenteric and omental fat assists in keeping the abdominal organs in their normal position. The presence of fat prevents an undue drag upon and stretching of the peritoneal attachments The importance of this fat has been overemphasized in the treatment of ptosis

All of the forementioned anatomic imperfections constitute the *enteroptotic habitus* The enteroptotic habitus is congenital Such factors as faulty posture, childbearing, loss of weight and the presence of large abdominal tumors or recurrent ascites are precipitating factors, they cannot produce visceroptosis except in a person predisposed by a constitutional somatic type which was inherited.

The so-called manifestations of visceroptosis are of psychoneurotic origin. Visceroptosis of constitutionally inadequate persons who live within their physical and nervous capacity is not associated with symptoms.

On examination no clinical importance need be attributed to the discovery of organs in a low position in persons of the habitus asthenicus. The presence of the slouching "fatigue posture" in the visceroptotic person may increase the likelihood of organic dysfunction and production of symptoms

The abdominal wall is examined for evidence of atony and weakness Very often the weak abdominal wall bulges in the flanks when the patient is in the dorsal decubitus position and protrudes excessively in its lowermost portion when the patient is upright Having the patient attempt to raise the head or legs from the examining table while reclining on the back demonstrates the efficiency of the abdominal musculature. The presence or absence of diastasis recti abdominis may likewise be detected in this way In some patients who have acquired ptosis, after bearing children or as the result of large abdominal tumors, diastasis may be extreme.

During the course of the examination of the abdominal wall, visible pulsations occurring synchronously with the heart beat are more prominent in the visceroptotic patient than in the nonvisceroptotic person.

Visible peristalsis may occasionally be observed through the very thin abdominal wall if excessive gas is present in the intestine. In some patients the transverse colon is palpable It is doubtful whether anyone can palpate or observe visible peristalsis

in a markedly dilated descending duodenum in a patient who has extreme duodenal ileus associated with visceroptosis.

The right lobe of the liver may extend to the iliac crest. Because of its free mobility the thin hepatic edge, even though low, may be difficult to palpate. If the liver becomes fixed in a low position it may resemble a tumor. The spleen in visceroptotic subjects is identified by the general contour and mobility and thus is differentiated from splenomegaly. The lower pole of the right kidney is palpable in the majority of patients. In the visceroptotic patient the kidney may be low in the abdomen, or even in the pelvis

The diagnosis of visceroptosis is not difficult The presence of the condition is usually suspected on physical examination and easily confirmed by roentgenologic study. The condition is not mentioned to the patient unless symptoms have been attributed to the visceroptosis by a less informed surgeon or physician

INTERNAL CONSTITUTIONAL DIFFERENCES

Stocks and races have had their origin from human beings living together and interbreeding. Interbreeding is a means of selecting and perpetuating certain arrangements of genes which control everything that an individual is, or that is possible for him to be and to do Inbreeding, despite the fact that each human being has some 44,000 pairs of genes which can be, to a degree, successfully rearranged in the formation of a new individual, may mean the survival or the extinction of these new individuals depending on the resulting constitution and adaptability of them.

Blood Groups. The blood groups O, A, B and AB are genetically separate, and an individual may inherit combinations of two of these genes The group substances which are responsible for the various types of blood are present in the bone marrow, semen, and brain tissues.

In addition to the O, A, and B series, serologists find other group factors which have differential world distribution. One of these is the M-N series An individual can be M, N, or MN These factors cause no agglutination of the blood in transfusions.

There are two major types of the rhesus series, Rh positive and Rh negative (see Erythroblastic Anemia, Chapter 12). It seems that in an inbreeding population either the Rh negative or the Rh positive group may be eliminated

GEOGRAPHIC BLOOD GROUP VARIABILITY IN THE UNITED STATES. In the United States blood group O percentage is increased by 0.32 on the average for each degree southward The most acceptable interpretation is that in the South the hereditary lines of the early settlers, many of whom were Scotch, Irish and Welsh in origin, have been subjected to less admixture from the outside than in the North

From north to south the B percentage averages 0.17 smaller per degree of latitude The A relationship, though significant, is deemed of little importance quantitatively

THE DETERMINATION OF PARENTAGE. Kolmer has summarized the serologic aspects of the determination of disputed parentage.

Disputed parentage occurs in cases in which a man, named by a woman as the father of a child born out of lawful wedlock, denies such paternity, or in which a husband denies paternity of a child born in lawful wedlock Disputes involving maternity are much less common and usually involve a woman who has secretly secured a child for the purpose of compelling an alleged father to marry her, or to obtain dower rights in her dead husband's estate, or in order that the child may become the heir to her husband's estate. Disputes also arise occasionally in relation to the parentage of infants born in hospitals and accidentally interchanged, as well as in the case of wet nurses who willfully substitute their own infants for those placed in their charge, for the purpose of having their own secure the benefits of better homes.

Interpretation of Examinations of Blood. The agglutinogens, A, B, M, N, and Rh are transmitted by heredity. Examinations in relation to disputed parentage are based mainly on determinations of the major blood groups (O, A, B, AB) of the man, the

Kretschmer, will apply to all racial stocks. A somatic type that might be difficult to classify in one racial stock might be well within the limits of normal within another racial stock

VISCEROPTOSIS. In all of the racial stocks represented in the United States of America there is one somatic type, the visceroptotic, of common occurrence, which has caused much speculation in regard to diseases which have been considered incident to it.

An understanding of visceroptosis can be had by reviewing the anatomy of the skeleton in relation to its contained viscera and the normal visceral supports The small centrally situated heart in the long thoracic cage is considered in diseases of the heart. The position of abdominal viscera depends normally on peritoneal attachments and on those conditions which influence intra-abdominal pressure. The diaphragm is an important structure in visceral support The efficiency and support of the diaphragm are in turn dependent on a vacuum in the thorax and on the cervical fascia The latter in its continuation through the pericardium is the supporting ligament of the diaphragm. A continuation of the support to the abdominal viscera given by the diaphragm is the transversus abdominis muscle In reality, the transversus abdominis muscle is the chief factor in regulating the piston action of the diaphragm.

Failure of visceral attachments and the abnormalities in position and mobility due to lack of normal fusion of viscera to the posterior peritoneum may permit ptosis. A normal lordosis with the thick psoas muscle forms a shelflike support for the kidneys and narrows the lower portion of the abdominal cavity. Retroperitoneal mesenteric and omental fat assists in keeping the abdominal organs in their normal position The presence of fat prevents an undue drag upon and stretching of the peritoneal attachments The importance of this fat has been overemphasized in the treatment of ptosis.

All of the forementioned anatomic imperfections constitute the *enteroptotic habitus* The enteroptotic habitus is congenital Such factors as faulty posture, childbearing, loss of weight and the presence of large abdominal tumors or recurrent ascites are precipitating factors; they cannot produce visceroptosis except in a person predisposed by a constitutional somatic type which was inherited

The so-called manifestations of visceroptosis are of psychoneurotic origin Visceroptosis of constitutionally inadequate persons who live within their physical and nervous capacity is not associated with symptoms.

On examination no clinical importance need be attributed to the discovery of organs in a low position in persons of the habitus asthenicus The presence of the slouching "fatigue posture" in the visceroptotic person may increase the likelihood of organic dysfunction and production of symptoms

The abdominal wall is examined for evidence of atony and weakness. Very often the weak abdominal wall bulges in the flanks when the patient is in the dorsal decubitus position and protrudes excessively in its lowermost portion when the patient is upright Having the patient attempt to raise the head or legs from the examining table while reclining on the back demonstrates the efficiency of the abdominal musculature The presence or absence of diastasis recti abdominis may likewise be detected in this way. In some patients who have acquired ptosis, after bearing children or as the result of large abdominal tumors, diastasis may be extreme

During the course of the examination of the abdominal wall, visible pulsations occurring synchronously with the heart beat are more prominent in the visceroptotic patient than in the nonvisceroptotic person

Visible peristalsis may occasionally be observed through the very thin abdominal wall if excessive gas is present in the intestine. In some patients the transverse colon is palpable It is doubtful whether anyone can palpate or observe visible peristalsis

nonpaternity cannot be proved. On the other hand, if the man belongs to group AB and the child to group O, or vice versa, nonpaternity is established, regardless of the group of the mother, although the chances of such proof are only about 5 per cent

The subgroups of A and AB corpuscles cannot be used for excluding paternity or maternity, but tests for the agglutinogens M and N give a man increased chances of proving nonpaternity. Men belonging to type MN, however, have no chance at all, whereas those belonging to M have 1 chance in 3, and in the case of N, 2 chances in 5. When the major blood groups and the subgroups M and N are determined at the same time, the chances of proving nonpaternity are significantly increased The chances of proving nonmaternity by determinations of the major blood groups alone are slight on account of the rare occurrence of AB, but maternity is disproved by any of the following four combinations. (1) alleged mother AB and child O; (2) alleged mother O and child AB; (3) alleged mother M and child N, (4) alleged mother N and child M.

If a child possesses agglutinogen M or N which is not present in the corpuscles of [illegible] is established. If either of the combinations, [illegible] ıan with type M child, is found, nonpaternity [illegible] s of particular importance when it is impos- [illegible]

The Rh-Hr blood types, however, have considerably enhanced the usefulness of blood tests in cases of disputed parentage, since these have increased the varieties of human blood that may be differentiated from 36 to 360. Under these conditions, an innocent man now has approximately a 50 per cent chance of being excluded when the tests are properly and skillfully conducted. Two Rh− parents can have only Rh− children. If one parent is Rh− and the other is Rh+, the children will all be Rh+ if the Rh+ parent is homozygous, or half the children will be Rh+ and half Rh− if the Rh+ parent is heterozygous. When both parents are Rh+, all the children will be Rh+ except when the parents are both heterozygous, in which case one fourth of the children will be Rh−.

Capacity for Resistance to Infectious Disease (Racial Susceptibility and Immunities). The genes in the human chromosomes control the capacities of the organism for actions and reactions in all spheres of activity including actions and reactions or susceptibility or immunity to microorganisms and viruses. Human beings by their varied manners of living in the past and at the present create environments which are to different degrees hospitable or hostile to the organisms of disease. The men and women who survived the vicissitudes of past environments did so because of a capacity to withstand infections. It does not seem unreasonable to believe that this ability to withstand infections influenced selection of somatic qualities just as much as did the rays of the sun, the temperature, and the altitude.

The spread of infectious disease depends on susceptibility of the host, the virulence of the disease agent, the number of contacts among individuals and the efficiency of their hygienic methods The capacity to resist disease is primarily physiologic, but certain anatomic attributes also are desirable, for instance a good pulmonary capacity in resistance to tuberculosis.

Resistance to infection is least during childhood and old age, when the sex hormones are not operative Sex hormones have much to do with immunization and resistance to disease. The slowly maturing individuals are relatively more vulnerable to infections for a longer time than are those who come to sexual maturity at an earlier age Thus, over the course of years, the slowly maturing, pinched-faced, weak-legged, narrow-chested, poorly co-ordinated adolescents tend to be discarded through natural selection. For example, it is Coon's impression that the prehygienic urban populations of the world, of the Near East, and the Mediterranean coast, and of the Inca and Aztec cities, were shorter, lighter, thinner-boned, and narrower-faced than those who lived in the surrounding country. The urbanites exhibited more asymmetries of body, thinner faces, and tended to have narrower noses than the ruralites. These undesirable anatomic weaknesses probably can be largely accounted for on the basis of poorer hygiene, less food, and more contacts and thus more infections among the urban dwellers than among their rural cousins. It seems

woman and the child. Examinations for the subgroups of A and AB corpuscles are not employed, but supplementary examinations for the agglutinogens M, N and Rh are of additional value and sometimes essential.

Table 16-1 shows what major blood groups are possible and what are not possible for the children of the various combinations of parents

Table 16-1. Possible and Impossible Blood Groups of Parents and Their Children

Groups of Parents	Groups of Children Possible	Groups of Children Not Possible
O x O	O	A, B, AB
O x A	O, A	B, AB
O x B	O, B	A, AB
O x AB	A, B	O, AB
A x A	O, A	B, AB
A x B	O, A, B, AB	—
A x AB	A, B, AB	O
B x B	O, B	A, AB
B x AB	A, B, AB	O
AB x AB	A, B, AB	O

From Kolmer, J A, Clinical Diagnosis by Laboratory Examinations, Ed 2, New York, Appleton-Century-Crofts, Inc, 1949, p 488

Agglutinogens A and B cannot be present in the corpuscles of a child unless present in the corpuscles of either or both parents A child of group O cannot have a parent belonging to group AB A child of group AB cannot have a parent belonging to group O

The tests may prove the nonpaternity of an accused man They cannot establish his paternity, however, because some other man of the same blood group may be the father. *If the man is AB and the child O, or vice versa,* nonpaternity is established regardless of the blood group of the mother If both father and child are A, nonpaternity cannot be established.

Table 16-2 shows what blood groups of the M-N series are possible and what are not possible for the children of the various combinations of parents.

Table 16-2. Possible and Impossible Combinations of Agglutinogens M or N of Parents and Their Children

Groups of Parents	Groups of Children Possible	Groups of Children Not Possible
MN x MN	MN, M, N	—
MN x N	MN, N	M
MN x M	MN, M	N
M x N	MN	M, N
M x M	M	MN, N
N x N	N	MN, M

From Kolmer, J A, Clinical Diagnosis by Laboratory Examinations, Ed 2, New York, Appleton-Century-Crofts, Inc, 1949, p 489

Men belonging to MN cannot prove nonpaternity If the child is M or N and these are absent in one or both parents, nonpaternity is established, also if the man is M and the child N, or the reverse

The chances of establishing nonmaternity by the major blood groups alone are slight *on account of* the rare occurrence of AB Maternity is disproved if an alleged mother is AB and the child O, or the reverse; also if the alleged mother is M and the child N, or the reverse.

In cases involving the parentage of infants accidentally interchanged in a hospital, or purposely exchanged by wet nurses, tests for agglutinogens M and N alone solve 40 per cent and tests for *agglutinogens A, B, M and N about 70 per cent.*

It may also be possible to make the grouping tests with the bloods of a man and a child as, for example, when a husband, suspecting his wife of infidelity, desires to obtain further evidence before making any charges If both man and child are found to belong to group A, it is useless to go further, since irrespective of the group of the mother,

Aside from dominant, recessive and sex-linked modes of transmission of disease, the possibility of mutation is to be considered. Mutations are of different kinds, and not all give rise to superiority of health and vigor Some result in what are known as disease and disability

In the practical application of these rules of genetics there is abundant evidence that many diseases of human beings are transmitted according to mendelian rule, but in most instances a genealogic analysis reveals a number of apparent discrepancies and irregularities which defy interpretation In part these discrepancies and irregularities can be accounted for on the basis of unknown genealogies which prevent accurate interpretations in diagnosis. Family genealogies are often unknown or inaccurate, particularly in regard to the undesirable members of the family, to illnesses and the cause of death.

Despite the smallness of human families the knowledge of forebears is limited. Less than 5 per cent of well informed human beings know the names of their great-grandparents. Fewer than 1 of every 10 patients know whether or not their grandparents had brothers or sisters. Much less knowledge therefore is available in regard to the health, sickness or disability which may have been present. For the foregoing reasons the occurrence of a given disease in a group of siblings without an accurate history of the same condition in ancestors cannot accurately be genetically interpreted. The diagnosis of a genetically recessive characteristic which is dependent on genes having a small incidence in the population—and it is only when two such genes are brought together by chance in the same individual that the disease assumes an overt form—may be difficult or impossible This speculation is supported by the observation that the mode of inheritance of a given disease may seem to change during several generations of the same family, and this cannot be explained except by splitting of the several pathologic genes in the manner mentioned. It is of practical diagnostic value to keep in mind that almost all sex-linked diseases behave like recessive characteristics

INTERNAL AND EXTERNAL CHARACTERISTICS

Body Odors. In the widespread contempt among the races, nearly every race is prone to charge all other races with being "smelly." A much publicized and somewhat dubious aphorism is to the effect that "we smell like what we eat" However, some races, apart from hygienic practices, exhibit odors which seem to be characteristic of themselves These odors are more readily perceived by individuals belonging to another race The Chinese and the Japanese, owing to their low nitrogen, cereal diet, are relatively free from any special racial odors. The Negro, both in Africa and elsewhere, seems to possess a distinctive body odor. The number of cutaneous glands conducive to offense is probably increased in this race. Among other groups, diet rather than an increased number of glandular elements may be the source of offense. Orientals complain of buttery odors of Europeans and of North Americans. Particularly, Orientals find difficulty in adjusting to the odors of European and American women The residents of Baltic regions are said to have a feculent odor The Eskimo smells like blubber even when the native dress has been abandoned The Brazilians are afflicted with body odors said to be Negroid in type but much less in degree The young and the old of any race are less odorous than the middle-aged The very lean and the very fat may be more offensive than those who enjoy normal nutrition, brunets more than blonds, women more than men Special acts and circumstances provoke the secretion of different odors within the sweat The menstruating woman or the pregnant woman may present odors apart from those associated with the genitalia

Bromhidrosis (Stinking Sweat). This disease of the sweat system also is termed osmidrosis. The disease may exist in spite of admirable efforts toward per-

from the evidence at hand that a poor grade of food and an unfavorable environment account for much of the so-called racial susceptibility to bacterial infections This is not true in the cases of viral and parasitic infections. The viral infections occur more readily in the well nourished than in the ill nourished. The parasites disregard the nutritional status of the host

Selection, Mutation, and Disease. The changes which occur in the genotype, and hence in its phenotypic expression in the individual, are controlled by selection Selection, however, does not originate changes of race or species New genes, or changes in the chemical composition of genes, are required for changes in race or species, and this is mutation

The exact cause of *mutation* is not known However, it was pointed out in the first part of this chapter that the influence of sunlight, cold, heat, humidity and altitude can change bodily function and influence anatomic structure There is no evidence that such factors ever influence the incidence of mutation, but the conditions present in the environment may be favorable to the life of certain mutants (dark skies for blondism) when they do occur and may thus perpetuate them If an attempt is made to weigh the molding influences of the environment against those of mutation and heredity, the result is to lose sight of the development of the individual as a whole. Premature conclusions in regard to the direct inheritance of physical characteristics, health or disease, or the acquired characters which have resulted from mutation in the environment, often lack the sort of judgment useful in diagnosis

The science of genetics teaches that heredity operates in orderly and predictable ways The expression of the genetic constitution is formulated by the mendelian rule

The mendelian rule implies that unit characteristics are transmitted in definite ratios by paired genes contained in the chromosomes of the germ cells Individuals receiving identical genes from each parent are termed *homozygous*, and those who have unlike genes, *heterozygous* Genes which always give rise to the characteristics which they convey are termed *dominant* Genes which are latent unless paired with identical genes from each parent are termed *recessive* The genes and the characteristics which they convey, which are contained within the same chromosome which determines sex, are designated *sex-linked*

Several instances of a given disease may occur among siblings despite the absence of a history of the same conditions in ancestors These sporadic occurrences may give the impression that the disease arises anew in each instance. According to the mendelian rule, however, this is to be expected of a recessive characteristic, which is dependent on genes having a small incidence in the population. When two such genes are brought together by chance in the same individual, the disease assumes an overt form For example, this is probably true in the sporadic instances of disseminated polyps of the colon.

When a disease behaves as a dominant characteristic in one family and as a recessive characteristic in another, there are among other interpretations the following possible explanations. (1) The disease is dependent on more than one pathologic gene, and these genes are closely associated in the chromosome and generally act as a unit but may become separated, so that a particular individual may not possess a complete set of these pathologic genes, but by chance mating the complementary genes necessary to produce the disease in overt form are obtained (2) The disease may occur as a dominant characteristic before the genes become separated and, after they are separated, may operate as a recessive trait

Probably another example of the splitting or the separation of genes is the apparent change in mode of inheritance of a given disease during several generations of the same family. Many of the sex-linked diseases behave like recessive characteristics. No sex-linked inherited disease of any type has been discovered which is restricted to and manifested only by the human female or which is even more frequent in the female than in the male.

In the realm of general and industrial toxicology, the probable cause of an affection or death may be disclosed by odors of the breath or the clothing or by odors emitted at necropsy. The worker in selenium, tellurium and arsenic has a garlic-like odor of his breath The odor of ethyl alcohol is readily detected. Errors may arise if too much emphasis is placed on the odor of alcohol on the breath, since the drinker, without being profoundly drunk, may be the victim of any of a long list of severe conditions leading to unconsciousness. Allyl alcohol, phenol and kindred chemicals, cresol, and lysol, sometimes used for purposes of suicide, possess revealing odors and thus facilitate diagnosis. The almond odor associated with hydrocyanic acid is so precise when present as to justify a working diagnosis of poisoning by a cyanide. In mercury poisoning the pronounced odor about the mouth is likely to result from stomatitis, but on rare occasions a metallic odor may be present Less frequently the same metallic odor may appear in lead poisoning In like manner odors may be associated with exposure to such other substances as carbon tetrachloride, trichloroethylene, gasoline, and benzol.

In the case of putrid odors from the *mouth*, difficulty may arise in determining the exact cause Gingivitis, stomatitis, purulent tonsillitis, Vincent's angina, bridgework, carious teeth, some pulmonary and gastric involvements—all may contribute a somewhat similar odor. The dentist, after drilling into an offending tooth, may be observed to sniff his drill after the dental canals have been reached. What he does after that may largely depend on the odor that he perceives. In some instances *ozena* (atrophic rhinitis) is accompanied by a foul and characteristic odor *Laryngeal diphtheria* in the necrotic stage emits a well-defined odor, but long before this period the diagnosis should have been made bacteriologically Such infections as typhoid fever, measles, scarlet fever and smallpox possess their own peculiar odors, none of which can be described as one apart from the others

Medicaments applied in the form of ointments, with ensuing absorption through the skin, may prove to be quickly injurious, and a diagnostic lead may be found in the lingering odor of the ointment

In rheumatic fever there has been described a highly differentiated odor of the skin set apart as sour or acid and said to be encountered in no other disease.

Gout is sometimes accompanied by an odor from the skin pathognomonic of that disease

The odor of *acetone* on the breath (apart from a worker employing acetone) immediately suggests the possibility of *diabetes* and calls for a more precise examination.

Figuratively speaking, a short path into the unconscious might be along the olfactory nerve In the *neuroses, inhibitions*, and *incompatibilities of marital life* disturbing odors may play an important but unrecognized role While these odors may not be accessible to the physician, an inquiry may reveal that odors are provocations for marital maladjustment

To a minor extent the absence of odor may attain medical import When fresh *feces* possess little or no odor, attention should be directed to the possibility of hepatic disease. In the presence of well-established jaundice the feces may be odorless.

The control of body odors comprises (1) systematic bathing and treatment for the curtailment of perspiration, (2) localized roentgen therapy and (3) local application of chemical antiperspirants and deodorants

Among active deodorants which operate by diminishing the flow of perspiration are the aluminum salts, particularly the chloride and sulfate, formaldehyde, alcohol, tannins and tannic acid, and iron salts (ferric chloride and others). Other materials such as zinc peroxide and oxide, hexamine, oxyquinoline sulfate, chloramine T, chlorthymol, and essential oils and perfumes act by nullifying the odor and are known as deodorizing agents.

sonal hygiene. All portions of the body may be involved in the productions c agreeable odors, but most blameworthy are the armpits, genital region, and A few persons may bathe the feet and change hose as many as four or five daily but still cause offense, chiefly to other persons, and an entire house, roo office may be made unlivable by the presence of one so afflicted.

The cause of this condition is not known, but it is oftenest associated with anemic, undernourished, alcoholic, or neurotic individuals. The state may be mittent. The offensive odors may long persist in a home or office after the p has departed

URHIDROSIS (Odor of Urine). The pathologic condition urhidrosis repr that abnormal state in which body waste ordinarily discharged in the urine l the body in perspiration, so that the offensive odor is that of urine and is c ammoniacal. The body odor encountered is not different from that of persons lack full control of the urinary bladder Any neglected infant presents the same not because of urhidrosis but because of wet diapers. This disorder may ar any person who has kidneys that are failing in their proper function. It rarely occur in otherwise perfect health

BODY ODOR-PRODUCING ORGANISMS Affections associated with abnorm of sweating may be the perfect ground for action of one or more bacteria, f or yeasts. Those bacteria which split urea, form indole, skatole, butyric acid, hy gen sulfide or other sulfur compounds, or any other odoriferous substances u certain conditions of growth on a particular cultural substance which may be pr in the surface or in the orifices of the body, may be expected to cause odors. *S tococcus foetidus* is the one species which has been given a special cognomen cating this quality

In any fungous infection, notably of the feet, offensive odors may be sev disturbing It is somewhat academic to set apart the extent of odors attribu solely to decomposing flesh in contrast to the fungi themselves. It neverthele mains that fungous disorders may be far more odorous than other affections of e severity in the same area. It appears probable that odorous offense from mem chiefly feet, may occur on a parasitic basis in the absence of open lesions. growth of such organisms in nearly normal interdigital macerated tissue may be cient to produce offensive odors. Persons who have such relatively innocuous i tions as tinea versicolor may present disturbing odors, chiefly associated with clot and recently occupied beds.

SIGNIFICANT BODY ODORS Olfactory diagnostic criteria continually were so out by physicians of former times. These physicians prided themselves that thr odor alone they were able to recognize such diseases as diphtheria, measles, monary abscesses, typhoid fever, leukemia, diabetes and some forms of insa and that by odors they could differentiate between many forms of "fevers."

It should not be inferred that the present-day diagnostician scorns odors in achievement of his diagnosis. Far from relegating odors to an outmoded past rating them as unworthy of a place in modern diagnostic methods, time and a every good diagnostician confronted with odors or their absence introduces evidence into his comprehensive appraisal For him, however, unlike his rem predecessor, acuity of the sense of smell is seldom a boasted prime implem Odors are now less important in diagnosis than formerly simply because i realized that the sense of smell is not in man, as in the dog, a dependable sense.

Odors as encountered in the work of the physician may reveal other th than a disease itself. The physician, through odors alone, records the impression t a patient is a tobacco user, an alcoholic, or given to low personal hygiene, that works in a certain trade or with certain chemicals, that she is menstruating, t certain drugs are being used in medication, or that certain foods have been ingest

* Weight is expressed in pounds

An anthropometric survey of men and women in the U S. Army who were from 17 to 26 years of age revealed an average mean stature of the 17-year-olds of 67 71 inches (172 cm) and an average weight of 139 5 pounds (63 3 kg) After 1 or 2 years of service in the Army, the mean maximal stature of 68 51 inches (174 cm.) was attained at the age of 21 years; however, after the age of 19 years the average increase was only 0 1 inch (0.25 cm). The thoracic circumference for the 17-year-olds averaged 34 5 inches (87 6 cm) and for the 26-year-olds 36.76 inches (93 4 cm) The neck, judging from these measurements, appears to stabilize in the twenty-fourth year Of the extremities, the only measurement which showed any increase after 17 years of age was in the breadth of the hands, which showed an average increase of 2 per cent between 19 and 22 years of age.

The data from the Quartermaster Corps on the 17-year-olds resembles

Growth [illegible] is on a primary longitudinal [illegible] axis and to one another, [illegible] architectural plan, growth determined by [illegible] influences builds the somatic type of the individual Symmetry [illegible] the growing child are controlled by genetic factors Certain of these factors control physical growth in linear, others in circumferential dimensions.

A knowledge and understanding of the family background is a necessity in evaluation of size, for there is no doubt that body build is inherited and too is a reflection of the family and the racial background.

Average Weight and Stature of Youths and Young Adults. Average weights for given heights and ages of girls through the eighteenth year and boys through the nineteenth year are presented in Tables 16-3 and 16-4.

* Weight is expressed in pounds

Some so-called pituitary dwarfs have hypoglycemic attacks which are probably due to deficiency (the gluconeogenetic factors) *of the adrenal In these a deficiency of* adrenal androgen is indicated by absence of sexual hair and decreased urinary excretion of 17-ketosteroids (less than 2 mg. daily).

Often in pituitary dwarfism no evidence of thyrotropic or adrenotropic failure can be detected, but lack of gonadotropic activity becomes conspicuous as the patients grow older. Usually there is a complete failure of sexual development. The testes or the ovaries remain small and immature and secondary sexual changes fail to appear. The urinary output of follicle-stimulating hormone is diminished (less than 6 mouse units per day). The absence of sexual hair, and the low values *for 17-ketosteroids and follicle-stimulating* hormone serve to distinguish cases of pituitary infantilism from hypogonadism due to primary ovarian or testicular deficiency.

Hypothyroid Dwarfism Dwarfism in hypothyroidism is characterized by stunting of growth and by delay in all the processes of maturation. Wilkins has observed that if the deficiency has existed from an early age, osseous development is retarded, infantile proportions of the upper and lower skeletal segments persist, dental development is retarded and the naso-orbital configuration retains infantile characteristics If thyroid deficiency does not develop until later childhood, when a more mature skeletal develop-

ed retardation

hypothyroid-

There is also

slow osseous development in patients who show delayed adolescent growth and development

Sexual Precocity and Dwarfism. Sexual precocity is at first manifested by an abnormally rapid rate of growth and osseous development, but premature fusion of the epiphysial lines usually causes cessation of growth before adult height has been attained In most cases of precocious puberty it is easy to explain the acceleration of growth on the basis of the early production of androgen However, rapid growth occurs in some cases of granulosa cell tumor of the ovary in which sexual development is due to estrogen elaborated by the neoplasm There is reason to believe that in such cases estrogen stimulates in turn the production of adrenal androgen, probably through its effect on the pituitary body

The common causes of dwarfism are severe and chronic disease occurring in childhood Almost any disease may stunt growth and, if sufficiently chronic, prevent development, and thus dwarfism ensues

Celiac disease, chronic ulcerative colitis, cystic fibrosis of the pancreas, renal disease such as polycystic kidneys and chronic nephritis, and hepatic disease or atresia of the bile ducts may be the cause of dwarfing Growth may be stunted without the appearance of any lesions of the bone Cardiac and pulmonary diseases which are accompanied by cyanosis often cause stunted growth

There are many children whose growth and sexual development are delayed Often but not invariably they have been smaller than the average throughout childhood and have consistently shown a delay of 2 to 4 years in their epiphysial development They remain sexually immature and continue to grow at a slow rate Their short height, lack of muscular development, and psychic immaturity, when they are compared with other children of the same age, make them more conspicuous at this time. Eventually puberty begins, but this may not occur until the patient is 16 or 17 years of age or older Adolescence may then progress rapidly, or there may be slow sexual development and somatic growth which may continue for a long time, owing to the fact that epiphysial ossification and fusion are delayed. Eventually these patients attain height within the normal adult range, although often they remain shorter than the average These differences in somatic and sexual maturation might depend on either genetic or nutritional influences affecting the entire organism, or on constitutional variations in the endocrine development and function of the individual That there is only a delay in growth and not a specific defect of some gland is shown by the fact that these patients eventually mature normally.

similar data obtained by the Brush Foundation over a 10-year period at Western Reserve University, Cleveland. The first period of the Brush Foundation studies covered fewer than 1,000 persons representing the economic group for which the average stature at age 17 years was 69.48 inches (176.5 cm.) and the average weight 147 5 pounds (66.9 kg.). The Army series at age 19 years, after 1 or 2 years of service, showed a mean weight averaging about that in the Brush series.

Dwarfishness (*Dwarfism*). A dwarf is an abnormally undersized person. Generally a person who has attained the age of an adult and who is less than 5 feet (152.4 cm) tall is a dwarf

Dwarfing may be hereditary in origin and dominant, as is revealed by the African pygmies It may occur sporadically in families The sporadic or the familial dwarf is often small at birth Growth is relatively slow from earliest infancy The centers of ossification appear at approximately the normal times and epiphysial union occurs normally The mental development is average. Sexual maturation takes place normally and at the usual time, and the features mature during adolescence. The child develops into a miniature but normal adult If the sporadic dwarf reproduces, the offspring are usually of normal size

Familial progeria with dwarfism (Hutchinson-Gilford disease) begins before the child is 1 year old. Between the onset and the age of 3 years, growth almost ceases and senile-like changes develop The features become sunken and drawn, the nose is thin and appears increased in length. The hair is thin and may be lost entirely Subcutaneous fat is lost The skin becomes atrophic and wrinkled There are deformities of the joints The epiphyses fuse prematurely In some cases there are arteriosclerosis and calcification of arteries Usually there is severe mental defect. The cause is unknown. It has been suggested that there are multiple genetic or germ plasm defects

Congenital absence of ovarian follicles has been observed in normal-appearing women (see Diseases of the Ovaries, Chapter 7). However, Wilkins has observed that a special type of genetic dwarfism is seen in the syndrome of ovarian agenesis and stunted growth Other congenital anomalies such as coarctation of the aorta, and defects of eyes and muscles are frequently present

In the syndrome of congenital ovarian agenesis, growth and development resemble those of the primordial, rather than the pituitary dwarf That is, epiphysial ossification is only slightly, if at all, delayed and epiphysial fusion occurs. The features mature as they ordinarily do during adolescence These patients do not have the childish facies seen in hypopituitary dwarfs The facial features are characteristically those of a mature woman with a poorly developed jaw and chin Frequently the diagnosis may be suspected from the facial appearance alone On examination these women have infantile sex organs.

Pituitary Dwarfism. Pituitary dwarfs are frequently of normal size at birth and during the first few years of life After [illegible]
cease entirely but usually continues at a [illegible]
opment, however, the epiphysial cente [illegible]
may fail to occur and the epiphysial lines may remain open or may close in adult life

The pituitary dwarf retains immature features and ages rapidly. In the twenties or the thirties, the skin may lose its elasticity and show aging but the features remain immature A lack of muscular development predisposes these patients to muscular asthenia and fatigability

It is rare that there are signs of tumor or other gross destructive lesions of the pituitary, such as changes in the sella turcica, constriction of the visual fields or evidence of increased intracranial pressure Dwarfism associated with xanthomatosis is of pituitary origin. Occasionally a craniopharyngioma or a glioma in the region of the optic chiasm or the hypothalamus may cause both dwarfing and diabetes insipidus In the absence of localizing signs pointing to a lesion in the pituitary region, proof that dwarfing is due to deficiency of the pituitary growth hormone depends on finding impairment of other pituitary functions. When a dwarf remains sexually infantile after adulthood, it is safe to presume that there is a deficiency of both the growth hormones and the gonadotropic hormones elaborated by the pituitary

The Cardiovascular System. Reduction in size and weight of the heart is by no means generally present in the senium. Atrophy of the striated muscle is not established with certainty Accumulation of lipochrome pigment within the muscle fibers takes place if the so-called brown atrophy occurs. The conduction system does not participate in any known senescent changes.

The changes in the endocardium and valves are those of atherosclerosis The valves lose their pliability because of an alteration of the texture of their elastic fibers, and deposition of fat and calcium. These changes are the most pronounced in the mitral and aortic valves

In the coronary arteries the elastic tissue and the ground substance of the intima are altered and eventually show deposits of cholesterol and calcium; in the media, however, deposits of calcium are rare.

The aorta loses its elasticity. This process leads to changes in the configuration of the aorta, and is most marked in areas exposed to special strain

As the atherosclerosis advances in the arteries, the elastic membrane of the intima splits, the elasticity of the vessel wall deteriorates, and deposits of calcium accumulate in the media.

Symptoms Prior to angina pectoris or congestive failure there are no distinct symptoms indicative of the aging heart

Examination The rate of the heart beat, after decreasing between birth and the tenth year of life, remains at a plateau from the third to the fifth decade. Thereafter, another slight slowing may occur in some persons. The rhythm of the pulse may be changed Premature contractions may be observed.

Electrocardiograms of older persons appear to some investigators to be indicative of significant changes Most cardiologists do not find electrocardiographic changes which are indicative of advancing years.

The cardiac output in men between 40 and 90 years of age reveals no evidence of decrease in discharge of blood referable to age.

Reduction of arterial elasticity as expressed in the quality of the pulse reflects the passive expansion and elongation of the arterial walls There is a relationship between elasticity and velocity as expressed in a greater rise in systolic blood pressure in less elastic arteries in response to the same cardiac output

The changes in blood pressure as age advances have been described in the section on hypertension The systolic blood pressure gradually rises without significant change in the normal limits of the diastolic pressure

The Urinary System. Arteriosclerotic involvement of the kidneys is common from middle age on. The parenchymal changes are referable to the vascular affections present Reduced blood supply to the renal parenchyma engenders the ischemic tissue reaction of simple atrophy characteristic of the slow progress of the vascular changes The number of functioning glomeruli is reduced in accordance with the degree of vascular change.

The elimination of metabolites under ordinary conditions remains unimpaired when sufficient functioning tissue is left in the kidneys. Extensive arteriosclerotic changes in the kidneys and the disease resulting therefrom are not characteristic of aging

The Reproductive System The changes of the genitals incident to advancing years have been described in the consideration of diseases of the reproductive organs Essentially these changes are shrinkage except in the case of the prostate gland, in which the change is one of hypertrophy.

The Nervous System. The pathologic changes that take place in the central nervous system are extensive. The extreme effects of the senium may leave the leptomeninges thickened and the seat of cavitation or focal gliosis.

The brain may be shrunken and unduly hard; the sulci are deepened and widened, especially in the frontal lobes The ventricles dilate, and their walls become

Diagnosis of Dwarfishness. Generally one type of dwarf cannot be distinguished from another on the basis of the size which the patient attained at some particular time before puberty. It is necessary to wait to learn what finally happens in regard to sexual development.

The diagnosis of dwarfism due to disease of bone depends on the roentgenographic findings and the absence of signs of endocrine dysfunction. The diagnosis of dwarfism due to severe chronic diseases which occurred in childhood (for example, rickets) depends on diagnosis first of the chronic disease which caused the dwarfism.

The correction of nutritional and metabolic disturbances usually leads to a resumption of growth when these factors are the primary cause of stunting. Refractory rickets is sometimes susceptible to treatment, with striking improvement in growth In hypothyroid dwarfism the response to administration of thyroid is very gratifying.

Gigantism. In the discussion of diseases of the pituitary gland in Chapter 14 it is mentioned that the diagnosis of gigantism is exceedingly difficult in the borderline case. Hyperactivity of the anterior lobe of the pituitary results in gigantism when the condition occurs in the adolescent, and in acromegaly when present in the adult. In all instances of gigantism due to hyperfunction of the pituitary, eventually the features of acromegaly develop The main point in the differential diagnosis between the genetic giant and the pituitary giant is the evidence obtained from the genealogic history plus the final development of the features of gigantism

The Senium. Feebleness of mind and body accompany advancing years There are no criteria for the prediction of the age at which feebleness will begin The best evidence indicates that aging begins with birth and progresses thereafter. It has become the custom of the medical profession to yield to the arbitrarily set age of 65 years as being the time that men and women are unfit for use. This arbitrary fixing of any age as the point at which there will be an end to the productive capacity of men and women is impossible to square with medical and historical facts concerning the accomplishments of aged men and women. Michelangelo finished painting the Last Judgment at the age of 66 years He completed frescos in Pauline Chapel in his seventy-second year After this he devoted himself to architecture and engineering until his eighty-ninth year despite fever, gallstones and gout.

Practically all of the symptoms and signs attributable to advancing years accompany arteriosclerosis and atherosclerosis These diseases may begin at any time in life, and if men and women are to be retired on account of the symptoms incident thereto, the retirement age should in some instances be at 40 years instead of 65 years and in others the number of years is not significant of capacity for work.

Most men and women mellow with age. They become docile and agreeable and philosophically inclined and are a wholesome influence on their friends and families. These men and women seem to have escaped the attentions of the medical profession, for they are rarely mentioned They do not need to consult physicians

Owing to the fact that the age of a person cannot be adequately expressed in biologic units which would indicate the physiologic age, it is realized that the complaint, the symptoms and the physical findings in the aged may be, although they rarely are, different from those in the younger age groups who have comparable diseases. For the sake of convenience, old age may be defined as the stage of life which extends from some time in middle life to the eightieth year. From 80 years on, advanced old age prevails.

With increasing age, body length decreases This change is partly real, owing to atrophy of the intervertebral disks, and partly illusory, resulting from an increasing forward bending of the spinal column and flattening of the plantar arches as the result of loss of muscular tone. Reduction in weight of most tissues and organs prevails with the advancing years.

Ménière's syndrome, suggests a lesion of the brain stem and is not a common complaint. Giddiness among elderly persons, like this symptom in younger persons, is often functional In some there may be an increased sensitivity of the carotid sinus.

In Woltman's experience in a series of 200 cases the disorders of elderly patients which were referable to the nervous system were, in the order of frequency of occurrence, disease of peripheral nerves, cerebral arteriosclerosis, psychiatric disturbances, residua of major vascular insults, major neuralgias, convulsive disorders, headache, parkinsonism, brain tumor and syphilis of the nervous system. The common complaints expressed by relatives in regard to these patients pertained to psychiatric disturbances Many of such patients are segregated at home because of conduct intolerable from a social point of view.

The symptoms of disease in the aged may not be fully manifest because of the pathologic changes in the brain The high incidence of neurosis is the same in the aged as in younger persons. Woltman observed, in the cases mentioned, that the same familiar neurotic complaints had been recorded in the histories of these same patients thirty or more years prior to the examination

Prior to a stroke there may be dull, persistent, unilateral pain. It may include half of the body or only part of it, especially the proximal part of a limb and the adjacent part of the trunk. This "thalamic syndrome" fluctuates greatly in intensity with the mood of the patient.

Pseudobulbar palsy may be a gradually acquired disability and complaint.

Gastrointestinal neuroses, depressive reactions, chronic fatigue states, anxieties, melancholia, headaches and giddiness all may be related to the aging process

EXAMINATION The commonest physical manifestations observed in the aged [illegible]

[illegible] impaired functions of nerves, muscles and bones The identification of Parkinson's [illegible]

[illegible] ances in gait may be observed such as walking with short steps and a distinctive hesitation and uncertainty of gait while walking Apparent locomotor difficulties may arise from poor vision

The pupils are often somewhat irregular and sluggish in their reactions, and conjugate movements of the eyeballs upward may be limited The oculi fundi may reveal evidence of arteriosclerosis. Cataracts and choroidal degenerations and arcus senilis are common The most distinctive evidence of advancing age in the eye is the loss of the bright hue to eye color The eyelashes and the eyebrows are apt to be coarse and out of control as the result of excessive growth

Impairment of hearing, especially for high tones, is common. Impairment of hearing may account for an apparent inattention and preoccupation.

The lack of co-operation during the examination of an aged patient may be the only objective finding Co-operation, particularly in the sensory tests, is poor, these patients either fail to answer or else give the same answer to all questions or stimulations Irritability may be manifest in some. Emotional instability is frequently observed in the aged However, it must be emphasized that it is commoner to find the aged more stabilized emotionally than they were when they were younger

The inability to sustain attention is often the basis for defects in memory. The memory often is clear for remote events but poor in recalling current events. Aphasias in both sensory and motor spheres are common if evidence of cerebral arteriosclerosis is present.

There is often unsteadiness in the Romberg position. In some patients there is no appreciation of vibratory sensations, and in a few a loss of appreciation of move-

rough and ridged The cortical lopographic configurations become thinner and less distinct than usual; the white matter and the deep nuclei are shrunken.

The nerve cells are atrophied, laden with pigment, vacuolated, and decreased in number, and their processes are reduced in number and replaced by gliosis. Corpora amylacea and senile plaques are common, as are also changes in the choroid plexus.

In the spinal cord there may be a marginal pallor, especially of the fasciculus gracilis

Arteriosclerosis is not invariably present in old age, but when present it involves especially the large vessels (atherosclerosis) of the base and pia In larger vessels of the brain the alteration is chiefly atherosclerotic. The vessels on the whole become *roughened, tortuous and hardened and unyielding, therefore, they may* indent neuronal structures such as the optic chiasm, the atheroma may ulcerate, set free an embolus, or form the site of a thrombus, an aneurysm or a hemorrhage. However, rupture of the larger vessels of the base of the brain is rare in the absence of aneurysmal formation. Advanced changes of the blood vessels of the brain may be present without clinical manifestations

In the peripheral nerves there may be a reduction in the number of fibers and an increase in the supportive tissues Aging persons have more discomfort attributable to the peripheral nerves than do younger people Feelings of numbness, paresthesias and pains in the course of one or more peripheral nerves may be the source of great worry in the senium

Essential hypertension in middle life reduces the size of the lumen of the arterioles, progressing to involve the smaller arteries. This gradual closure of the smaller arteries reduces the quantity of blood which can be delivered to the tissues. Reduction of blood supply causes reduction in function of the tissue deprived of adequate amounts of blood. The manifestation of this slow starvation of the tissue consists of loss of function without pain The closure of the lumen of an artery of medium size by a thrombus, for instance, a leg artery, is manifested by pain and often sudden death of the tissues distal to the closure if the collateral circulation is not adequate. Closure of the arteries in the aged person is common due to the reduced, roughened, irregularly sized lumen of the vessel. The reduction in the size of the lumen is produced by atherosclerosis incident to aging

SYMPTOMS. The chief complaint of many aged patients is weakness On inquiry, however, the physician learns that the basic difficulty is not weakness but impairment in use of the lower limbs because of pain, ataxia, spasticity, or a tremor Often the pain is of skeletal origin and not due to vascular disease When it is due to atherosclerosis it takes the form of claudication The spasticity is characteristic of pyramidal neuron lesions and is a part of a Parkinson syndrome due to vascular disease in the brain The tremor has been present for years, especially under conditions of fatigue, and other members of the family have been affected *similarly In* most instances tremor in the aged as in younger persons is heredofamilial and not of vascular origin unless it too is a part of a Parkinson syndrome.

Impairment in memory is often the chief complaint On analysis it is often obvious that the imperfections of memory are due to poorly sustained attention, which is often greater than the patient's general behavior suggests.

Headache, bregmatic or frontal in situation, and generally of a dull heavy type, but sometimes *stabbing and sharply localized and not greatly influenced* by straining or jarring of the head, may be a complaint

Aging patients may have a persistent symmetric burning of the tongue and *inside* [illegible] findings, to which has been given [illegible] occurs in women more than the age [illegible] with depression, and not to age.

A commonly occurring [illegible] Intense vertigo, like that of

one or more of the operators of the motor vehicles involved or in the pedestrian when the latter is affected These personal factors comprise: (1) Temporary or permanent physical or mental deficiency prevents the involved person from being able to do any better One or more of the operators or the pedestrian has not had the proper experience, skill or training in protection of himself from physical harm, or if he has had such experience and training, he may have lost such as the result of accident or disease or through the normal processes of age. (2) The most important group of persons involved in accidents includes those who profess not to want to have an accident but who maintain a careless, reckless, inattentive and generally faulty attitude. They are inherently awkward, often preoccupied with emotional and neuromuscular tensions, and are afflicted with feelings of hostility or guilt

The somatic defects which prevent proper action or which may interfere with a person who is operating a motor vehicle may be classed as follows: (1) diseases which affect locomotion or the mechanical structures of the body including bones, joints and muscles, and peripheral vascular or peripheral nervous structures; (2) diseases of the cardiovascular, respiratory, hemic, lymphatic, digestive, urogenital, endocrine and nervous systems; (3) diseases of the organs of special senses.

The influence of the nerves, as controlled finally by the cerebrum in the operation of a motor vehicle, is that ability to perform synchronizing, smooth, steady acts and movements resulting in proficiency, deftness and good control. These are the organized habits of the motor and sensory nerves which have been gained by a lifetime of cultivation and by correction of many awkward movements incident to learning to perform skilled acts The loss of these organized habits of motor function may be the result of interruption of the functions of the motor nerves, as occurs in a host of diseases of the peripheral nerves (injury), of the spinal cord (poliomyelitis), injury of the cerebellum as in ataxia (tumors, birth injuries, vascular disease), lesions of the basilar nuclei of the brain (extrapyramidal neurons as in Parkinson's disease), and diseases or injury of the cerebral cortex which result in an inability to initiate movement Likewise an interruption of the function of the sensory neurons interferes with the performance of co-ordinated movements, many times because of inability to know where the part is or how far to move it, as occurs in locomotor ataxia

These aberrations of function of the nervous system in disease can be easily recognized even if not diagnosed They are permanent and progressive and once established should prohibit their victims from operation of motor vehicles.

The interruption of synchronized, smooth, steady movements which result in proficiency, deftness and good control is more frequently due to narcotic and sedative drugs than to disease. The chronic addiction to alcohol or drugs, or the immediate acute effects of these drugs, produce awkwardness incompatible with performance of the movements of organized habits of the motor and sensory nerves These conditions are definite indications for not operating a motor vehicle.

Diseases of the cardiovascular system, especially in aging persons, may influence the ability to operate a motor vehicle. These diseases often interfere with the functions of (1) the brain, manifested by symptoms such as amnesias, aphasias, encephalopathies, and hemiplegias, (2) the heart, manifested by angina pectoris and coronary occlusions, (3) the extremities, manifested by arterial spasm, as in Raynaud's disease and Raynaud's phenomenon, and occlusive arterial disease, such as is present in atherosclerosis and in endarteritis obliterans or thromboangiitis obliterans.

A sufficient degree of amnesia may be reason to forbid a patient to operate a motor vehicle Aphasia, either motor or sensory, and hemiplegia disqualify one for the operation of a motor vehicle. The rest of the cardiovascular diseases are rarely

ments of the joints is present. The tendon reflexes may be unequal or absent. The plantar response may be plantar extension (Babinski's sign). Impairment in superficial sensibility and, occasionally, evidence of degeneration of anterior horn cells are common findings if the attention of the patient can be maintained long enough to test for these abormalities. The urologist may find a cord bladder to account for urinary symptoms.

DIAGNOSIS The diagnosis of the senium, the feebleness of mind and body incident to old age, cannot be made unless such signs and symptoms are present. There is no age at which these may be expected to be present In many aging men and women the usual manifestations of aging are never present. More commonly men and women gradually slow down with the advancing years, they shrink up bodily and become mellow and placid mentally, and seek, not the physician, but spiritual comforts These men and women are not the subjects for medical reporting, for they are not seen by physicians. They have formed, in the past, a great stabilizing influence on society The future, with a promise of enforced retirement, threatens to deprive society of this desirable heritage, since these men and women will be uprooted, so to speak, and cast away Many of them will not have the solace of interests because they have not had time to do anything more than their daily work

QUALIFICATIONS OF OPERATORS OF MOTOR VEHICLES

In a broad classification of motor vehicle accidents there are those due to (1) adverse road conditions, (2) mechanical failure of the vehicle and (3) the human factor, the operator. Here the interest is in the human factor.

There are various groups of operators of motor vehicles and these are determined by the use of the motor vehicle, for instance, whether the vehicle is engaged in transportation in the public interest or whether it is owned and operated for private use in business and in pleasure. In practice, the physician is aware that the physical and mental qualifications of an operator of a cab or a semitrailer should be much different from those of the farmer who operates a one-half ton truck for use on the farm and for going to town and to church Between the qualifications of the operators of vehicles in the public interest and those of the certain farmers whose qualifications comprise the ability to start, steer and stop their vehicles are the qualifications of the numerous persons who own and operate their own vehicles for business and pleasure.

Among the persons who consult the physician of their own volition or those referred to the physician by members of their own families or by officers of the law in regard to their qualifications to operate a motor vehicle it is evident that there are those who have had more motor vehicle accidents than others Certain variations in the number of accidents a given person has are permissible if the number of accidents falls within the limits permitted by a simple algebraic law (Poisson's law)

In recent years it has been repeatedly demonstrated that some persons have more than their share of accidents as permitted by Poisson's law Permanent somatic weaknesses or deformities are not the cause of the excessive number of accidents that these persons have. The National Safety Council's statistical yearbook *Accident Facts* (1948) reveals that bodily defects, visual and other, were reported as a cause in only 2 per cent of some 5,000 accidents analyzed. "Improper attitude" was reported in 50 per cent of the cases, "a lack of knowledge or skill" in 30 per cent and "no personal cause" in 18 per cent It is evident, therefore, that there is an individual human element in those who have accidents, and motor vehicle accidents are no exception to this rule

In all instances of motor vehicle accidents etiologically the personal factors are by far the most important. In most accidents there are personal factors present in

the semicircular canals, such as may occur in Ménière's syndrome, may be of sufficient degree to disqualify for the operation of a motor vehicle.

The proper official, in many states, may require an aging person, on renewal of a driver's license, to take an examination, as upon the original application, and so notifies him by letter. The aging person brings such a letter to the physician for advice. It is the physician's duty personally to conduct the specific examinations with regard to the applicant's physical and mental condition and if the results are satisfactory, to find out who notified those who issue drivers' licenses that the patient was incompetent; often the licensing office has been notified by some "friend" or relative or member of the patient's immediate family that it is unsafe "at his age" to operate a motor vehicle The physician can then act promptly and correctly, for the physician knows that most persons drive for a lifetime without a serious accident. If age brings some impairment of vision and some slowing of mental and physical response, they drive more carefully and more slowly, not necessarily because they have become converts to safety but simply because it is more comfortable Age alone, or rather the number of years a person has lived, is never in itself a disqualification for the operation of a motor vehicle. A tottering old man, who may be 50, 60, or 80 years of age, should not be sanctioned by the physician as being physically fit for the performance of any duty that might endanger his own life or the lives of others.

The age at which a youth may safely operate a motor vehicle is variable This age is often arbitrarily set by law in the neighborhood of 16 years The skillful young driver can take chances that the elderly driver cannot take; conversely, the careful driver can get along with slower reactions and less perfect vision than can the careless operator Thus it is difficult to set definite standards for any one of these many variables. To date, the best measure of the person's ability as a driver is his or her own accident (and near-accident) record, irrespective of the age

The psychologic factors which interfere with the safe operation of a motor vehicle pertain to the so-called accident proneness of the person. Accident proneness may be inborn or acquired When the quality is inborn, the subject has an accident when an accident prone situation is met. These persons unconsciously have purposive accident tendencies as expressions of hostility or guilt Any person may become accident prone if he operates a motor vehicle when he is preoccupied by emotional and neuromuscular tensions, if fatigue or severe pain is present, if stung by a bee while driving, or if under the influence of alcoholic liquors or narcotics or atropine

All persons [illegible] of high velocity [illegible] [illegible]ds, are accident [illegible] is increased by the presence of excessive fright Likewise accidents are likely to be more serious to those who are not fearful of such hazards than to those who are aware of danger.

The Operation of Motor Vehicles by Drivers Under the Influence of Alcohol. The action of small amounts of alcohol on the central nervous system has assumed great importance owing to the increased numbers of automobiles in use and the high speeds at which they are driven Impaired judgment and slowed reflexes may make all the difference between safety and death on the public highway The danger is especially great since alcohol disappears from the blood relatively slowly, and its action, therefore, persists much longer than is generally recognized It should be understood that for such use of alcohol the terms drunkenness and intoxication are not appropriate The best term is under the influence of alcohol.

Courts of law have had considerable difficulty in deciding cases of accidents in which alcohol has been claimed as a contributory factor, and physicians have not been able to help as much as it is desired in arriving at decisions Chemical tests

of a nature to disqualify for the operation of a motor vehicle unless there is the habit of recurring severe pain.

There are two groups of patients who have habitual loss of consciousness who should not operate a motor vehicle. (1) epileptic persons and (2) those who have extremely hypersensitive carotid sinuses. An epileptic person's sensorium is dulled by the action of sedative drugs. In addition to this, a seizure may come on without a recognizable aura so that caution for protection of himself and others cannot be taken. The person who has a very sensitive carotid sinus may momentarily lose consciousness by a quick turn of the neck, especially if tight neckwear is worn.

A third group of patients who must be considered respectively, and on the basis of their individual histories, comprises diabetic patients, who may have insulin reactions, and those who have hyperinsulinism

Diseases of the hemic system, except from weakness, do not prevent the patient from driving a car. Massive lymphedema such as may occur occasionally in the feet and legs causes a morbid degree of awkwardness Likewise diseases of the digestive system, except for the subacute and chronic dysenteric diseases such as chronic ulcerative colitis and acute, painful, thrombosed hemorrhoids of a severe degree, are not contraindicative for operation of a motor vehicle

Despite a lack of statistical evidence, it is generally believed that eyesight is an important attribute for operation of a motor vehicle, and physical examination for a driver's license usually includes tests of vision or requires the applicant to furnish proof of fair vision with or without the use of glasses These examinations include acuity as tested by means of a Snellen chart. An acceptable safe level at which to grant general driving privileges is 20/40, though opinion in the various states differs, so that levels from 20/30 to 20/70 are accepted

If the applicant must wear glasses in order to pass the tests, his license is ordinarily restricted to driving with glasses If he fails to meet the 20/40 test he may consult a specialist on vision and then have a retest Even if he then fails, he may still, after special study, be given a restricted license permitting him to do the kind of driving he is "able to do in reasonable safety" Some drivers who have visual acuity of 20/200 and even lower, have demonstrated their ability to drive safely under certain limited circumstances The AAMVA standard further says. "The screening standard, therefore, is a flexible rather than fixed standard"

Tests for color vision utilize either colored materials or the Ishihara chart. Color blindness is a hazard in traffic only if the driver is unable to distinguish red from green, or rather to discriminate between the yellow-red and blue-green used in traffic signals Even this is not so important today when nearly all such signals have been standardized, with red at the top and green at the bottom

In the operation of a motor vehicle a phoria may be important.

Restricted visual field is a hazard in operation of motor vehicles, particularly in right angle collisions, unless the driver recognizes his deficiency, drives more slowly when approaching an intersection, and turns his eyes or even his head to see what is coming. As in other items, the danger lies in unawareness of the defect quite as much as in the defect itself.

Tests of night vision appear not to have been developed to the point at which it would be feasible to undertake such procedures Satisfactory night vision includes the ability to see well with low illumination, ability to see against glare, and a rapid recovery from glare blindness

Generally, defective hearing plays little if any part as a cause of unsafe operation of a motor vehicle. Those who have defective hearing have developed a sharp visual alertness. The handicap of defective hearing is not a road hazard but may be hazardous to the motor vehicle, for the operator may not hear the noise created by mechanical imperfections in the vehicle and thus the machine may be severely damaged because of continued use after trouble has developed Disturbances of

the semicircular canals, such as may occur in Ménière's syndrome, may be of sufficient degree to disqualify for the operation of a motor vehicle.

The proper official, in many states, may require an aging person, on renewal of a driver's license, to take an examination, as upon the original application, and so notifies him by letter. The aging person brings such a letter to the physician for advice. It is the physician's duty personally to conduct the specific examinations with regard to the applicant's physical and mental condition and if the results are satisfactory, to find out who notified those who issue drivers' licenses that the patient was incompetent; often the licensing office has been notified by some "friend" or relative or member of the patient's immediate family that it is unsafe "at his age" to operate a motor vehicle. The physician can then act promptly and correctly, for the physician knows that most persons drive for a lifetime without a serious accident. If age brings some impairment of vision and some slowing of mental and physical response, they drive more carefully and more slowly, not necessarily because they have become converts to safety but simply because it is more comfortable. Age alone, or rather the number of years a person has lived, is never in itself a disqualification for the operation of a motor vehicle. A tottering old man, who may be 50, 60, or 80 years of age, should not be sanctioned by the physician as being physically fit for the performance of any duty that might endanger his own life or the lives of others.

The age at which a youth may safely operate a motor vehicle is variable. This age is often arbitrarily set by law in the neighborhood of 16 years. The skillful young driver can take chances that the elderly driver cannot take; conversely, the careful driver can get along with slower reactions and less perfect vision than can the careless operator. Thus it is difficult to set definite standards for any one of these many variables To date, the best measure of the person's ability as a driver is his or her own accident (and near-accident) record, irrespective of the age.

The psychologic factors which interfere with the safe operation of a motor vehicle pertain to the so-called accident proneness of the person. Accident proneness may be inborn or acquired When the quality is inborn, the subject has an accident when an accident prone situation is met. These persons unconsciously have purposive accident tendencies as expressions of hostility or guilt Any person may become accident prone if he operates a motor vehicle when he is preoccupied by emotional and neuromuscular tensions, if fatigue or severe pain is present, if stung by a bee while driving, or if under the influence of alcoholic liquors or narcotics or atropine

All persons caught in severe inclement weather such as winds of high velocity (30 miles per hour or more), rain, or snow, or on icy or muddy roads, are accident prone. The likelihood of accidents under these adverse conditions is increased by the presence of excessive fright Likewise accidents are likely to be more serious to those who are not fearful of such hazards than to those who are aware of danger.

The Operation of Motor Vehicles by Drivers Under the Influence of Alcohol. The action of small amounts of alcohol on the central nervous system has assumed great importance owing to the increased numbers of automobiles in use and the high speeds at which they are driven. Impaired judgment and slowed reflexes may make all the difference between safety and death on the public highway. The danger is especially great since alcohol disappears from the blood relatively slowly, and its action, therefore, persists much longer than is generally recognized It should be understood that for such use of alcohol the terms drunkenness and intoxication are not appropriate. The best term is under the influence of alcohol.

Courts of law have had considerable difficulty in deciding cases of accidents in which alcohol has been claimed as a contributory factor, and physicians have not been able to help as much as it is desired in arriving at decisions Chemical tests

for alcohol in the blood or the urine may be employed for such purposes, for behavior reactions can be correlated with the alcoholic content of the body fluids.

However, evidence obtained from analyses of the blood or urine is not admissible in the courts of law because such evidence, if positive, would violate the individual's rights guaranteed by the Fifth Amendment of the Constitution of the United States unless permission was granted for its use.

With reference to the operation of a motor vehicle, when there is less than 0.05 per cent of alcohol in the blood, or equivalent amounts in the other body fluids or in the breath, the subject should be presumed to be not under the influence of alcohol. The presence of 0 15 per cent or more in the blood is presumptive evidence that the subject is under the influence of alcohol If the blood content of alcohol is between 0 05 and 0.15 per cent, other tests and observations must be taken into consideration in determining the degree to which the subject is affected The average adult must ingest at least two 12 ounce bottles of beer or 2 ounces of 100 proof whiskey for the blood to contain 0 05 per cent alcohol

In general, the concentration of alcohol in the blood is 1.2 times as high as in the brain, 0 8 as high as in the urine, and 2,000 times as high as in the expired air It reaches its maximal level in the blood within an hour after ingestion and is oxidized at the rate of 0.15 to 0.185 gm per kilogram of body weight per hour Even small doses will affect adversely rapid and accurate co-ordination

Accidents may be used to bring about dependence and compensation either in the form of sympathy or financial return. They may be the result of fatigue and falling asleep at the wheel.

COMMUNICABLE AND INFECTIOUS DISEASES

The infections and communicable diseases which usually remain confined to a topographic area, an organ or a system have been described in their appropriate places. For instance, communicable diseases which affect the salivary glands, the organs of locomotion, the genitalia, the skin, the respiratory passages, the digestive system, the liver, or the cranial portion of the central nervous system have been described under the respective organs or systems.

It is now proposed to describe some disorders caused by diverse microscopic and ultramicroscopic organisms which are disseminated through the lymph or blood streams and which are characteristically manifested by fever and are usually communicable

Communicable Diseases. A communicable disease is one capable of being transmitted from one person to another It is re-emphasized that not all communicable diseases are considered here At this time there are two categories of communicable diseases under discussion and both of these are characterized by widespread dissemination through the body by the lymph or the blood or both. These categories are (1) Those organisms like the streptococcus and the staphylococcus which can be communicated from one person to another and which usually originate only a localized infection However, these organisms are capable of passing the local barriers to infection and on into the lymph or blood streams and then cause widespread foci or generalized disease (2) Those organisms which immediately pass from the portal of entry into the lymph and blood and cause localized disease depending on their tropic properties subsequent to dissemination. In the first category the disease originates at the portal of entry of the infecting organism and subsequent to the original local infection there is a bacteremia or septicemia. In the second category there is no disease or at most minimal disease at the portal of entry

Transmission of Communicable Diseases. The bacteria, some of the viruses and higher plant organisms are passed from one host to another on dust particles, drops of sputum or nasal secretions These means of transmission of infection are designated air-borne Infections transmitted by food or drink are said to be transmitted by indirect conveyances. Direct infections ensue from corporal contacts, use of common utensils, clothing or linens Some viral, rickettsial, and parasitic diseases require mechanical or biologic vectors for their transmission The biologic vectors are often arthropods

The Control of Communicable Diseases. There are certain diseases due to plant and animal parasites or to filtrable viruses and rickettsias which are easily communicable from one person to another These diseases are designated communicable diseases, and notification of their presence in a community to the local or state health departments is required and may be mandatory by law.

The following lists of communicable diseases have been taken from Reprint No 1697 (revised, 1950), Public Health Reports, prepared by the United States Public Health Service.*

* Included here by permission of the United States Public Health Service

LIST OF DISEASES OF WHICH NOTIFICATION IS REQUIRED

Actinomycosis
Amebiasis
Anthrax
Bartonellosis
Boutonneuse fever
Brucellosis (undulant fever)
Chancroid
Cholera
Conjunctivitis, acute infectious (of the newborn, not including trachoma)
Dengue
Diphtheria
Dysentery, amebic
Dysentery, bacillary
Encephalitis, infectious (lethargic and nonlethargic)
Favus
German measles (rubella)
Glanders
Gonorrhea
Hepatitis, epidemic
Hepatitis, serum homologous
Hookworm disease (ancylostomiasis)
Influenza
Keratoconjunctivitis, infectious
Leprosy
Malaria
Measles (rubeola)
Meningococcus meningitis (cerebrospinal fever)
Mumps (infectious parotitis)
Paratyphoid fever
Plague, bubonic, septicemic, pneumonic
Pneumonia, acute lobar
Poliomyelitis
Psittacosis
Puerperal infection (puerperal septicemia)
Q fever
Rabies
Rickettsialpox
Rocky Mountain spotted (or tick) fever
Scarlet fever (scarlatina)
Septic sore throat
Salmonellosis
Smallpox (variola)
Swimming-pool conjunctivitis
Syphilis
Tetanus
Trachoma
Trichinosis
Tuberculosis, pulmonary
Tuberculosis, other than pulmonary
Tularemia
Typhoid fever
Typhus fever
Whooping cough (pertussis)
Yellow fever

COMMUNICABLE DISEASES OR INFESTATIONS OCCURRING IN THE UNITED STATES AND INSULAR POSSESSIONS, BUT FOR WHICH NOTIFICATION TO THE HEALTH AUTHORITIES IS NOT EVERYWHERE REQUIRED

Ascariasis
Chickenpox
Coccidioidomycosis (coccidioidal granuloma, "valley fever")
Common cold
Enterobiasis
Filariasis
Hemorrhagic jaundice (spirochetosis icterohaemorrhagica, Weil's disease)
Histoplasmosis
Impetigo contagiosa
Lymphogranuloma venereum (inguinale) and climatic bubo
Pediculosis (lousiness)
Rat-bite fever
Relapsing fever
Ringworm (dermatophytosis)
Scabies (the itch)
Schistosomiasis
Vincent's infection (Vincent's angina, ulcerative or necrotic stomatitis, trench mouth)
Yaws (frambesia)

DISEASES OF CONCERN TO HEALTH OFFICERS BECAUSE OF THEIR GROUP OR EPIDEMIC OCCURRENCE AND THE PRACTICABILITY OF THEIR PREVENTION, AND FOR THESE REASONS OFTEN INCLUDED AMONG THOSE NOTIFIABLE TO THE HEALTH AUTHORITY, BUT NOT TO BE CONSIDERED COMMUNICABLE

Botulism
Food infections and poisonings
Pellagra

The Subcommittee on Communicable Disease Control of the Committee on Research and Standards of the American Public Health Association has formulated certain definitions (Reprint 1697 from the Public Health Reports, Revised 1950) which may be of great value to the physician in the presence of communicable and infectious diseases

Dissemination of Infection. The progress in dissemination of infection of organisms of disease or their toxins, and the clinical manifestations of the process, are as follows:

1 The organism gains the portal of entry and establishes the focus or locus of infection

2 The infection extends from the focus to adjacent or surrounding structures or regions. Signs of such extension are evident, for instance, lymphangitis, but the infectious process and its manifestations still are limited topographically.

3 The established focus or an extension of the focus persists after the dissemination of the infecting agent or its toxins produces manifestations in other organs or systems or in the body as a whole.

The manifestations of an infectious disease which affects the body as a whole are the result of the dissemination of the infecting agent and its toxins through the hemic and lymphatic systems and occasionally through the nervous system (rabies). Often the infecting agent is overcome by the defensive mechanism of the body, so that persistent disease, bloodstream infection or septicemia does not develop. However, the development of septicemia originates disease of the body as a whole.

BACTEREMIA. Bacteremia is a temporary invasion of the blood by bacteria with or without evidence of a continuance of the infection

The blood is frequently invaded by microorganisms which, under normal conditions, are rapidly removed by phagocytosis by the cells of the reticuloendothelial system. Streptococci, occasionally, may be revealed by blood cultures in rheumatoid arthritis. Likewise streptococci and staphylococci may be present in dental infections after chewing; in as many as two thirds of all who have extraction of teeth under general anesthesia, occasionally after extraction under local anesthesia; and after tonsillectomy In such instances there are no clinical evidences of infection although it is visualized that by this method of dissemination localized infection of the fixed tissues may occur

SEPTICEMIA Septicemia occurs when the immunologic resistance of the blood is broken down by unusual numbers or virulence of microorganisms, which multiply in the blood, with the production of toxins and the signs and symptoms of infection. On some occasions the invading microorganisms are not unusually virulent, but the resistance of the host is very low, so that septicemia develops. Secondary infections of the fixed tissues, and particularly of the lungs, pericardium and central nervous system may ensue if the resistance of the patient is low or if the virulence of the invading bacteria is high

The terms bacteremia and septicemia, however, commonly are employed synonymously because it is frequently difficult to draw a sharp distinction between them For example, the occurrence of positive results on blood cultures in the early stage of typhoid fever may be only a bacteremia, since it is usually temporary and occurs at a time when the patient is not severely ill, but if it persists, or becomes more pronounced, it may become an overwhelming septicemia

A true septicemia may be cryptogenic when resistance is low. Furthermore, it may develop very rapidly after an initial infection of a mucous membrane and particularly of the respiratory tract as, for example, the septicemias in the early stages of meningococcal meningitis and pneumococcal pneumonia

The pyogenic bacteria, especially streptococci, staphylococci, pneumococci and meningococci, are the ones most likely to produce septicemia. *Salmonella typhosa, Brucella melitensis, Escherichia coli, Salmonella choleraesuis, Bacillus anthracis, Streptobacillus moniliformis, Actinomyces necrophorus* and the gonococcus less commonly cause septicemia The toxin-producing bacilli, like *Corynebacterium diphtheriae* and *Clostridium tetani* and other clostridia are rarely present in the blood, except *Clostridium perfringens Escherichia coli, Pseudomonas aeruginosa, Alcaligenes faecalis, Hemophilus influenzae, Klebsiella pneumoniae* and the bacteroides rarely multiply in the blood

Septicemia, a general infection resulting from what was originally a local process, may originate from a recognizable focus of infection, as unclean traumatic wounds, puerperal sepsis, pneumonia, gonorrhea, and typhoid fever. In the majority of such cases septicemia is due to the streptococcus or the staphylococcus, but there often are combined or mixed infections; that is, the septicemia may be

caused by the simultaneous presence of the *Streptococcus pyogenes* and the *Salmonella typhosa*, the *Diplococcus pneumoniae*, or the Klebs-Löffler bacillus.

In other cases the focus of infection is not recognizable during life (cryptogenic septicemia) and perhaps not at necropsy. Generally, in these cases of unrecognizable focus, the patient is already ill of some malady, acute or chronic, but in a certain proportion the infection occurs in persons who are in good health

A streptococcal septicemia often occurs during the course of a local or a general infection as a secondary or an intercurrent event in chronic diseases, especially in arteriosclerosis, cirrhosis of the liver, Hodgkin's disease, leukemia, and the chronic forms of nephritis, valvular heart disease, and tuberculosis and other maladies. Because of the fact that these infections are likely to close the scene, they are spoken of as terminal.

When septicemia starts from a local infective focus, the symptoms of the invasion may begin immediately At the onset there is usually chilliness rather than rigor, with fever, moderate at first, but which rises and tends to become of the continued type, with decided daily remissions. There are headache, anorexia, prostration and perhaps delirium. The pulse is rapid, small, and compressible. The tongue shows a marginal redness, and may become dry and brown, evidence of dehydration from the fever There may be nausea, vomiting, and diarrhea, and the spleen may be palpably swollen Petechial spots in the skin and mucous membranes are common, slight jaundice often develops; and scarlatiniform rashes and complicating infection by the groups of herpes simplex viruses may appear on the lips and in the mouth The urine frequently contains albumin, leukocytes, erythrocytes, and tube casts. If the septicemia is cryptogenic, and especially if it is due to the presence of the streptococcus, the fever is high and irregular, and there are recurrent slight chills.

Septicemias are prone to cause localized disease in some region, organ or system of the body. The common sites for the localization of disease from the presence of circulating germs in the blood include the endocardium, especially the valves of the heart, and the pleural, pericardial and peritoneal cavities. The central nervous system likewise is often affected, meningitis or abscesses originating within the organs of this system. The organ of special sense most commonly affected by streptococcal infection is the eighth cranial nerve. Otitis media affecting the special sense organs of hearing is one of the commonest causes of deafness. Conjunctivitis is exceedingly common.

Septicopyemia The presence of septicemia is evidence that the defensive mechanism of the host has been overcome and that pathogenic bacteria have entered the circulatory system from a focus of infection and have established a habitat within the blood stream The term septicopyemia derives its meaning from the fact that it indicates a combination of pyemia and septicemia Differentiation of septicemia from septicopyemia rests on bacterial invasion of the body as a whole. In septicopyemia the bacteria are fed into the blood stream by means of the intermittent breaking off and casting into the circulation of vegetations containing the bacteria. Blood cultures in septicemia are consistently positive, whereas in septicopyemia they may be intermittently positive. Septicemia may develop during the course of many infections, but streptococcal infections are the commonest of all. The most known example is bacterial endocarditis.

THE STREPTOCOCCAL INFECTIONS

The streptococci belong to the family Lactobacteriaceae, tribe Streptococceae, genus *Streptococcus*, type species *Streptococcus pyogenes* The versatility of these organisms as disease agents and their extensive distribution in both man and animals render them potent agents of disease.

On the basis of the Lancefield group-specific and type-specific substances, the streptococci are arranged alphabetically in defined groups from A to I, and the bacteria in each group are further divided into types which are numbered 1, 2, 3, 4 and so on. In group A, 60 or more types are listed

The *epidemiology* of streptococcal infections involves a host-parasite relationship and the environment in which the host-parasite relationship is maintained. The spread of streptococcal infections exemplifies air-borne infections.

In the tropics the hot climate at low altitudes does not favor development of streptococcal infections Ascent from the low levels to the high levels reveals a steadily increasing morbidity rate for streptococcal diseases. The relation of temperature to the morbidity rate of scarlet fever, for example, is illustrated by the seasonal incidence of this disease and other streptococcal infections in temperate climates.

The type distribution of streptococci is cosmopolitan In an extensive study of air-borne diseases during the recent war, streptococci from twenty-two countries were collected simultaneously and typed It was found that every type of streptococci was represented in each country In every locale, at any given time, the existing streptococcal diseases are produced by the types of pathogenic streptococci that are predominantly present, while in that same locale other types of streptococci may be present but not actively producing disease This situation is not static. A particular type of streptococcus may induce scarlet fever for a long time It then may lose the ability to produce the erythrogenic toxin that seems to be characteristic of the disease and become inactive as a producer of scarlet fever without, however, any decrease in its virulence as a producer of other streptococcal diseases Different types of streptococci may simultaneously cause the same disease independently of each other For instance, in a given community a streptococcus of one type may have been producing sporadic cases of scarlet fever, when suddenly the disease assumes epidemic form and it is found that the epidemic cases are caused by another type of streptococcus. When the epidemic has passed, sporadic cases of scarlet fever due to the first type of streptococci again occur A second epidemic of *scarlet fever may now be initiated by an increase in the number of sporadic cases* The kinds of streptococcal diseases in any locality are constantly varying, not because of altering environmental conditions but because of changes within the streptococci themselves.

There is a seasonal variation in carrier rate that parallels the morbidity rate of streptococcal disease

Carriers are more dangerous in the spread of streptococcal diseases than are persons acutely ill from the diseases, since the sick do not get around A carrier disseminates a disease by exhaling air-borne bacteria which are transmitted to nearby persons by direct inhalation or by indirect or delayed inhalation after the carrier has gone, by handshaking or by handling articles and food The spread of streptococcal disease through foods or drink (milk) is slow compared with air-borne spread by an active carrier

The streptococcus produces a variety of toxic products, endotoxins, exotoxins, hemolysin, erythrogenic toxin, leukocidin and fibrolytic substances. In response to these products the host reacts by developing all of the ordinary immunologic reactions An infection by a streptococcus confers a kind of immunity for indefinite periods.

The streptococcus seems to be susceptible in a semispecific manner to the bacteriophage

It is agreed that the streptococcus group A of Lancefield, containing the subgroups 1 to 60 or more, causes the greater part of the *streptococcal diseases* In occasional instances other groups, for instance, groups B and C, may be etiologic agents.

As a rule during a localized infection by a streptococcus the host resistance does not permit establishment of another locus elsewhere in the body. *During the* time a virulent species of infecting streptococcus is circulating in the blood stream, however, if there is not a sufficient defensive force, that is, if the host resistance is not strong enough, the organisms establish themselves in other organs or structures of the body.

The complications of streptococcal disease are in reality progressions of the

original acute focal infections, and they may involve all the topographic or systemic divisions of the body.

In the *integumentary system* streptococcal involvement is by localization in the skin, subcutaneous areolar tissues or mucous membranes in parts of the body distant from the original focus, as cellulitis, that is, Ludwig's angina; in the breast, especially the lactating breast, as mastitis and breast abscess.

In the bones and joint structures the streptococcus causes acute suppurative disease of joints, osteomyelitis, bursitis, abscess of muscle, tenosynovitis and other acute pyogenic processes of this system.

In the *respiratory system* the streptococcus may localize in the nasal accessory sinuses, causing sinusitis, or in the lungs, originating pneumonia The pneumonias produced by streptococci usually are of bronchopneumonic distribution and manifestations Pulmonary abscess without pneumonia may occur. After epidemics of the exanthems, especially measles, secondary streptococcal pneumonia as a complication is to be expected Terminal and streptococcal pneumonia and septicemia frequently occur during postoperative convalescence and in the aged

In the *cardiovascular system* localization of streptococci, producing pyogenic endocarditis and pericarditis, in a heart already injured by disease or by congenital defect, is not unusual. The *venous* division of the cardiovascular system frequently is involved and the involvement is manifested by acute phlebitis, which may proceed to abscess formation In all of these streptococcal infections there is tachycardia The pulse rate is out of proportion to the degree of fever, even though the heart is not affected

In any of the manifestations of the streptococcal state, whether the infection is limited to the original focus or has extended and set up a focus or foci in other regions of the body, the cellular elements of the blood are disturbed A polymorphonuclear leukocytosis is present except when a virulent strain of the streptococcus quickly overwhelms the resistance of a person who was in good health prior to the infection, or in a person seriously debilitated owing to any cause prior to the infection In each of these instances there is little or no increase in the number of leukocytes. In an occasional patient when resistance is overcome there is definite leukopenia. An unusual but significant exception to the rule that there generally is leukocytosis by polymorphonuclear leukocytes is the occasional accompanying eosinophilia Eosinophilia may indicate that there has been previous circulation of a similar antigen

Direct extension of streptococcal infection from the primary focus, usually in the skin, is first through the *lymphatic system* or the circulatory system. Extension through lymphatic channels is manifested by enlargement of lymph nodes and by lymphangitis, reddened streaks radiating from the original focus Cellulitis and abscess formation may be primary in the original focus or secondary to it Cervical adenitis accompanies many of the acute infections by the streptococcus.

In the *digestive system* occasionally a blood-borne streptococcal appendicitis occurs. Reflex digestive symptoms of anorexia and vomiting, however, are common manifestations of most of the acute streptococcal infections The accessory digestive glands may be affected The parotid, the submaxillary or the sublingual glands may be affected These infections usually resolve but may terminate in abscess formation Acute inflammation of the ducts attends these infections The incidence of cholangitis and jaundice is low and is difficult to determine; that of pancreatitis is even lower. Streptococci ingested in contaminated food are likely to result in epidemics of sore throat or tonsillitis, but rarely in gastroenteritis, since these bacteria, unlike the staphylococci, do not cause a specific form of food poisoning.

In the acute streptococcal infections considered thus far, the portal of entry of the streptococcus is through the oral or the nasal cavities or the skin, and the infections involve the urogenital system seldom and only secondarily.

The possibility of the primary entrance of the streptococcus through the orifices of the *urogenital system* is real. Of the primary ascending streptococcal infections, the commonest is pyelonephritis. Occasionally acute cystitis, pyelonephritis or perirenal abscesses may be hematogenous in origin. Streptococcal infections may occur locally or generally after instrumentation of the urinary tract, the organisms establishing themselves at a point of injury or entering directly the lymphatic and circulatory systems That these infections may occur from the same groups and types of organisms that produce scarlet fever in the usual way is evidenced by such connotations as puerperal scarlet fever. Along with other pyrogens the streptococcus is a prominent etiologic agent in the production of puerperal or childbed fever. Acute glomerulonephritis, often associated with scarlet fever, does not result from localization of the streptococci in the kidneys.

The *endocrine system* usually escapes the acute streptococcal infections.

Localization of the streptococcus in the *central nervous system* may occur during an acute streptococcal infection from any portal of entry. Unless the organism enters during surgical operation or through traumatic wounds, streptococcal infections of the central nervous system are always borne by the blood stream. The common manifestation is acute purulent meningitis. Brain abscess also occurs. Either of these diseases may come on after an infection in the skin or in an orifice of the body that may have been too mild to attract the attention of the patient.

Scarlet Fever. SYMPTOMS. Scarlet fever is caused by an erythrogenic streptococcus

The incubation period of scarlet fever is uncertain, from 1 day to 7 days, sometimes 11 days or longer The onset of symptoms likewise is exceedingly variable. In many instances the onset is abrupt, with vomiting and fever The temperature rises abruptly and may reach 103 to 105 F (39.4 to 40.5 C), reaching a fastigium on the second day and slowly receding during the following week.

There are chilly sensations, but rarely is there a chill. The pulse from the beginning is fast, out of proportion to the rise in temperature.

The disease may begin as a sore throat, or the manifestations may begin with suddenness and severity, with hyperpyrexia, delirium and prostration.

EXAMINATION. On examination it is observed that synchronously with establishment of the height of the fever the rash appears, first on the neck and thorax, whence it may remain localized or spread over the whole body within the next 24 hours. After 2 to 4 days the rash disappears or begins to fade rapidly. The developing rash of the tongue and the subsequent lingual desquamation have been given suggestive titles, "strawberry tongue" and "raspberry tongue." The papillae of the tongue are reddened and swollen During the height of the rash the skin from a distance appears uniformly and brilliantly scarlet, but on examination the eruption is observed to consist of fine, closely set red points on a diffusely reddened background. A transient blanching of the rash is produced by pressure on the skin The cutaneous manifestations in scarlet fever may be atypical or lacking Sometimes punctate rashes occur, either alone or with the general rash, distributed irregularly over various regions of the body. The mucous membrane of the mouth and throat is brilliantly and deeply erythematous; the tonsils are diffusely reddened.

When the fever subsides, desquamation begins, usually proceeding in the regional order in which the rash appeared. Complete desquamation, which includes the tongue and the mucous membrane of the mouth may occur and if so, it is a slow process requiring from 1 to 2 months The cuticle usually separates in small scales, but it often can be peeled away in large flakes.

In severe scarlet fever the rash may be irregularly distributed and hemorrhagic, and each day it may become darker in color. Clear vesicles develop and become turbid as time passes. The entire skin may be covered, with small yellow vesicles

on a red background (scarlatina miliaris) Widespread purpuric eruptions may appear at the onset of symptoms or may attend desquamation. Ecchymosis in dependent parts such as the scrotum may occur.

The leukocyte count is from 15,000 to 40,000 per cubic millimeter of blood, indicative of the response to the invading organisms. The spleen may be enlarged, but the enlargement is not diagnostic. Urinary changes are significant of dehydration and fever or of cloudy swelling of the kidneys.

DIAGNOSIS. The diagnosis of scarlet fever usually can be made by the sudden onset of high fever, vomiting, extraordinarily rapid pulse, the reddened swollen papillae of the tongue, and the early appearance of the rash. Throat cultures reveal the presence of a hemolytic streptococcus

Acute follicular tonsillitis may run a clinical course indistinguishable from that of scarlet fever, especially when scarlet fever does not present a cutaneous rash or when it is accompanied by an atypical rash.

Diphtheria may be accompanied by a cutaneous eruption over the thorax. This eruption is not so brightly colored as that observed in scarlet fever. In any event, the diagnosis of either scarlet fever or diphtheria is not based on the appearance of the cutaneous eruption Cultures from the throat grown on appropriate mediums will enable one to make the proper differentiation

Rubella is attended by a cutaneous eruption resembling that of scarlet fever, except that the rash in rubella is not punctiform. When rubella is suspected, the patient should be isolated and kept strictly away from pregnant women, since rubella during pregnancy may cause malformations of the fetus.

The Dick test determines susceptibility to scarlet fever The test is carried out after a preparation of the toxin has been made so that the skin test dose of the toxin is contained in 0.1 ml. of the preparation. The dose is injected intradermally into the flexor surface of the forearm A circular or oval area of erythema 1 cm. in diameter or larger occurring at the site of injection 24 hours after injection indicates that the subject is susceptible to scarlet fever

COMPLICATIONS Otitis media is one of the commonest and most important complications of scarlet fever. The streptococcal focus in scarlet fever is the throat, from which the infection ascends through the eustachian tubes to involve the middle ear. Otitis media may come on at any time during scarlet fever or during convalescence from the fever It is manifested by recurrence or enhancement of fever and by pain in the ear with evidence of increased tension on the membrana tympani unilaterally or bilaterally Williams pointed out that 10 8 per cent of otitis media and 1.1 per cent (15,733 cases) of mastoiditis and sinusitis of accessory sinuses are complications of scarlet fever Thrombosis of the lateral sinuses, meningitis and brain abscess may result from otitis media Paralysis of the facial nerve may result from bone necrosis incident to middle-ear disease

In the second or third week or later, glomerulonephritis often arises as a sequel of any one of the acute streptococcal diseases, but often from scarlet fever. Acute glomerulonephritis is manifested by edema and the presence of erythrocytes and tubular casts in the urine. Usually in the streptococcal infections the urine remains essentially negative during the course of the disease except for small amounts of albumin, not more than grade 1 (on a basis of 1 to 4, grade 1 being the least amount) Mild forms of glomerular involvement, glomerulitis, may occur and may do great injury to the kidneys, injury which may not be manifested until months or even years later and then as chronic glomerulonephritis If nephritis occurs recovery is to be expected in most instances Rapidly progressive nephritis, however, is accompanied by hyperazotemia and edema of the glottis and is followed immediately by generalized edema. The mortality rate in these rapidly developing nephritides may be high.

Acute follicular tonsillitis, epidemic streptococcal sore throat, and phlegmonous

or suppurative tonsillitis are all streptococcal infections by strains of the strep
coccus which are not at the time producing an erythrogenic toxin.

Ludwig's Angina. Ludwig's angina is a rare disease caused by a streptococ
infection, either following a sore throat or occurring secondarily as a complicati
of one of the specific infections, especially diphtheria or scarlet fever. The disea
is characterized by a swelling beginning in the submaxillary region or regions, a
spreading to the floor of the mouth and the front of the neck. There are fever a
much pain, with dysphagia and difficult mastication and articulation. Grave dyspn
may supervene from compression of the larynx or edema of the glottis.

Erysipelas. SYMPTOMS Erysipelas is a streptococcal infection. The incubati
period varies from 3 to 7 days. The disease commences with a chill or chilline
followed by a rise of temperature to 103 to 105 F (39.4 to 40 5 C). In previous
strong and healthy persons the constitutional depression may be slight, but in t
old or debilitated, or in chronic alcoholics, there may be great prostration, d
tongue, feeble pulse and delirium

EXAMINATION. In an erysipelas not secondary to surgical operation or injur
on examination a reddened spot is observed, usually on the bridge of the nose
on one of the alae, occasionally on other parts of the face, on the ear, or on t
scalp The spot becomes apparent with the onset of the fever This reddened ar
rapidly enlarges; the skin becomes swollen, erythematous and tense and is ofte
studded with vesicles or small bullae, especially on the eyelids, ears, and forehea
The pain is burning and intense The inflammatory area has a well-defined, som
what raised margin, and as it extends, the areas first attacked become somewh
lighter in color and less swollen than earlier in the disease. When the greater portio
of the face is involved, the eyes are swollen shut, the nose is bulbous, the lips an
ears are thickened and edematous The cervical lymph nodes are enlarged. Sma
cutaneous abscesses are common on the neck, cheeks, and forehead, and there ma
be extensive suppuration under the scalp The mucous membrane of the mouth an
throat is reddened, and in rare cases the inflammation may extend to the laryn
and cause edema Leukocytosis is present, and the urine is often albuminous.

DIAGNOSIS The diagnosis is based on the clinical findings and is supported b
positive cultures of virulent streptococci from wounds or from the throat.

COMPLICATIONS AND SEQUELAE Septicemia, pyemia, ulcerative endocarditis
peritonitis, meningitis, and articular rheumatism are relatively frequent complica
tions of erysipelas. Pericarditis, pleurisy, acute nephritis, pneumonia and otiti
media occur less frequently Despite meningeal symptoms such as delirium, coma
and meningismus, meningitis is rare

Puerperal Infection. Puerperal infection by the streptococcus is one of the
most serious diseases produced by this organism

The common lesion of puerperal fever is *endometritis* Three or 4 days afte
delivery the patient suddenly experiences malaise and complains of headache and
a feeling of chilliness, or she may have a well-defined chill, the temperature rising
to 103 F (39 4 C) or higher Generally only one chill occurs, after which the tem-
perature remains constantly elevated. The pulse becomes extremely rapid, and
later it is weak and of small volume

The endometritic implication is slight The lochia is thin and not profuse The
patient may complain of intense pain, which is at first limited to the lower portion
of the abdomen but gradually extends over the entire abdomen At the same time
there is marked tympanites, and the abdominal walls are rendered tense by the
distended intestines. If a fatal issue ensues, death usually occurs within 10 days
after delivery, the patient gradually failing In other cases, however, the clinical
symptoms do not correspond to the gravity of the lesion, the temperature is but a
little elevated, the pain slight, and the abdominal symptoms are slight or even

absent, the serious character of the condition being indicated only by the rapid and compressible pulse and the drawn and haggard facies.

In cases of postpartum *pyemia* the symptoms are characteristic. The initial chill occurs by the end of the first week, and the temperature does not remain constantly elevated, but instead there are an intermittent fever and chill, with remission, recurring in succession The symptoms vary considerably, according as the cause is the dislodgment of a single thrombus or is the repeated entry into the blood of small infected particulate matter. In the first event a metastatic abscess develops at some one point, the symptoms depending on the organ involved. In the second event, if thrombi are being constantly dislodged, there may be symptoms referable to various organs

One of the most constant manifestations of postpartum pyemia is bronchopneumonia which contributes to the fatal termination. In other instances swellings at the various joints occur in association with the pneumonia or without it. Suppuration of the joints may lead to total destruction of the joint tissues. Abscesses also may develop in the internal organs or appear on the surface. They may occur in the eye and may lead to its destruction. The course of pyema varies according to the organs attacked and the resisting powers of the patient, and weeks, or sometimes months, elapse before death occurs or recovery ensues

In rare instances the infection is so virulent that the bacteria do not have a chance to become localized in any one organ, and both they and their toxins are found in abundance in the circulating blood, with very slight implication of the uterus. This results in the so-called *acute septicemia—sepsis foudroyante*—which represents a most rapidly fatal form of infection, the patient occasionally dying on the second or third day after delivery in a condition of shock, and without the development of local symptoms Streptococcal septicemia in the postpartum patient has been known to end fatally within 18 hours after the initial rise of temperature.

Occasionally the thrombotic process involving the pelvic veins may extend to the femoral vein, and sometimes to the saphenous vein, on one side or both sides, giving rise to *phlegmasia alba dolens*

EXAMINATION. On examination there is some tenderness in the lower part of the abdomen, and the uterus is larger and more doughy in consistency than normal The lochial discharge is sometimes increased in quantity, is partly bloody, partly purulent in character, and may be practically devoid of odor In severe streptococcal puerperal infection, when the fever is high, there may be very little lochia

DIAGNOSIS The diagnosis of streptococcal puerperal infection is usually established by the history, the examination and the character of the lochia if any be present. The diagnosis of pelvic or generalized peritonitis is based on physical examination and symptoms. The diagnosis of pyemia and septicemia is established by blood culture

As has been stated, the commonest puerperal infection is some form of endometritis, and the differential diagnosis comprises a decision whether the presenting variety is septic, putrid, or gonorrheal Cultures of the lochia often reveal the causative organism

Streptococcal Infections Produced by Miscellaneous Aerobic Streptococci. Aerobic streptococci are separable into four divisions hemolytic streptococci, entero- [illegible]

[illegible] grown on blood agar plates, but a competent bacteriologist can distinguish the differences between these streptococci and the pathogens

Chronic Focal Streptococcal Infections. In the British Museum is preserved large collection of clay tablets, which at one time constituted a part of the library of Ki Ashurbanipal, of Assyria, of the Sargonid dynasty (668-626 B C.). In one of the lett of the Court physician to his king, a most remarkable diagnosis of a dental ailment h been described... Unfortunately we shall never know the name of the physician w wrote it, as the tablet is broken and the fragment which would have contained the supe scription is lost... The physician writes to the king saying "The inflammation whe with his head, his hands (arms), feet (legs), are inflamed, is due to his teeth. His tee must be drawn it is on this account that he is inflamed, he will reduce (it(?)) throu internal (channels) (?). Then will all be well" (The foregoing quotation is from the It Journal; for the source of this translation we are indebted to C. J Gadd, Keeper of t Museum)

Since this centuries-old communication, clinical experience has proved abu dantly that serious diseases may arise from a chronic focus of infection. In ma instances the infecting organisms have been traced from their focus, for instanc the throat, to tissues in remote parts of the body In such cases the causative rel tion is a proved fact The difficulty in the practice of the theory was recognized l Frank Billings and his students, Ernest E Irons and Edward C. Rosenow, wl subsequently originated and sponsored much work on chronic foci of infection This difficulty is the laborious and complicated problem of determining the exa nature of the relationship between a focus of infection and, let us say, chron arthritis, and often the task is insurmountable

The desirability of finding and removing local and often symptomless infectio is generally recognized However, the removal of teeth and tonsils, operations o the nose and nasal accessory sinuses, treating or cauterizing a cystic cervix, an massaging the prostate on the chance of possible relationship between infection an the bizarre complaints of neurotic persons are not scientific procedures. The remova of definite chronic alveolar infections and definitely infected tonsils, however, shoul be done as treatment for local conditions Promises of relief from chronic existin diseases, or of benefit from treatment, should not be given

The diagnosis of a chronic focus of infection as the cause of systemic diseas usually cannot be made until the focus has been removed and until clinical progres of the disease indicates that the focus was the causative factor in its production.

The *Streptococcus viridans*, or green-producing streptococcus, generally is a harmless saprophyte Some varieties of the streptococcus, however, are pathogen since they produce abscesses at the roots of the teeth, sinusitis, and disease of th middle ear These latter organisms, therefore, are prominent in the theory of chroni focal infections because the focus, according to this theory, often is symptomless Many allergic and toxic disorders, due to long-continued growth of bacteria in th bodily tissues, are attributed to the presence of these organisms.

The definite and important disease produced by the *Streptococcus viridans* is *subacute bacterial endocarditis*. During febrile periods of the disease the organisms can be cultured from the blood stream In this disease there almost always has been some sort of predisposing injury or deformity of the heart or its valves prior to the establishment of the growth of the bacteria on the cardiac valves, for example, an ancient rheumatic fever or a congenital defect Previous to inauguration of antibiotic therapy, prognosis in this condition was almost invariably hopeless

In recent years another streptococcus has been observed which has been designated as "S. B E.," simply indicating that the organism causes serious if not always fatal streptococcal endocarditis So far as has been stated, this organism does not participate in chronic foci of infection

THE STAPHYLOCOCCAL (MICROCOCCAL) INFECTIONS

The staphylococci belong to the family Micrococcaceae, genus *Micrococcus*, and species *Micrococcus pyogenes* var. *albus* and var. *aureus*, and *Micrococcus citreus*.

In warm climates, or during the warm seasons in the temperate zones, staphylococcal infections are commoner than elsewhere or in cold weather, and predominantly affect manual workers, who are subjected to trauma to the skin, as by sweaty clothing, or by other dermal irritants such as heat, wetness, dusts or particulate matter. Cutaneous wounds and the accompanying traumatized tissues afford a favorable field for the infection. Debilitated persons, young or old, during convalescence from fevers are particularly subject to staphylococcal infections. The presence of hyperglycemia or azotemia or both furthers the bacterial action. Some persons have allergic cutaneous reactions due to staphylococcal infections.

The diseases produced by the staphylococcus, *Staphylococcus aureus* in particular, may be manifested in any of the chief topographic areas or systems of the body. These diseases are considered in their appropriate places in this text.

Diseases due to staphylococci occur sporadically, endemically and epidemically.

The staphylococci, which in man are parasitic on the skin and in the mucous membrane of the bodily orifices, live in commensalism with other bacteria. Williams, Miles and associates observed that the nasal occurrence rate for *Staphylococcus aureus* among people of the working class who came to the hospital for the first time fluctuated between 19 and 65 per cent during the period from October to July. The mean rate, 47.4, agreed with the carrier rates that had in the past been determined mainly in hospital patients and personnel. The persons studied consisted of three groups. (1) outpatients attending the hospital for the first time with recently inflicted wounds, (2) male inpatients, in a ward, with established wound sepsis and (3) the nursing staff of the same ward The outpatients studied had a gross nasal carrier rate of 47.4 per cent and a wrist carrier rate of 18 4 per cent. The nasal carrier rate of the inpatients studied, calculated from their admission swabs, was 49 4 per cent. The nasal carrier rate among the nurses was significantly higher than for the newly admitted patients. The authors expressed the belief that carriage or noncarriage of staphylococci therefore appears to be a more or less persistent phenomenon. There appears to be a relationship between the carriage of staphylococci in the nose and on the skin.

From the study of Williams and Miles of infection and sepsis in industrial wounds of the hand they concluded that the incidence of *Staphylococcus aureus* contamination of small wounds of hands cultured within 6 hours after infliction was about 20 per cent; the positive incidence of cultures for *Streptococcus pyogenes* was 1 to 2 per cent Staphylococcal wound contamination was commoner in skin carriers of a staphylococcus which was of the same phage type as the one isolated from the wound Sixty per cent of the staphylococci isolated from wounds were derived from the patient's own skin, and no infections were derived from the wounding agents. Self-infection of this sort is rare in streptococcal infections.

Severe wound infections of the hand which ended in a general sepsis were almost always staphylococcal in origin and never due to simple streptococcal infections. About half of the staphylococcal and one fourth of the streptococcal infections were introduced into the wounds However, the streptococci so introduced, in contrast to the staphylococci, which are in 60 per cent of the cases from the patient's own skin, are from sources extrinsic to the patient.

Of the possible factors which predispose to infection and sepsis only staphylococcal skin carriage and wound contamination by staphylococci could be shown to have a constant effect.

The bacterial flora of accidental wounds is a complex mixture of bacteria. Rustigian and Cipriani delineated the characteristic flora of wounds as often being composed of *beta hemolytic streptococci*, *Staphylococcus aureus* and *Staphylococcus albus*, enteric streptococci, *Clostridium*, *Proteus*, *Pseudomonas* and coliform bacteria.

Staphylococcal Food Poisoning. The sickness which follows ingestion of food containing living viral or bacterial agents which are capable of producing infection is *food infection*. Food infection is distinguished from food poisoning. *Food poisoning* may result from dead bacteria or their toxins, chemical agents, plant products and other miscellaneous poisons contained in the food. Etiologically, food poisoning is diagnosed by laboratory methods.

The history of a patient ill with food poisoning should contain the following information: the first symptoms observed by the patient, and the time of the appearance of each successive symptom; the presence or absence of pain, vomiting, diarrhea and constipation; an itemization of all food eaten during the preceding thirty hours, the number of persons who ate the same food, the number who became ill, and the effect on any animals which were fed remnants of food during this time Any food which has not been consumed is examined for abnormalities of appearance, odor, or taste and any such abnormalities are recorded. An aliquot of food, specimens of vomitus and feces are submitted for laboratory examination if this is deemed necessary Extensive examination of food is made only when the health and welfare of the community as a whole are endangered Small epidemics such as may follow the eating of a custard-filled cake at a church dinner are not investigated

It is probable that staphylococcal food poisoning is the commonest type of bacterial food poisoning The poisoning is produced by the enterotoxin elaborated by the staphylococcus The enterotoxin is present in food before it is eaten The other toxins elaborated by staphylococci are lethal toxin, hemolysin, and dermonecrotic toxin

Dack has summarized the factors which are concerned in the production of enterotoxin by staphylococci as follows. (1) the number of organisms, (2) the number of organisms of other types in the food which may overgrow the staphylococci or cause such spoilage as to prevent the food from being eaten, (3) the nature of the food which is infected, and (4) the temperature at which the infected food is kept In temperatures of 16 to 46 C (60 8 to 114 8 F), from 4 to 8 hours are required for the staphylococcus to elaborate enterotoxin, the exact length of time depending on the perishability of the food

The enterotoxin is resistant to cold, and very resistant to heat, although it gradually loses its potency when exposed to high temperatures.

The chief vehicles for staphylococcal food poisoning are cream-filled bakery goods, cheese, doughnuts, milk, ice cream, meat and meat sandwiches. Staphylococci are ubiquitous and are present on the skin, in the respiratory passages and in the air and consequently food may easily become contaminated Persons who have coryza or those with infected abrasions of the hands should not handle food.

The onset of symptoms occurs in 1 to 6 hours after the ingestion of the contaminated food. Salivation associated with nausea is followed promptly by vomiting, retching, abdominal cramps, and diarrhea After the patient vomits there is relief for a time, but vomiting soon recurs The vomitus may contain blood. In some patients, vomiting or diarrhea may be the only symptom The diarrhea may begin with a soft stool which is later followed by profuse watery stools; the latter may subsequently contain blood The severity of the attack varies There may be headache, muscular cramps, and sweating. A period of anorexia may follow the acute attack and may be accompanied by less frequent bouts of nausea, vomiting and diarrhea lasting from 1 to 3 or 4 hours.

Examination, in mild instances of food poisoning, reveals no definite abnormalities attributable to the poisoning. The toxic condition is purely symptomatic.

In severe cases, prostration and dehydration may be marked and fever or subnormal temperature may be present

Symptoms of food poisoning coming on about 4 hours after ingestion of dairy products, meat or cheese sandwiches usually are due to staphylococcal toxins The diagnosis of staphylococcal food poisoning is justified

Laboratory diagnosis involves detailed bacteriologic procedures which consist, first, of culturing the staphylococcus and second, of proving that the particular type of staphylococcus produces an enterotoxin. Not all staphylococci are producers of enterotoxin Generally, the pathogenic strains are highly pigmented and hemolytic.

Complete recovery is the rule An occasional death has been reported. Recovery is usually prompt and occurs in from 1 to 5 days.

Staphylococcal Enteritis (*Hemolytic Staphylococcus aureus, Coagulase Positive*). The importance of staphylococcus as an etiologic agent in severe enteritis is not known. Finland has recently recorded that patients who have been receiving aureomycin or terramycin may develop diarrhea, and that shock and death may ensue. It is presumed that the intestinal flora has been destroyed by the antibiotic with a subsequent overgrowth of the *Micrococcus pyogenes* or staphylococci

PNEUMOCOCCAL SEPTICEMIAS AND EXTRAPULMONARY INFECTIONS

The pneumococci belong to the family Lactobacteriaceae, tribe Streptococceae, genus *Diplococcus*, and species *Diplococcus pneumoniae*. The pneumococcus has a capsule, stains readily with all the usual aqueous aniline dyes, and is gram-positive.

Dochez and Gillespie divided certain pneumococci into types I, II and III and relegated all other pneumococci to type IV. In 1932 Cooper and her associates identified and reclassified 29 types of these previously considered as group IV. However, more recent studies have revealed criteria for division of pneumococci into 75 types

The pneumococcal diseases probably develop on the general plan followed by other pyogenic coccal infections, that is, the infection is disseminated from an acute or a chronic focus in the nose or throat, with subsequent spread by way of the lymphatic channels and the blood vessels and establishment of some other locus in the body From the secondary focus, which is often the lungs, the infection gives rise to severe manifestations, such as acute arthritis, sinusitis, otitis media, mastoiditis, empyema, carditis, peritonitis, meningitis or ulcerative conditions of the eyes. Any of these infectious diseases, especially if it apparently is of spontaneous occurrence in a child, requires consideration of the pneumococcus as the etiologic agent.

During the course of pneumococcic pneumonia, any of the foregoing diseases may set in as a complication In addition there may be formation of abscess at the site of hypodermic injection or in the muscles over the lower part of the thorax and upper part of the abdomen, or in both places Localization of pneumococci in the muscles, with subsequent formation of abscess, occurs probably in hemorrhagic regions of muscles The hemorrhages into the muscles are secondary to coughing.

Endocarditis and *meningitis* may occur together or separately during the course of pneumonia An endocarditis usually is superimposed on rough arteriosclerotic valves or on valves already affected by rheumatic fever. If, during the course of pneumonia, there is a sudden appearance of a diastolic murmur, it should suggest a possible complicating endocarditis If there is a cardiac murmur which changes in quality during the course of pneumonia, the presence of endocarditis should be suspected The definite manifestations of endocarditis are embolic phenomena. During the course of pneumonia the occurrence of meningitis may be the first indication of endocarditis, the meningitis resulting from infected thrombi from the heart. A statement concerning the frequency of this complication cannot be made The meningitis usually comes on at the height of the fever during the course of pneumonia In the majority of cases the meningitis is not distinctly manifested unless the

base of the brain is involved, and this is not common. In any event, when meningitis attends pneumonia, the prognosis is exceedingly bad.

Peritonitis is a rare complication in lobar pneumonia. Peritonitis may begin synchronously with involvement of the pleura in pneumonia or it may extend from the thorax through the diaphragm into the upper portion of the abdomen. Pneumococcic peritonitis independent of pneumonia occurs more frequently in children than in adult patients. Peritonitis may develop during the course of severe pneumonia, but often it cannot be recognized.

Jaundice during the course of pneumonia occurs rather frequently during some epidemics. It seems that jaundice is commoner among Negroes than among whites. Jaundice that develops during the course of lobar pneumonia should not be considered as an exceedingly unfavorable complication.

Parotitis, nephritis and *arthritis* have all been proved to be complications of pneumococcal infections.

A pneumococcal septicemia may be manifested as an atypical pneumonia. Atypical pneumonia in the aged, in adult persons debilitated by chronic disease, and in children may cause a severe illness resembling a septicemia, while infection remains limited to the lungs. Likewise there may be present the manifestations of a septicemia with the disseminating focus in the lungs with minimal manifestations of pneumonia. Almost any infectious illness in the aged and the debilitated that does not conform to definite patterns of disease may be a form of atypical pneumonia with or without extrapulmonary disease.

THE HEMOPHILUS GROUP

The organisms *Hemophilus influenzae*, hemophilus of Koch-Weeks, *Hemophilus parainfluenzae, Hemophilus hemolyticus, Hemophilus suis*, and *Hemophilus haemoglobinophilus* belong to the genus *Hemophilus*, which is a member of the family Parvobacteriaceae.

Various members of the genus *Hemophilus* are important in human infections. *Hemophilus canis* and *Hemophilus ducreyi* affect the genital region and cause soft chancres and chancroids. *Hemophilus pertussis* is associated etiologically with whooping cough. A hemophilic bacillus ("Bacillus X") causes a fatal subacute bacterial endocarditis, the organism is identical with that described in the throats of normal persons.

Hemophilus influenzae. *Hemophilus influenzae*, genus *Hemophilus*, of the family Parvobacteriaceae, is often called also Pfeiffer's bacillus, *Bacillus influenzae* and Koch-Weeks bacillus.

The adult person appears to possess effective resistance to *Hemophilus influenzae*. If the normal defense mechanism be altered, as occurs in severe pandemics of influenza caused by filtrable viruses, a greater prevalence of severe *Hemophilus influenzae* infections in adults is to be expected.

Hemophilus influenzae is regularly found in the respiratory passages in members of families of children in whom this organism has caused meningitis in a brother or sister. Of the adults of the family the mother is the only member who harbors the *Hemophilus influenzae* with any degree of frequency. *Hemophilus influenzae* persists in the nasopharynx for long periods after its elimination from the spinal fluid.

Infection by this organism is not distinctive. It often occurs early as a complication of viral influenza, though this early occurrence is not definite enough to be of value in diagnosis, since pneumonia, streptococcal, staphylococcal, or pneumococcal, can come on early during the course of influenza.

In infection of the respiratory tract a cough may be present which may resemble a whooping cough and may persist for several weeks after the attack has otherwise subsided. Such a cough in adults may be thought to be a second attack of whooping cough.

Hemophilus influenzae may be responsible for an obstructive laryngeal, laryngo-

tracheal or laryngotracheobronchial infection in children 2 years of age or older. The onset is sudden, and the course fulminating. The entire length of acute illness is usually less than 24 hours. During the course of an infection in the upper part of the respiratory tract there is a sore throat Dyspnea starts abruptly and increases within a few hours to such a degree that tracheotomy is imperative. On examination of the pharynx there is diffuse erythema, often with evident edema, and when the tongue is pressed downward, the enlarged red, misshapen, edematous epiglottis is easily seen.

Hemophilus influenzae can produce primary respiratory and extrarespiratory disease. As a primary respiratory disease in most children it produces nasopharyngitis with fever. Many recover from the infection spontaneously. In others sinusitis or otitis media develops. Any portion of the respiratory tract from the epiglottis and surrounding structures to the alveoli may be affected From these foci in the respiratory tract, invasion of the blood may occur. The meninges and joints are sites of predilection for localization. Rarely pericarditis or subcutaneous abscesses result. The severe *Hemophilus influenzae* infections found with greatest frequency are meningitis, obstructive infections of the respiratory tract, pyarthrosis, pneumonia and empyema.

The diagnosis of *Hemophilus influenzae* infections depends on positive cultures of the organism in the body fluids.

In infants and children *Hemophilus influenzae* is a frequent cause of meningitis. The manifestations of influenzal meningitis do not differ from those due to other varieties of bacterial meningitis Therefore etiologic diagnosis depends entirely on a bacteriologic identification *Hemophilus influenzae* pneumonia, empyema, pyarthrosis and other less frequently occurring clinical diseases such as ethmoidal sinusitis with periorbital cellulitis and edema, and pericarditis may occur but they are not solely characteristic of this infection.

The precipitin test can provide immediate diagnosis when organisms are numerous This test can be used for immediate diagnosis of *Hemophilus influenzae* in spinal fluid, in exudate from the middle ear or in a joint exudate, or in empyema fluid.

MALLEOMYCES MALLEI AND GLANDERS AND FARCY

Malleomyces mallei, the causative organism of glanders or farcy, belongs to the genus *Malleomyces*, tribe Pasteurelleae, family Parvobacteriaceae.

When the disease is localized in the nose, it is known as *glanders* The more chronic and constitutional form of glanders, marked by thickening of the superficial lymph vessels, is known as *farcy*. However, both glanders and farcy occur either in acute form or in chronic forms

The essential lesion caused by *Malleomyces mallei* is a granuloma When the lesion begins under the skin, it develops rapidly into formation of abscess, when under the mucous membrane, into ulcers Similar nodules may occur in internal organs

In order that the symptoms of glanders or farcy may be interpreted, a history of association with, or handling of, horses, mules or asses is necessary, because the disease does not occur spontaneously in any other farm animal. The protean manifestations in both the acute and the chronic stages may resemble other diseases

Acute glanders begins with an infection at the site of cutaneous injury with swelling, redness and lymphangitis. There are a high fever, headache, backache and anorexia. From 1 to 4 days later the mucous membrane of the nose becomes involved, ulcers form rapidly, and there is a mucopurulent discharge. Ulcers and abscesses begin to break out over the face and about the joints The nose swells and cutaneous eruptions ensue The lymph nodes of the neck are enlarged, and within a few days the symptoms of pneumonia develop. Whole regions of the subcutaneous tissue may break down and gangrene may follow.

The disease acute farcy is very much like acute glanders except that it is a more

generalized infection with less localization in the nose and about the face. Little is known of the chronic forms of the disease.

On examination the findings depend on the stage of development of the disease The initial lesion in the skin is a nodule at the site of the infection surrounded by a region of lymphangitis and swelling A generalized eruption ensues which may resemble the eruption in smallpox or syphilis The findings as the disease progresses depend on the organs involved. Pneumonia is a constant development

Bacteriologic examination with injection of guinea pigs offers the only dependable diagnostic criterion for these diseases The prognosis is always bad No specific remedy is known In a few instances of the so-called chronic type recovery may have occurred Fortunately, the disease is exceedingly rare and in recent years has become much rarer

Syphilis, tuberculosis, epithelioma and a variety of other diseases, including granuloma inguinale, lymphopathia venereum, chancroid and mycotic lesions, are differentiated by bacteriologic methods, as are typhoid fever, acute rheumatic fever, and general septicemia from any cause.

MALLEOMYCES PSEUDOMALLEI

Melioidosis is a glanders-like disease of rodents, transmissible to man, which occurs in India, the Malay States, and Indo-China Melioidosis is distinct from tularemia, which is caused by *Pasteurella tularensis*, although clinically the two diseases resemble each other closely

THE SALMONELLAE

The enteric group of bacteria (Enterobacteriaceae) includes gram-negative, nonsporulating rods Some (*Salmonella*) are the etiologic agents of gastroenteritis, typhoid fever, paratyphoid and other enteric fevers, and of various types of septicemic infections; others (*Shigella*) cause bacillary dysentery, still others are intestinal saprophytes but may cause pathologic processes in the urogenital and respiratory systems and after wounds or injuries (see pp 965 and 763)

The Salmonellae *Salmonella*, a genus of bacteria of the family, Enterobacteriaceae, comprises gram-negative, nonspore-forming, motile bacilli The different species are closely related antigenically All are usually pathogenic for man or animals

There are three main types of clinical manifestations of salmonella infection, namely, the enteric fevers (typhoid and paratyphoid fevers), gastroenteritis, and a localizing type with foci in one or more organs accompanied by septicemia.

Salmonella typhosa (*Typhoid Fever*) The bacillus of typhoid fever, species *Salmonella typhosa*, genus *Salmonella*, tribe Salmonelleae, family Enterobacteriaceae, is often termed *Bacillus typhosus*, or *Bacillus typhi abdominalis*

Salmonella typhosa has no distinctive physical features that differentiate it from the other species of salmonella It is actively motile, has 12 or more flagella peripherally arranged, it stains readily with the usual aniline dyes, and is gram-negative The final differentiation of the bacillus is best based on specific agglutination

Smooth motile and smooth nonmotile forms contain special antigenic factors called the H factors in the flagella or in the soluble specific substances as do the other species of salmonella An antigenic pattern has been evolved for the four varieties of *Salmonella typhosa*, and their relationships have been established in part Immunization with pure O antigen produces O antibodies; immunization with the motile OH organisms produces both H and O antibodies. The H antigen and antibody apparently have no relation to protection.

The source of typhoid fever is typhoid bacilli living within the bodies of infected persons Infection with typhoid fever means that the infected person has ingested something that was contaminated by the fecal excretion of a typhoid carrier or a typhoid patient.

Generally one attack of typhoid fever protects against a subsequent infection Circulating antibodies disappear from the typhoid convalescent within the first 7 or 8 months after recovery. The permanent immunity is explained as a special endowment of the tissue cells. There are present in the blood serum of the typhoid immune human being bacteriolytic, bactericidal and agglutinating substances, and to a lesser extent precipitating and opsonic bodies.

Agglutination (Widal reaction) is a specific immunologic phenomenon employed in the diagnosis of typhoid fever. The test antigen is a suspension of heat-killed typhoid bacilli. The test is performed by determining by dilution the smallest amount of the patient's serum which can agglutinate the organism If the organisms are agglutinated by the patient's serum, the Widal reaction is positive, and the patient is considered to have typhoid fever if he is ill with a fever which has lasted for at least 10 days or more, and if he has not had the disease within recent years. Exception to this rule is that a patient who has had a prophylactic vaccination against typhoid fever may give a positive Widal reaction. False positive Widal reactions may be present in a patient who has been vaccinated against typhoid and paratyphoid fevers if the test is performed during the course of fever and infection with organisms other than typhoid bacilli (anamnestic reaction).

The interpretation of positive results obtained by the modern Widal reaction is as follows· (1) for O agglutinins, the significant titers, as reported from the laboratory, are those above 1 50 since a few normal persons have titers as high as 1:50 and rarely 1:200 or above, (2) for H agglutinins, titers of 1:80 or above appear to have some diagnostic significance. It is emphasized that the results of these agglutination tests are to be interpreted only with a full knowledge of the history of the patient, especially with reference to previous vaccination against typhoid fever, that the repetition of the test should be made in order to secure an index of the rise or fall of the agglutinin titer, and that only when the titers are high, O 1.500 or H 1:1,000, can they be said to be diagnostically significant The presence of O agglutinins in high titers with H agglutinins absent or present in low titers strongly suggests typhoid fever, even in a previously vaccinated person If there is a high titer of F [illegible]
absent or present in low titer, this suggests
possibly nonspecific stimulation as from a fe
than typhoid fever in a vaccinated person A very high H titer above 1:1,280 may be significant even in vaccinated persons The determination of O and H agglutinins does not serve to distinguish typhoid infection from infections with the closely related members of the enteric group of organisms, especially *Salmonella paratyphi* and *Salmonella schottmuelleri.*

If a polyvalent antigen is employed with proper technic, the complement fixation reaction or test is of high specificity. About one half of patients who have typhoid fever give positive reactions between the first and second weeks of the disease and between 90 to 95 per cent of patients who have typhoid fever give positive reactions after the second week of the disease

Carriers The most important channels of transmission of the typhoid organism from the carrier or the sick person to those who are in good health are, in the following order, drinking water, milk, uncooked vegetables, shellfish, and flies, which may play an important role in carrying of typhoid bacilli from feces to food In recent years, with improved sanitary measures in operation in the sickroom, contact infections become more and more important Contact infection takes place from fomites, fingers, food to mouth, towels, bedclothing and underclothing

As soon as the typhoid bacilli are ingested, they begin to grow in the intestine. During the latter period of the incubation time they begin to appear in the feces After the second week of the disease large numbers of the bacilli are passed *in the stools* Large numbers continue to be discharged in the stools until toward the end of the disease They are continuously discharged in small numbers throughout convalescence, and sometimes for months or years thereafter During the second and *third or later* weeks of the disease the organisms appear in the urine. Unusual routes of discharge of the bacilli from the patient are in pus from suppurations and in the sputum. When recovery from typhoid fever is evident, *Salmonella typhosa* is usually eliminated from

the patient's body within a few weeks or months thereafter. Occasionally this does not happen. The patient seems to be unable to get rid of the bacilli, but under these conditions a specific bodily resistance develops in the affected one which holds the bacilli dormant in the tissues. However, if these apparently dormant bacilli retain their virulence and if the host is capable of harboring and growing virulent bacteria within the body without causing manifestations of the disease, that person is known as a carrier. In addition to those who continue to harbor and to discharge typhoid bacilli after recovering from the disease, there are a certain number of so-called healthy carriers who give no history of ever having had the fever.

Typhoid carriers have been designated as intestinal carriers, gallbladder carriers, hepatic and biliary duct carriers, depending on the situation of the focus capable of producing virulent organisms Occasionally there is a chronic urinary carrier, but these are less common than the chronic fecal carriers.

A diagnosis of the carrier state can be made only by a demonstration of the typhoid organisms in some of the secretions The carrier state cannot be diagnosed on the basis of serologic reactions The person who has active typhoid fever and the so-called healthy person who is a carrier are the most dangerous sources of the disease to the community

PROPHYLACTIC VACCINATION AGAINST TYPHOID AND PARATYPHOID FEVERS Travelers into regions where the water supply is unsafe or uncertain, those living in rural regions who have shallow wells for water supply, families of typhoid fever patients, physicians, nurses, and others in attendance are exposed to the infection and may contract it despite sanitary regulations and should be protected by vaccination or active immunization. *Salmonella paratyphi* and *Salmonella schottmuelleri* are included with *Salmonella typhosa* in the preparation of typhoid vaccines. Often commercial vaccine does not contain the paratyphoid organisms Typhoid vaccines are administered subcutaneously, intracutaneously, and by mouth The intracutaneous method is the best of the three methods, since it is sure of conferring immunity and is followed by less reaction than the other methods.

The reactions to the subcutaneous injection of typhoid fever vaccine occur within 24 hours to 48 hours There are local tenderness and swelling about the site of the injection In rare instances an abscess forms.

The general reactions, if any be present, consist of headache, malaise, fever, chills, and occasional nausea and vomiting, and in a few instances there is diarrhea The patient may be incapacitated for from 1 to 2 days. These reactions follow most frequently the second injection of the vaccine There is less likely to be a reaction after the injection if the patient does not exercise, and if he eats a restricted diet.

PATHOLOGY The demonstrable lesions begin by a preliminary hyperplasia of the reticuloendothelial system of the Peyer's patches of the intestines As the disease advances, there is sloughing, leaving shallow ulcerations parallel to the long axis of the intestines The ulcers heal as the disease regresses and leave no scars after healing.

The spleen is enlarged from reticuloendothelial hyperplasia Focal necrosis in the liver, in the meninges and in the periosteum is commonly observed The tibiae and the vertebrae are the bones most commonly affected by such a necrosis

If hemorrhage has occurred, it may be difficult to determine which ulcers were its source Perforation of the ileum with an ensuing peritonitis may be present.

More than one half of those who have typhoid fever are between 12 and 35 years of age. The sexes are equally affected. House infection occurring in one member, and usually in several members, of a family is common. Boys often are infected while swimming in the water of polluted streams. Sporadic instances of typhoid fever occur which are usually due to contact infection, often from carriers. The morbidity from typhoid fever is the highest in the summer and autumn months Incidence is least from January to April The incubation period is variable, usually from 8 to 1[illegible] days. However, the incubation period may be from 1 day to 3 weeks. [illegible]

SYMPT[illegible]

Anorexia, [illegible]

first thing, however, that makes the patient aware that all is not well is the presence of a fever. Typhoid fever is classically described as following a characteristic course. The fever gradually rises. This rise has been called the stadium incrementi (lasting about 1 week). The fever then reaches a level or establishes itself at about the same height (lasting about 1 week). This continuous fever is called the acme. After the acme the fever becomes markedly remittent (1 week to 10 days later). This remittent fever is called the amphibolous stage and finally ends by lysis. The lysis is called the defervescence. Immediately following the lysis there are a few days of subnormal temperature. The earlier clinicians classified the fever and the clinical symptoms of typhoid diseases according to the weeks of the disease. This practice is schematic and of very little value to practical diagnosis.

Accompanying the fever as the disease develops there are headache, pain in the back, chilly sensations, sometimes actual rigor or chills, anorexia, disinclination for exercise, nosebleed, slight abdominal distention, rarely diarrhea and usually constipation.

Examination after the fever has become fully developed reveals a slow pulse when contrasted with the elevation of the temperature. The pulse is often dicrotic. Sometimes coarse rales are heard in the lungs The spleen is often palpable. The psyche may be a little dull There is rarely delirium before the second week of the disease. The skin is dry and hot. It is infrequent for herpes or signs of coryza to appear early in the course of the disease

All the subjective symptoms are exaggerated until about the tenth day, when the patient no longer complains of the headache and becomes more apathetic and dull. This apathy and mental dullness is present during the course of many severe fevers, and it is designated as the typhoid state. Now the patient may become restless and delirious The delirium is more characteristically manifested during the night hours than in the daytime In the severer forms of the disease jumping of the tendons (subsultus tendinum) may be noticeable. If the typhoid state is well developed, there is a tendency of the patient to pick at the bedclothes (carphologia). Involuntary urination and defecation are common in delirious patients

Intestinal hemorrhage is common during the last part of the second week. The hemorrhage may be just a diapedesis of blood from the hyperemic, spongy, swollen Peyer's patches along the small intestine. As the danger of intestinal hemorrhage decreases at the beginning of the third week of the disease, the danger of perforation of an ulcer with subsequent peritonitis increases.

Variations in the severity of the symptoms of typhoid fever are great. In some instances the fever is never high and does not last more than a few days In others during the first few days or weeks the fever is high and then quickly disappears (typhus abortivus). The symptomatology in abortive typhoid resembles that of typhus fever or Brill's disease. In still other cases the patients continue to be up and about (walking typhoid).

During the fourth week of the disease recrudescence or relapse may occur. In these, the fever begins to subside over a period of several days Then there is a rise and the fever may remain up for several days to weeks. Recrudescence or relapse of typhoid fever may recur more than once, for as long as 2 months after the disease Recrudescent typhoid fever usually is of shorter duration and often is less severe than the first attack

Examination. The pulse rate is slow, out of proportion to the height of the fever. During the first 7 or 8 days a scattered petechia-like skin eruption, rose spots, may be observed intermittently on the abdomen, the thorax, and the back. When present, these spots are helpful diagnostically. The spleen as a rule becomes definitely palpable during the second week. Abdominal distention is present from the onset, but it is more marked as the disease progresses There may be a considerable amount of intestinal noises and gurgling on palpation.

Bedsores are likely to develop in the patients who are very ill. The points of pressure, the lumbosacral regions, are most likely to be involved by bedsores or decubitus ulcers

Bronchopneumonia with an ensuing circulatory failure may be present in those seriously ill In 3 or 4 weeks, if the patient survives, there is a fall of temperature by lysis, the *stadium decrementi*. The pulse rate, which has been increased after the slow pulse in the beginning, again decreases and there may be a definite bradycardia.

In patients who have been very ill, who have become greatly exhausted and emaciated, a posttyphoid psychosis may develop These posttyphoid psychoses are exhaustion psychoses and usually clear up when the patient has regained some of the lost body weight and strength

There is almost always leukopenia, the total leukocyte count not exceeding 7,000 or 8,000 per cubic millimeter of blood Often the leukocyte count is as low as 3,500 cells per cubic millimeter In many instances there is a relative increase in the large mononuclear cells The leukocyte count promptly increases, however, if a complication such as intestinal perforation occurs The blood culture is positive during the first week of the disease The Widal reaction is negative during the first week. If the Widal reaction is positive during the first week of the disease, caution is used in its interpretation, for the patient may have had typhoid vaccination.

DIAGNOSIS. *The diagnosis of typhoid fever is based on the demonstration of Salmonella typhosa* in the blood, feces or urine or on sternal aspiration There is no one symptom nor even a combination of clinical data which will suffice for making a definite diagnosis other than demonstration of the organisms of typhoid fever. A combination of fever, slow pulse, rose spots on the skin and palpable spleen usually indicates typhoid fever However, this combination of symptoms is rarely present in sporadic cases It is observed in districts where typhoid occurs epidemically and in a severe form.

COMPLICATIONS The complications of typhoid fever are (1) those which arise locally from the destructive effects of the intestinal lesions, (2) those referable to the septicemia, and (3) those which may arise as the result of prolonged fever and wasting of body tissue

The local complications arise from ulceration and necrosis of the Peyer's patches and are manifested by intestinal hemorrhage and intestinal perforation

Intestinal hemorrhages are more frequent during the second and third weeks of the disease than at other periods The bleeding may occur as a single hemorrhage or as a series of hemorrhages The bleeding may be insignificant in amount or large enough to be fatal. Large hemorrhages are the commonest cause of death in typhoid fever

Intestinal perforation and peritonitis are less common than hemorrhage The perforation usually occurs during the third, fourth, or fifth week of the disease but may occur as long as three months after the fever has subsided, and is likely to develop during or soon after straining defecation. The site of the perforation is usually the base of an ulcer situated toward the lower end of the ileum or even in the colon.

Surgical treatment is ineffective for hemorrhage in typhoid fever It may be curative in perforation and should be carried out immediately.

During the period of the septicemia, as in any septicemia, the complications which may arise are carditis or myocardial insufficiency, pneumonia, meningitis, osteomyelitis and furunculosis. Cystitis and at times nephritis may occur. Typhoid parotitis occurs in some cases

Complications arising from the presence of prolonged fever are mainly venous thrombosis in the deep veins of the pelvis or in the upper part of the leg An attack of typhoid fever often leaves a patient with a swollen edematous leg; the swelling and edema may clear up but often are permanent. In regions where typhoid fever

is rampant, there may occur a combination of venous thrombosis involving the leg from the hip downward and osteomyelitis involving the bones of the same leg. Typhoid osteomyelitis often settles in the tibia Frequently it is an exceedingly chronic disease. For years an open sinus which on occasions discharges small pieces of bone may persist (see p. 279)

Salmonellosis and Gastroenteritis. The usual sources of human salmonellosis are human carriers The organisms may be obtained in insufficiently cooked pork and fowl; eggs, water; food contaminated by rodents during storage; pets and farm animals.

About 160 strains or "types" of salmonella have been described. These strains differ from each other in their serologic and biochemical behavior.

The *Salmonella paratyphi* organisms cause (1) a disease which simulates typhoid fever, recognizable as different from true typhoid fever only by isolation and identification of the specific paratyphoid organism, and (2) a type of food poisoning in which after a short incubation period, a few hours, there are symptoms of gastroenteritis which are often explosive and severe.

A diagnosis can be established by isolation of the specific organism

Salmonellosis and Food Poisoning. Food poisoning by bacilli of the salmonella group occurs epidemically when rats and mice have access to human food and contaminate it with urine and feces. The common food vehicles for a spread of salmonellosis are cheese, milk, meat, sausage, salami, milk products, mayonnaise, chicken salad, and cured fish

There are two characteristics of salmonellal food poisoning: (1) all persons who partake of the food are affected, (2) salmonellal infection of the intestinal tract requires a long incubation period, sometimes 3 days, after ingestion of the food. When there is no infection of the intestinal tract, the symptoms of food poisoning in those who have a salmonellal infection begin from 6 hours to 3 days after ingestion of the food

The symptoms commence with severe cramps in the abdomen, and diarrhea, tenesmus, nausea and vomiting may occur In the more acute forms there may be fever and prostration In the acute stage of food poisoning by salmonella, it cannot be determined whether there is an infection or whether the poisoning is due to food intoxication The symptoms of the acute phases of salmonellosis are identical with those of shigellosis.

The diagnosis is made by the isolation of the organism by bacteriologic technics.

Salmonella septicemias are not clinically distinguishable. They follow food infection. During the course of the septicemia, foci of infections may occur and persist in the pelvis, gallbladder, kidney, heart, lungs, bones or any other tissue of the body. A chronic carrier state may persist, usually in the gallbladder. *Salmonella choleraesuis* is the common organism present in these infections.

THE FRIEDLANDER ORGANISMS

The organisms of the Friedlander group are short, nonmotile, nonspore-forming, gram-negative bacilli which characteristically possess large capsules They occur in the nose, mouth and intestinal tract of normal persons, in the lungs of patients with pneumonia and other respiratory diseases, and in suppurative infections of other parts of the body away from the respiratory tract They are enteric bacteria.

Klebsiella pneumoniae. *Klebsiella pneumoniae* is known also as Friedlander's

In recent years it has been learned that *Klebsiella pneumoniae* is important in the production of disease outside of the respiratory tract. The gastrointestinal and biliary tracts account for more than half of all the infections caused by this organism.

The biliary and urinary tracts when affected by stone, neoplasm or external pressu are easily rendered susceptible to infection by *Klebsiella pneumoniae*, and sep cemia, hepatic abscesses, meningitis, pelvic abscesses and subphrenic abscesses ma their appearance.

The symptoms are those of localized or generalized infection (septicemia often of a severe degree. Of late it has been recognized that *Klebsiella pneumoni* infections may also run a chronic course, and that they occur in many extrapu monary lesions.

The findings on examination depend on the situation of the lesions or lesio Isolation and identification of *Klebsiella pneumoniae* is the only means of diagnosi

Klebsiella pneumoniae may be isolated in blood from a patient who has a se ticemia, although the portal of entry may remain obscure.

THE VIBRIO COMMA AND ASIATIC CHOLERA

The causative organism of Asiatic cholera, type species Vibrio comma of the gen Vibrio, tribe Spirilleae and family Pseudomonadaceae, has long been termed the comm bacillus

It is generally agreed that vibrios carry an endotoxin and infect only man. The remain viable in feces and in river water for more than 2 weeks, and in sea water fo less than 1 week.

Immunity following recovery from cholera is of uncertain duration. It lasts fro 6 months to a year. The vaccine is prepared and administered in the same manner a typhoid vaccine It may be administered along with triple typhoid vaccine.

Cholera *has its endemic center in Asia Epidemics and pandemics are prevalen* along the rivers in the East and Middle East. In times past cholera epidemics oc curred along the Mississippi River and some of its tributaries. The *Vibrio comm* may be harbored in the biliary passages of human beings, and these persons ar carriers The presence of cholera means food contaminated by insects and rodents or drink containing the vibrios, or both.

The intestinal wall is irritated by the toxic action of the vibrios which remai localized in the intestinal tract Invasion of the blood stream is unknown. In th rapidly fatal infections there is insufficient time for extensive pathologic change to tak place *In more prolonged illnesses the mucosa of the small intestine is deeply injecte* and may show areas of sloughing Sometimes most of the small bowel is denuded of it epithelial lining The kidneys may reveal a toxic nephrosis

SYMPTOMS The symptoms of cholera commence with a profuse watery diarrhea and vomiting The diarrhea may be painless or associated with abdominal cramps Quickly the stools become colorless and thin and contain small white flocculi in suspension (rice-water stools). Enormous quantities of rice-water stools are dis charged during a 24-hour period The vomitus usually assumes the same rice-water appearance as the stools The abdominal cramps may be agonizing in character. As vomiting and diarrhea continue cramps appear in the muscles of the arms and legs The muscles become acutely contracted. Often the patient rapidly passes into a state of collapse and dies in from 10 to 12 hours after the onset.

EXAMINATION. Owing to the rapid loss of fluid by the diarrhea and vomiting, the cheeks are sunken in appearance, the nose becomes pinched and thin, the eyes are retracted and the eyeballs are soft, and the skin and the fingers are shriveled. The surface of the body is cold and wet. Respirations are rapid and shallow, and the patient may not be able to speak. Often a whisper asking for water is the only attempt made at speaking. The pulse is thready, weak and rapid. Rectal tempera- ture varies from 101 to 105 F (38 3 to 40.5 C). The patient is restless, throws his arms and legs aimlessly around until his strength fails As long as strength permits and consciousness is present he asks for water.

Recovery may be obtained by the rapid parenteral administration of fluids If the patient recovers, there is a gradual cessation of vomiting and purging, the pulse

at the wrist soon becomes palpable, and there is a return of some of the warmth to the surface. On continued administration of fluids, the secretion of urine returns and the recovery may be remarkably fast.

DIAGNOSIS The diagnosis is established by isolating the cholera vibrio from the stools and sometimes also from the vomitus of patients. By the time the diagnosis is thus attained, the patient from whom the material for culture was obtained is dead or is well on the road to recovery. However, these procedures must be carried out to make sure that the disease is cholera and if so to set up controls for protection of those still well.

In the presence of an epidemic the disease may be clinically recognized by the suddenness of the onset, the severity of the symptoms and the rapidity of the course which distinguishes it from all other diarrheal diseases. Sporadic and mild infections with *Vibrio comma* are more difficult to recognize.

Epidemiology Unit No 50 in 1945 reported a study of cholera in Calcutta. Some 400 patients were divided into 5 groups, group A being treated with sulfaguanidine, group B kept as a control, group C treated with sulfadiazine, group D treated with penicillin and group E treated with sulfadiazine and penicillin combined. Seemingly the most beneficial therapeutic agent was transfusions of blood plasma and not chemotherapy Of 35 severely ill patients treated with plasma plus chemotherapy, none died Of 19 similar patients treated with chemotherapy alone; 3 died, and of 24 control patients 23 died Rehydration will effectively lower the expected death rate in cholera. The addition of adequate amounts of blood plasma to the therapy of cholera will further improve the chance of recovery.

THE BRUCELLAE AND BRUCELLOSIS (USUALLY MILK BORNE)

(*Malta Fever, Melitococcosis, Mediterranean Fever, Rock Fever, Gibraltar Fever, Texas Fever, Rio Grande Fever, Neapolitan Disease, Bang's Disease, Brucellosis*)

The genus *Brucella* is of the tribe Brucelleae of the family Parvobacteriaceae. Three species are found in manifest and in latent infections. *Brucella melitensis* (*Bacterium melitense* Bruce, *Micrococcus melitensis*, *Alcaligenes melitensis*, caprine Brucella), *Brucella abortus* (*Brucella melitensis* var *abortus*, *Alcaligenes abortus*, abortion or Bang's bacillus, bovine Brucella) and *Brucella suis* (*Brucella melitensis* var. *suis*, porcine abortus strain)

These organisms are cosmopolitan in distribution The organisms of bovine origin more easily affect man Caprine infections are obtained from the milk of goats and cheese made from this source

The production of artificial immunity in animals by means of vaccines consisting of living brucella of reduced virulence has been accomplished. In common use for vaccines are the strains S19 and 45 of *Brucella abortus*. The avirulence of the strains used for vaccination is only relative and occasionally may cause the disease when used for purposes of vaccination. Undulant fever in human beings has been caused by vaccination.

The agents of infection enter the body through the mouth or through the skin. The organisms entering through the mouth may gain entrance to the tissues by passage through the lymphatic system in the throat or the mesenteric lymph nodes. Once inside, the infection is spread through the blood stream The nodular reactions are evidences of the response of the reticuloendothelial system to the presence of the bacterial proliferation. The renal pathologic changes may be due to the elimination of brucella through the glomeruli.

Brucellar lesions are infectious granulomas They appear in varying sizes as the result of repeated disseminations of the organisms into the blood stream. The occasional suppurative lesions in various organs illustrate the ability of these organisms to grow in different tissues.

The disease is acquired by drinking contaminated milk or by contact with an infected animal.

SYMPTOMS. The average incubation period in man varies from 5 to 30 days. The infection may be manifested as a subacute septicemia or as focal or localized infections. When granulomas form, the disease is chronic.

The symptoms commence with excessive fatigability, weakness, headache and backache The temperature rises slowly to 102 to 105 F (38.9 to 40.5 C). There are chills and profuse sweating The average duration of the febrile period in a severe infection is about 3 months. However, the fever usually lasts from 3 to 5 days to 10 to 20 days. Often there is one long febrile period which subsides by lysis. However, repeated relapses of fever may occur within 2 years after the initial infection Relapses of fever may remind the physician of the possibility that brucella organisms may be causing the patient's illness

A loss of appetite and constipation are incident to the fever. The patient, despite daily fever, may appear comfortable and well. A mild obstructive jaundice may develop. This stage of the disease may progress to a more chronic form, or a chronic brucellosis may be the primary manifestation of the infection.

In chronic brucellosis the symptoms are vague and not particularly characteristic of any infectious diseases. They are fatigability, myalgias, arthralgias, neuralgias, headache, giddiness, ocular fatigue, sweating, nasal catarrh, chronic sore throat, often cough, tachycardia, irritability, depression, and various disturbances of digestion Women often have menstrual and reproductive disturbances

A definite type of chronic spondylitis is caused by an infection with brucella (see Diseases of the Bones, Chapter 7) In almost one half of these patients transient arthritis may be present. The arthritis comes on suddenly and is severely manifested in the hip, knees, shoulder and ankle joints. It usually clears in from 3 to 5 days or persists

During the chronic stage lesions of the central nervous system may reveal themselves These symptoms are those of a subacute or chronic meningitis associated with a pleocytosis of 150 to 200 cells in the spinal fluid with the lymphocyte prominent in the count As the meningitis subsides signs of meningomyelitis and focal cerebral lesions manifested as monoplegia, paraplegia or hemiplegia may appear. Organisms can be cultured from the spinal fluid The protein concentration of the spinal fluid is increased

An endocarditis may become manifested which cannot be suspected from symptoms alone Bronchopneumonia is a serious manifestation of this disease.

EXAMINATION. The physical examination is destitute of findings which may indicate the seriousness of the disease. The physical findings if any will depend on the localization of the infection. In the chronic forms there may or may not be a low-grade fever at the time of the examination. The liver may be slightly enlarged. The heart may be enlarged and there may be systolic murmurs There may be an increased redness of the mucous membranes Often there is more than the usual sensitiveness on palpation of the lower part of the abdomen on the right side. The joints may be swollen and tender Leukopenia usually is present during the acute stages of the disease. However, moderate leukocytosis occasionally occurs There may be lymphocytosis during all phases of the disease An increase in the numbers of lymphocytes is accompanied by immaturity. The erythrocytes in the chronic stages of the disease may be somewhat reduced in number and there may be a mild macrocytic hypochromic anemia

DIAGNOSIS. The diagnosis of brucellosis is definitely established by isolation of the organisms from the lesion, blood, urine, or feces Isolation of the organisms bears no definite relation to any given stage of the disease nor to the presence of organisms in the blood. Positive blood cultures have been obtained as early as the first day of illness and as late as a year or more subsequently. The organisms are excreted irregularly in the urine and in the stools. They can be recovered from

the spinal fluid and pus in instances of meningeal involvement or in suppurative lesions.

Agglutination tests are diagnostically helpful In instances of suspected brucellosis a negative response to agglutination tests may be helpful in eliminating the possibility of the disease

Agglutinin titers of 1:80 or more occur in about 90 per cent of brucellar infections by the end of the second week and may eventually reach 1:10,240. Agglutination titers of more than 1:200 in the presence of clinical symptoms suggestive of brucellosis constitute presumptive evidence of active infection. In the absence of symptoms an agglutination titer of 1:80 may be evidence of frequent exposure but it is not diagnostic.

Many other diagnostic tests have been employed, for instance, the bactericidal test and the opsonocytophagic test These tests are valuable in the hands of trained observers accustomed to making the proper interpretations of the response provoked by the test.

THE PASTEURELLAE (FLEA BORNE—AIR BORNE)

Pasteurella pestis and the Plague. *Pasteurella pestis* of the genus *Pasteurella*, tribe Pasteurelleae, family Parvobacteriaceae, is the cause of plague.

Pasteurella pestis has two antigens. Cultures with well-developed antigens agglutinate in specific immune serum. Antigens are heat-labile. The vaccine now used is an alcohol-precipitated vaccine.

Plague is primarily a disease of wild rats and other rodents and is transmitted from one to another by the bites of infected fleas (see Fleas, Chapter 20). Infections in man are accidental, from the bite of infected fleas, except in the pneumonic type in which the organisms are inhaled

Plague is endemic in various parts of the United States, and occasionally human infection occurs

In the western states human infection formerly had been observed only in California, but in recent years infections have been observed in Oregon, Montana, Idaho, Nevada, Utah, Wyoming, Washington, Arizona, New Mexico, Colorado, North Dakota, Oklahoma, Kansas, and Texas Surveys have been conducted in more than 600 counties of the 17 westernmost states, and plague has been found nearly 4,000 times in the wild rodents of 132 counties of 15 of these states.

An attack of plague often confers a lasting immunity. The immunity following a natural plague infection is probably relative, for recovery from the natural disease has in a number of instances been followed by a second infection

In India vaccination reduces the risk of contracting plague to one fourth and the risk of death to one eighth. In Java the death rate was reduced to an average of 17.5 per cent. It fell from one fourth to less than one twenty-fifth of the original mortality in the course of a 5-year vaccination campaign

Pasteurella pestis produces in man three types of disease which are termed respectively bubonic plague, pneumonic plague, and septicemic plague. The origins of bubonic plague and pneumonic plague are related to the portal of entry of the pasteurella When the infected fleas bite the lower extremities, the plague bacilli spread rapidly through the lymphatic structures and there is an enlargement of the lymph nodes in the groin These enlarged lymph nodes are termed *buboes;* hence *bubonic plague* The lymph nodes rapidly become necrotic and suppurate, and abscess formation and septicemia ensue. Foci may be established in the lungs and elsewhere in the body

When infected droplets of moisture containing the bacilli are inhaled, the speedily ensuing infection is termed *pneumonic plague* There is a severe, widely dispersed pneumonia which involves the lungs completely Severe respiratory failure with deep

SYMPTOMS The average incubation period in man varies from 5 to 30 days. The infection may be manifested as a subacute *septicemia or as focal or localized* infections When granulomas form, the disease is chronic.

The symptoms commence with excessive fatigability, weakness, headache and backache The temperature rises slowly to 102 to 105 F (38 9 to 40.5 C). There are chills and profuse sweating The average duration of the febrile period in a severe infection is about 3 months. However, the fever usually lasts from 3 to 5 days to 10 to 20 days. Often there is one long febrile period which subsides by lysis. However, repeated relapses of fever may occur within 2 years after the initial infection. Relapses of fever may remind the physician of the possibility that brucella organisms may be causing the patient's illness

[illegible] nt, despite dail [illegible] ndice may deve [illegible] a chronic *brucellosis may be the primary manifestation of the infection*

In chronic brucellosis the symptoms are vague and not particularly characteristic of any infectious diseases They are fatigability, myalgias, arthralgias, neuralgias, headache, giddiness, ocular fatigue, sweating, nasal catarrh, chronic sore throat, often cough, tachycardia, *irritability, depression, and various disturbances of diges*tion Women often have menstrual and reproductive disturbances

A definite type of chronic spondylitis is caused by an infection with brucella (see Diseases of the Bones, Chapter 7) In almost one half of these patients transient arthritis may be present The arthritis comes on suddenly and is severely manifested in the hip, knees, shoulder and ankle joints. It usually clears in from 3 to 5 days or persists

During the chronic stage lesions of the central nervous system may reveal themselves. These symptoms are those of a subacute or chronic meningitis associated with a pleocytosis *of 150 to 200 cells in the spinal fluid* with the *lymphocyte promi*nent in the count As the meningitis subsides signs of meningomyelitis and focal *cerebral lesions manifested as monoplegia, paraplegia or hemiplegia may appear.* Organisms can be cultured from the spinal fluid. The protein concentration of the spinal fluid is increased

An endocarditis may become manifested which cannot be suspected from symptoms alone Bronchopneumonia is a serious manifestation of this disease

EXAMINATION The physical examination is destitute of findings which may indicate the seriousness of the disease. The physical findings if any will depend on the localization of the infection In the chronic forms there may or may not be a lowgrade fever at the time of the examination. The liver may be slightly enlarged. The heart may be enlarged and there may be systolic murmurs. There may be an increased redness of the mucous membranes Often there is more than the usual *sensitiveness on palpation of the lower part of the abdomen on the right side* The joints may be swollen and tender. Leukopenia usually is present during the acute stages of the disease. However, moderate leukocytosis occasionally occurs There may be lymphocytosis during all phases of the disease. An increase in the numbers of lymphocytes is accompanied by immaturity. The erythrocytes in the chronic stages of the disease may be somewhat reduced in number and there may be a *mild macro*cytic hypochromic anemia

DIAGNOSIS The diagnosis of brucellosis is definitely established by isolation of the organisms from the lesion, blood, urine, or feces. Isolation of the organisms bears no *definite relat*ion to any given stage of the disease nor to the presence of organisms in the blood. Positive blood cultures have been obtained as early as the first day of illness and as late as a year or more subsequently. The organisms are excreted irregularly in the urine and in the stools. They can be recovered from

patient from whom the material for culture was obtained will be dead. Bacteriologic study, however, is necessary, for by the time the laboratory renders the report, other patients will have come under observation who contracted the disease from the original patient. The diagnosis in this instance is then certain.

DIAGNOSIS. The diagnosis depends on obtaining and identifying the *Pasteurella pestis*. The sputum does not show the *Pasteurella pestis* in the early stages of the disease. Blood cultures are of no great help in establishing an early diagnosis. Bacteremia usually does not occur until the last day or two of the illness. In an epidemic early and frequently repeated bacteriologic examinations of the sputum by an experienced examiner are necessary in order to make the correct diagnosis

The primary pneumonic form of plague is most difficult to differentiate from infection by the streptococci or pneumococci or from an influenzal type of bronchial pneumonia.

It is impossible to differentiate pestis minor from tularemia except by agglutination tests and blood cultures

Pasteurella multocida and Hemorrhagic Septicemia (Bites or Contacts). *Pasteurella multocida*, which causes hemorrhagic septicemia in animals, is indistinguishable from *Pasteurella aviseptica, Pasteurella bollingeri, Pasteurella suiseptica, Pasteurella muriseptica*, and *Pasteurella cuniculicida* All are coccobacilli and gram-negative They are all closely related, are saprophytic and parasitic and are capable of infecting many different animals Individual susceptibility in all species of animals and in man varies from extreme susceptibility to complete resistance.

Human infections with *Pasteurella multocida* may not be suspected. In suspected instances of the infection the disease follows animal bites or exposure to carcasses of cattle, pigs, or rabbits. The consumption of infected rabbits may cause enteritis, conjunctivitis, and appendicular abscesses In the septicemic distribution of the infection the symptoms vary widely and may be manifested by recurrent chills and fever, pneumonia, empyema, meningitis, and puerperal sepsis

The diagnosis is established by identification of the organism bacteriologically.

Pasteurella pseudotuberculosis. The large, gram-negative, elongated *Pasteurella pseudotuberculosis* organisms are pleomorphic.

Pasteurella pseudotuberculosis causes spontaneous infections in rodents, pigeons, turkeys and canaries In a small number of human infections it has been isolated from the blood stream during life, and from the characteristic necrotic lesions at necropsy. The mode of infection is not known.

There is a prodromal feeling of being unwell followed by an acute onset with headache, chills, fever, and general pains in the extremities and back. The fever is of an irregular or remitting type as observed in septicemia At times the temperature reaches 105 F (40 5 [illegible] e
degrees of leukocytos [illegible]
times the spleen as w [illegible]
serous cavities as a further indication of the septicemia.

The diagnosis is accomplished by identification of the organism through bacteriologic procedures

Pasteurella tularensis and Tularemia (Contact, Insect Bites). The species [illegible] remia, belongs [illegible] The organism [illegible] rugged surviving power It has been known to have survived for weeks in hides, and for months in carcasses and in water

Pasteurella tularensis causes a specific infectious disease of wild mammals in which it is maintained as a heterogeneous infection through a variety of insects acting as reservoirs and vectors

Tularemia is known to occur in the ground squirrel, hare, rabbit, guinea pig, woodchuck, muskrat, wild rat, wild mouse, European water rat, opossum, kitten, young coyote, grouse, quail, sheep and gray fox. The red fox is not infected. When the infec-

cyanosis and death ensue. The deep cyanosis and rapidly fatal course originated the term Black Death in the fourteenth century The pneumonic form of the disease is likely to predominate during the early period of an epidemic.

It is to be remembered that the patient who has pneumonic plague is likely to infect doctors and other attendants of the sick one and that even adults attending funerals of those dead from plague may become infected.

When the portal of entry is not definite, during the course of one of the conventional forms of plague, septicemia may be the dominant manifestation and thus the disease deserves the name *septicemic plague*.

Another form of the disease, *sylvatic plague*, is transmitted by the bite of a flea which normally feeds on wild rodents This disease in man differs somewhat in details from the ordinary forementioned types of plague. The fleas bite on the upper extremities, and the original buboes occur in the axillae. This form of plague frequently changes to pneumonic plague In this variety of plague the role of fleas in the transmission of *Pasteurella pestis* is established experimentally.

In the rural regions of sylvatic plague men and children who handle or play with wild rodents are more frequently attacked than are others who do not indulge in such practices.

SYMPTOMS. After an incubation period of 2 to 6 days the symptoms commence with a chill. The temperature increases to 101 F (38 3 C) and may be as high as 105 F (40 5 C) The fever is associated with severe generalized headache; often there is vertigo, and soon extreme prostration ensues In bubonic plague the early symptoms are those of a severe infection. In pneumonic plague the inception of the disease and the onset of symptoms often resemble those of an acute influenza of the respiratory type There are fever and chills and dry cough, associated with increased respiratory and pulse rates. The cough soon is productive of frothy, blood-streaked sputum which later becomes grossly bloody

In all forms of plague the intoxication is extreme. There are a rapid pulse, a bluish or definitely cyanotic color of the face, delirium, and a rapid decline Death occurs within a week from the onset of symptoms. In debilitated victims plague is characterized by extreme intoxication, increasing from hour to hour, and death occurs before any physical signs of the disease can be detected.

Pestis Minor In contrast to the serious types of plague, there is a form of the disease which often is called pestis minor In pestis minor the patient may be up and about and able to carry on his usual occupation, unaware of fever or of swollen lymph nodes Pestis minor is not so contagious as the other types of plague.

EXAMINATION After the general signs of infection have been present for 24 or at most for 48 hours, the bubo usually is found on examination. It is the enlargement of a solitary lymph node, at first no more than 1 cm. in diameter, moderately firm and tender to pressure As the disease develops, more nodes may become involved and may become adherent to each other. The periglandular tissue and overlying skin are edematous and inflamed The bubo may be situated in any part of the body, but it usually is in the inguinal region In 1 case out of 5 it is situated under the arms and in only 1 case in every 10 is the bubo in the cervical region. In 1 to 3 days after the onset of fever with or without the known presence of the bubo, minute hemorrhagic spots may appear in the skin.

[illegible] informative There [illegible] lobe of the [illegible] ionia, is not present Plague pneumonia is of a lobular type which may later coalesce to involve the whole lung if the patient lives long enough. Leukocytosis is present.

Puncture of a much swollen lymph node with a fine needle and aspiration of a few drops of its contents for bacteriologic examination may be done. By the time the bacteriologic examination is finished, there are 6 chances out of 10 that the

patient from whom the material for culture was obtained will be dead. Bacteriologic study, however, is necessary, for by the time the laboratory renders the report, other patients will have come under observation who contracted the disease from the original patient.

DIAGNOSIS. *Pasteurella pestis* The sput tages of the disease Blood cultures are of no great help in establishing an early diagnosis. Bacteremia usually does not occur until the last day or two of the illness In an epidemic early and frequently repeated bacteriologic examinations of the sputum by an experienced examiner are necessary in order to make the correct diagnosis.

The primary pneumonic form of plague is most difficult to differentiate from infection by the streptococci or pneumococci or from an influenzal type of bronchial pneumonia.

It is impossible to differentiate pestis minor from tularemia except by agglutination tests and blood cultures.

Pasteurella multocida and Hemorrhagic Septicemia (Bites or Contacts). *Pasteurella multocida,* which causes hemorrhagic septicemia in animals, is indistinguishable from *Pasteurella aviseptica, Pasteurella bollingeri, Pasteurella suiseptica, Pasteurella muriseptica,* and *Pasteurella cuniculicida* All are coccobacilli and gram-negative. They are all closely related, are saprophytic and parasitic and are capable of infecting many different animals Individual susceptibility in all species of animals and in man varies from extreme susceptibility to complete resistance.

Human infections with *Pasteurella multocida* may not be suspected. In suspected instances of the infection the disease follows animal bites or exposure to carcasses of cattle, pigs, or rabbits. The consumption of infected rabbits may cause enteritis, conjunctivitis, and appendicular abscesses. In the septicemic distribution of the infection the symptoms vary widely and may be manifested by recurrent chills and fever, pneumonia, empyema, meningitis, and puerperal sepsis

The diagnosis is established by identification of the organism bacteriologically.

Pasteurella pseudotuberculosis. The large, gram-negative, elongated *Pasteurella pseudotuberculosis* organisms are pleomorphic

Pasteurella pseudotuberculosis causes spontaneous infections in rodents, pigeons, turkeys and canaries In a small number of human infections it has been isolated from the blood stream during life, and from the characteristic necrotic lesions at necropsy. The mode of infection is not known.

There is a prodromal feeling of being unwell followed by an acute onset with headache, chills, fever, and general pains in the extremities and back The fever is of an irregular or remitting type as observed in septicemia. At times the temperature reaches 105 F (40 5 C) Anorexia, abdominal tenderness, constipation and variable degrees of leukocytosis are usual Within a few days after onset the liver, and sometimes the spleen as well, become palpable and tender There may be effusions into serous cavities as a further indication of the septicemia.

The diagnosis is accomplished by identification of the organism through bacteriologic procedures

Pasteurella tularensis and Tularemia (Contact, Insect Bites) The species *Pasteurella tularensis* (*Bacterium tularense*), which causes the disease tularemia, belongs to the genus *Pasteurella,* tribe Pasteurelleae and family Parvobacteriaceae. The organism is pleomorphic Both ovoid and bacillary forms exist. This organism has a rugged surviving power. It has been known to have survived for weeks in hides, and for months in carcasses and in water.

Pasteurella tularensis causes a specific infectious disease of wild mammals in which it is maintained as a heterogeneous infection through a variety of insects acting as reservoirs and vectors

Tularemia is known to occur in the ground squirrel, hare, rabbit, guinea pig, woodchuck, muskrat, wild rat, wild mouse, European water rat, opossum, kitten, young coyote, grouse, quail, sheep and gray fox. The red fox is not infected. When the infec-

tion occurs in summer, it is usually acquired by the bite of an insect, for instance, the deer fly or horse fly

The insects known to carry tularemia are the deer fly, ticks and stable flies. When the infection occurs as the result of transmission by the wood tick, it is not necessary that the tick ever should have had direct contact with an infected animal, for it has been shown that there is hereditary transmission of the infection by female wood ticks to their eggs, larvae and nymphs Ticks harbor the infection throughout the winter and thus keep it active from year to year. The tick, therefore, constitutes the principal means for the natural transmission of the disease. The arthropods directly related to human diseases are the Rocky Mountain tick (*Dermacentor andersoni*), the Western wood tick, the common Eastern dog tick, the Lone Star tick and the deer fly (*Chrysops discalis*) The mosquito (*Aedes cinereus*) in Sweden may transmit tularemia

Infection as a result of eating of infected flesh is rare because the germ is destroyed readily by cooking of the meat Tularemia could appear in epidemic form if a number of persons partook of insufficiently cooked infected flesh. The infection most commonly is acquired by the dressing and handling of the infected animal or bird or the wearing of infected clothing, such as gloves, or the use of infected hand towels.

The infection is most prevalent in the summer, when it is transmitted by ticks and by flies. The incidence of the disease is increased during the hunting season on cottontail rabbits, usually from November to January.

An early but transitory bacteremia originates diffusely scattered foci of necrosis in the spleen, liver, lungs, lymph nodes and bone marrow The infection may involve the lungs, pericardium, pleura and peritoneum Tularemia produces a lobular type of pneumonia that is secondary to the general bacteremia There are hemorrhagic effusion, abscesses, and localized or general pneumothorax. With the appearance of antibodies bacteremia disappears, but new lesions may develop by lymphatic extension When the formation of antibodies is slow or insufficient to prevent it, the organisms are dispersed through both the systemic and pulmonary circulatory systems, resulting in the formation of miliary foci of necrosis in nearly every organ, and death ensues

SYMPTOMS In the usual instance of the disease, 3 or 4 days after contact, there develops a papule at the site of inoculation, often on the hand. In 7 or 8 days the papule becomes an open ulcer Synchronously with ulceration a regional lymphadenopathy appears. There is fever which lasts about 1 month. The fever, attended by chills, usually shows an initial rise, a remission and a secondary rise. There are anorexia, sweats, malaise, and headaches The acute stage is followed by a period of weakness and prostration lasting from 3 to 6 months. In about one third of those who have the disease the swollen lymph nodes may suppurate and discharge through the skin. The rest of the lymph nodes remain hard and discrete. In some instances suppuration may occur many months after clinical recovery has taken place.

In some the disease is manifested as a septicemia from its onset, or develops into a severe septicemia resulting in early death from the fourth to the eleventh or twelfth day

In a general way the symptoms depend on the portal of entry of the infection If the infection has been obtained from the inhalation of droplets of infected material, a pneumonic form of the disease develops. However, a pneumonia may arise in an ulceroglandular infection The onset may be sudden with a chill, fever, dyspnea, cough, pain in the chest and profuse sweating These patients appear extremely ill and frequently are suspected of having typhoid fever.

If some infected material is spattered into an eye, the primary lesions occur there. The primary ocular lesion is often situated on the lower lid.

Irrespective of how the disease gets to the eye, the infection is followed by general infection of the conjunctiva and lacrimal sac which is characterized by congestion, lacrimation, injury to the eye and involvement of the lymphatic structures.

Ingestion of *Pasteurella tularensis* causes a necrotizing pharyngitis, abscesses in

the roof of the mouth, enlargement of the submaxillary and cervical lymph nodes, and ulcers, hemorrhages and points of necrosis in the gastrointestinal tract.

EXAMINATION. The portal of entry or site of inoculation in the skin is revealed by the presence of an ulcer. From the site of inoculation the bacteria spread along the superficial and deep lymphatic structures, with the result that dermal lymphadenitis occurs and regional lymph nodes are enlarged in 9 of 10 cases. In the absence of discoverable primary lesions lymphatic invasion is not evident. The initial lesion and the lymph nodes are tender and painful Occasionally a maculopapular eruption is present on the arms, neck and chest In many cases the original lesion is *all that is ever present Secondary manifestations do not occur.*

The rest of the observations on examination depend on the complications, if any, which are present In the eye the infection causes the conjunctiva to become acutely inflamed, greatly swollen and very painful Multiple small, discrete, yellow nodules make their appearance on the conjunctiva and at the same time the periauricular, cervical and submaxillary lymph nodes become swollen and tender. The active inflammation lasts from 3 to 5 weeks and only rarely results in permanent scarring of the cornea or involvement of the media

The physical signs of tularemic pneumonia are those of a bilateral atypical pneumonia Physical examination of the chest may reveal no abnormal findings even though pleuropulmonary involvement can be demonstrated roentgenographically. In some instances the pneumonic consolidations resemble those in tuberculosis.

If the organisms reach the central nervous system, a severe meningitis ensues.

During the acute stage of tularemia either leukopenia or leukocytosis may be observed. Agglutinins do not make their appearance in the blood until after the second or third week of the disease Ordinarily the organisms cannot be obtained from the blood before the third day, nor after the twelfth However, in some instances the presence of agglutinins in the blood has been revealed 25 years after the patients have recovered from the disease

DIAGNOSIS The diagnosis preferably is established by isolation of the organism. There is usually an initial bacteremia for a week In some, the disease takes the form of a septicemia from the onset, and in these the cultures from the blood may be positive.

Pasteurella tularensis may be recovered during the first week of disease by inoculation of guinea pigs or by direct culturing into suitable mediums. Pus taken from suppurating lymph nodes early in the disease contains viable bacteria, but the late adenopathies usually prove to be sterile on culture. At necropsy the acute necrotic lesions in the liver, spleen, lungs and bone marrow readily yield viable organisms.

Specific antibodies appear in the blood during the second week, increase in the third week, and reach maximal titers in the fourth and fifth weeks. Tularemia serum agglutinates *Pasteurella tularensis* to a much higher degree than *Brucella abortus* or *Brucella melitensis*

Intradermal injection of antitularensis serum causes an immediate erythematous, edematous reaction which is bacterial specific. This test may be diagnostically useful, but it has not been generally used as such an aid

THE ANTHRAX BACILLUS (CONTACT)

Anthrax is primarily a disease of sheep, cattle, horses and swine. The spores of the bacillus remain viable in soil almost indefinitely In the United States, southeastern South Dakota, northeastern Nebraska, extending southward to include part of the Texas Gulf Coast and the lower Mississippi valley from Arkansas to and including the Delta region are particularly affected

tion occurs in summer, it is usually acquired by the bite of an insect, for instance, the deer fly or horse fly.

The insects known to carry tularemia are the deer fly, ticks and stable flies. When the infection occurs as the result of transmission by the wood tick, it is not necessary that the tick ever should have had direct contact with an infected animal, for it has been shown that there is hereditary transmission of the infection by female wood ticks to their eggs, larvae and nymphs Ticks harbor the infection throughout the winter and thus keep it active from year to year The tick, therefore, constitutes the principal means for the natural transmission of the disease The arthropods directly related to human diseases are the Rocky Mountain tick (*Dermacentor andersoni*), the Western wood tick, the common Eastern dog tick, the Lone Star tick and the deer fly (*Chrysops discalis*). The mosquito (*Aedes cinereus*) in Sweden may transmit tularemia.

Infection as a result of eating of infected flesh is rare because the germ is destroyed readily by cooking of the meat Tularemia could appear in epidemic form if a number of persons partook of insufficiently cooked infected flesh. The infection most commonly is acquired by the dressing and handling of the infected animal or bird or the wearing of infected clothing, such as gloves, or the use of infected hand towels

The infection is most prevalent in the summer, when it is transmitted by ticks and by flies The incidence of the disease is increased during the hunting season on cottontail rabbits, usually from November to January

An early but transitory bacteremia originates diffusely scattered foci of necrosis in the spleen, liver, lungs, lymph nodes and bone marrow The infection may involve the lungs, pericardium, pleura and peritoneum Tularemia produces a lobular type of pneumonia that is secondary to the general bacteremia There are hemorrhagic effusion, abscesses, and localized or general pneumothorax. With the appearance of antibodies bacteremia disappears, but new lesions may develop by lymphatic extension. When the formation of antibodies is slow or insufficient to prevent it, the organisms are dispersed through both the systemic and pulmonary circulatory systems, resulting in the formation of miliary foci of necrosis in nearly every organ, and death ensues.

SYMPTOMS In the usual instance of the disease, 3 or 4 days after contact, there develops a papule at the site of inoculation, often on the hand In 7 or 8 days the papule becomes an open ulcer Synchronously with ulceration a regional lymphadenopathy appears. There is fever which lasts about 1 month. The fever, attended by chills, usually shows an initial rise, a remission and a secondary rise. There are anorexia, sweats, malaise, and headaches. The acute stage is followed by a period of weakness and prostration lasting from 3 to 6 months. In about one third of those who have the disease the swollen lymph nodes may suppurate and discharge through the skin The rest of the lymph nodes remain hard and discrete. In some instances suppuration may occur many months after clinical recovery has taken place.

In some the disease is manifested as a septicemia from its onset, or develops into a severe septicemia resulting in early death from the fourth to the eleventh or twelfth day

In a general way the symptoms depend on the portal of entry of the infection If the infection has been obtained from the inhalation of droplets of infected material, a pneumonic form of the disease develops. However, a pneumonia may arise in an ulceroglandular infection. The onset may be sudden with a chill, fever, dyspnea, cough, pain in the chest and profuse sweating. These patients appear extremely ill and frequently are suspected of having typhoid fever.

If some infected material is spattered into an eye, the primary lesions occur there. The primary ocular lesion is often situated on the lower lid.

Irrespective of how the disease gets to the eye, the infection is followed by general infection of the conjunctiva and lacrimal sac which is characterized by conges-

[illegible] the lymphatic structures

[illegible] izing pharyngitis, abscesses in

perfringens, rarely sporulate. The natural habitats of the clostridia are the soil and the intestinal tract of higher animals and man.

Gas Gangrene Group. The five most important species of the gas gangrene group are *Clostridium perfringens*, *Clostridium novyi*, *Clostridium septicum*, *Clostridium bifermentans* and *Clostridium histolyticum*. All of these produce soluble toxins which can be neutralized by their respective antitoxins.

The clostridia of gas-forming gangrene have in common the ability to produce a rapidly spreading edema of the subcutaneous connective tissue attended by the formation of gas bubbles Blood vessels thrombose. Destruction of muscles ensues. The gas increases in the tissues, the skin acquires a dusty hue, and a tympanic note on percussion is present. A localized gas gangrene may be manifested by only a foul-smelling discharge containing gas bubbles

When the clinical evidence of the presence of gas gangrene is clear, the practice is to give a polyvalent antitoxin.

The *Clostridium tetani* infection has been considered in Chapter 6.

Clostridium botulinum (*Food Poisoning and Botulism*). Two subspecies of *Clostridium botulinum* have been identified and these different strains or subspecies or types produce specific toxins. The soil is the reservoir of these organisms. Their spores may be present on a wide variety of vegetables and fruits These organisms do not grow in the human body The disease termed botulism is a toxemia and not an infection. It follows the ingestion of preserved foods in which the organisms have grown and produced the toxin The preserved or inadequately cooked home-canned vegetables have been allowed to stand, and have been eaten without further cooking In Europe botulism results from eating smoked, salted or spiced meats In the United States the poisoning results from eating inadequately sterilized canned vegetables or fruits

SYMPTOMS. Usually several members of a family or a party who have consumed the same food are affected at the same time

From about 12 to 48 hours, or occasionally several days, after ingestion of the infected food there are nausea, dryness of the mouth with thick scanty saliva, vomiting, diarrhea, and dimness of near vision due to paralysis of accommodation The pupils are dilated and fixed but sometimes they may react even in fatal botulism Diplopia and ptosis of the eyelids are soon followed by abolishment of all ocular movements Articulation becomes indistinct and swallowing is difficult Food and drink are regurgitated through the nose or aspirated into the larynx

EXAMINATION. A general muscular weakness is present. The arms and legs cannot be voluntarily moved nor can the head be raised The muscles of respiration are weak and breathing is difficult One movement of a part may be performed but not repeated owing to fatigue The tendon reflexes are within normal limits of response. There is profuse sweating The pulse is rapid and feeble.

The mental condition is unaltered but when botulism is fatal, there may be terminal coma, stupor or convulsions In uncomplicated botulism the temperature is normal The spinal fluid shows no change Usually death occurs in from 4 to 8 days as a result of paralysis of respiration, circulatory failure, or pneumonia. If convalescence is possible, if the patient survives longer than a week, complete recovery is expected In instances of small doses of the toxin recovery is more quickly accomplished than when the dose [illegible]

[illegible] 12 and 48 hours or longer after eating poisoned foods, with the subsequent occurrence of bulbar palsy and finally general weakness of both smooth and striated muscles, are suggestive of botulism. The coincidence of a similar illness of several persons who partook of some of the same foods renders the diagnosis of botulism certain. The demonstration of the toxins or of the bacilli in aliquots of the food may be helpful in the diagnosis

The death rate averages 50 per cent In cases of survival, partial paralysis may persist for 6 to 8 months. In treatment for botulism polyvalent A and B antitoxin is used.

The disease in man is primarily a cutaneous infection which frequently progresses to a fatal septicemia. It affects dwellers in agricultural areas, but more usually workers in establishments where animal products, such as hides and hairs, are processed. The use of items such as shaving brushes or furs made from contaminated animal products may result in an occasional infection.

The pathogenesis of the disease is not fully explained. There is often evidence of a local lymphatic spread of the bacteria once the infection starts. Ultimately there may be bacteremia. The accumulation of bacteria in the blood stream may not be evident until shortly before death.

The incubation period is from 1 to 3 days.

The disease is suspected if a patient who has handled raw animal products such as hides or wool, or dead animals at a rendering plant, presents himself with a cutaneous lesion which has begun as a small red macule which enlarged and was followed, after 2 or 3 days, by local edema

The anthrax vesicle, filled with clear fluid, occupies a central position on the macule and soon spreads by vesiculation in a satellite fashion The lesion becomes necrotic, and the black eschar present in the older lesions is characteristic. The cutaneous lesion is not painful, but enlargement and tenderness of regional lymph nodes occur Malaise, fever and general prostration develop in accordance with the severity and extent of the infection.

Woolsorters' disease occurs in those who have handled wool of animals with anthrax The patient has a chill, fever, headache and pains in the back and legs. The respirations are rapid and attended by severe pain in the chest. There is cough but little expectoration. Examination reveals diffuse medium rales in the chest The temperature rises to 103 to 104 F (39 4 to 40 C) The heart sounds are enfeebled, and collapse and death occur in from 1 to 3 days

The fever rises rapidly and subsequently subsides.

In those in whom no primary lesion is present there may be great swelling of the eyelids, head, arms and hands. The edema may be generalized Areas of cutaneous gangrene may appear

Direct microscopic examination of material from a cutaneous vesicle or from an internal source may reveal the gram-positive rods and permit a tentative diagnosis. Detection of the organism is best done by inoculating mice with material from the lesion, blood, tissues, foods or articles suspected of being contaminated.

Anthrax often is a fatal infection Death may come in from 3 to 5 days. Those who recover do not have severe and rapidly progressive skin lesions

A feature of anthrax infection is the extreme fear and anxiety its presence engenders in the patient.

Anthrax Food Poisoning. Anthrax may be acquired from drinking the milk or eating the flesh of an infected animal The symptoms are those of intense bacterial food poisoning. There are vomiting, diarrhea, fever and pains in the abdomen, back and legs. Blood may be vomited or passed in the feces Soon cyanosis, anxiety, and feeble pulse and heart sounds are present to be followed by collapse and death in from 2 to 7 days The fever is not more than 100 F (37 8 C).

In some severe infections, endocarditis, peritonitis and meningitis are dominant manifestations.

The diagnosis is established by obtaining the anthrax organisms from the infected food or obtaining it from those infected by the foods

THE CLOSTRIDIA (PUNCTURE WOUNDS)

Organisms of the genus *Clostridium*, of the family Bacillaceae, order Eubacteriales, are anaerobic or micro-aerophilic rods, producing endospores. A few species, like *Clostridium perfringens*, produce capsules, the majority do not Some, like *Clostridium*

released by rupture of the bacterium and its conversion into a mass of bacteriophage or viral particles.

Some viruses, as revealed by biochemical studies, have a tendency to assume the crystallization forms. This may indicate that these particular viruses lie at the lowest level of life or on the borderline between life and nonlife Observations that some viruses resemble enzymes which can be synthesized in the laboratory seem, in a small way, to support this view

Luria learned that in the bacterial viruses considered to be composed of a number of vital elements several elements could be destroyed by ultraviolet radiation Evidence was advanced that a virus thus treated was singly unable to reproduce itself; when two or more partially destroyed viruses entered a single bacterium, however, an apparent combination of the remaining uninjured elements occurred, resulting in a new individual, which was able to reproduce itself and to destroy the bacterium.

Delbruck and Bailey studied the reproductivity and method of establishment of mutant strains of virus. Their work suggests an interchange of material between the parent viruses typical of the interchange of parent factors in formation of new individuals which is characteristic of sexual reproduction.

The implications are that viruses have a natural method for production of infinite numbers of new strains closely approximating the sexual mechanisms of higher organisms. The probabilities are that new disease-producing forms will occur frequently. However, new mutant strains of viruses may be produced for the benefit of all of us. For example, the 17D strain of yellow fever virus and vaccinia virus are mutations of the viruses of yellow fever and smallpox which are beneficial.

Viruses differ in their individual nutritional requirement or tropism. This variation may depend on only slight tissue or environmental differences The variation may reach to new cells or tissues, sometimes with complete loss of the initial tropism. It may occur independently of variation in the antigenic constitution of a virus.

Some authorities have adduced evidence from observations on bacteriophagy that the antigenic constitution of the host cell and susceptibility to a given virus are related The antigenic constitution may be associated with variation of tropism or may occur independently of it Variation of antigenic constitution has an important bearing on the serologic identification of viruses Such variations do not occur often, so that it has been possible to base much of what is known about differences among viruses on serologic observations

Viruses differ in their individual proliferative powers There are low-titer and high-titer viruses. Little is known regarding the factors which determine these individual differences They appear to be represented in both the host and the parasite Low-titer strains may not lack in invasiveness and may become widely disseminated in the tissues of the hosts Such strains may be partly responsible for subclinical infections and naturally acquired active immunity to individual viral diseases, for instance, poliomyelitis

It is not known how viruses act to produce injurious effects on the cells they invade. The lesions caused by viruses range from rapid cell death to stimulation of cell growth and multiplication The stimulation of cell growth is magnificently demonstrated by those viruses capable of the production of tumors.

Cell inclusion bodies may be produced by viruses and if so they are termed specific incl ... ises are termed nonspecific ... The formation of inclusion ... in cells which succumb quickly to a virus. The presence of characteristic inclusion bodies is diagnostically helpful, but their absence does not exclude the presence of a viral infection

The diseases caused by viruses are as varied as any other group of infectious diseases. Some viral infections occur regularly in a clinically evident form; others

LISTERIA MONOCYTOGENES AND LISTERELLOSIS

The *Listeria*, a genus of the family Corynebacteriaceae, are cosmopolitan in distribution. Species *Listeria monocytogenes* is the causative organism of listerellosis.

In children and young adults there are a septicemia, a purulent meningoencephalitis and local hepatic necrosis. The symptoms resemble those of other septicemias, purulent meningitides or encephalitis. There is a mononucleosis. The blood response may closely resemble that of infectious mononucleosis. However there is no known relationship between listerellosis and infectious mononucleosis

The spinal fluid contains *Listeria monocytogenes* and both mononuclear and polymorphonuclear leukocytes The blood contains a heterophil antibody which agglutinates erythrocytes of the sheep (a positive Paul-Bunnell test)

The diagnosis depends on the demonstration of the organism in the lesions of internal organs or from the spinal fluid.

ERYSIPELOTHRIX AND ERYSIPELOID (SKIN ABRASIONS)

Erysipelothrix rhusiopathiae differs from *Listeria monocytogenes* in being nonmotile and in manifesting a predilection for the skin, endocardium and joints. The disease erysipeloid is a localized cutaneous infection, although septicemia with endocarditis and involvement of joints may occur The infection confers no immunity

The infection develops subsequent to an abrasion incurred while handling fish or shellfish, meat or poultry. After an incubation period of from 2 to 7 days pain is present at the site of inoculation and is attended by edema and a brilliant purplish red erythema There is peripheral extension of the erythema with clearing of the central portion of the lesion

The diagnosis depends on the isolation of *Erysipelothrix rhusiopathiae*. This can be accomplished by intraperitoneal injection into a white mouse of a suspension of material obtained at biopsy.

VIRAL AND RICKETTSIAL DISEASES

VIRAL DISEASES

The biologic position of the agents classified as viruses is not uniform. The chlamydozoa of psittacosis and lymphogranuloma venereum are gram-negative organisms measuring 400+ millimicrons in size From this the size ranges downward to that of the virus of poliomyelitis, which measures from 8 to 12 millimicrons Generally viruses are organisms of the order Virales They are smaller than most bacteria, are capable of multiplication only within a living susceptible host cell, and pass through standard filters holding back bacteria

An acceptable view of the origin of viruses is that they are degraded descendants of larger pathogenic microbes as suggested by the range of visible forms between bacteria and certain viruses. Rickettsias and the psittacosis viruses resemble bacteria, but their requirements for growth are those of viruses. The smallest viruses have but small resemblance to either rickettsia or bacteria

Concerning the origin of viruses Burnet wrote. "Every virus particle, like any other organism, derives by genetic descent from some similar particle and in its turn possesses the power to produce under appropriate conditions replicas of itself."

It seems that the adaptation of viruses to an intracellular life may be evidence of their loss of the power of chemical synthesis, and therefore they have come to live and to reproduce in an environment in which synthetic chemical power of their own is not necessary.

By means of the electronic microscope it has been observed that bacterial viruses can enter bacteria, where they reproduce themselves in large numbers, later they are

In the animal kingdom the forms which are attacked range from insects to man In many instances the infections caused are limited to one species or type of host, while in others the same viruses affect unrelated hosts In some cases the infections induced are associated with clinical manifestations, in others the infections are apparent in one type of host and inapparent in another.

In some viral infections the manifestations and the pathologic changes are definitely limited to an organ or a system, while others seem to be manifested as generalized, blood-disseminated infections. In this text those viral infections which seem to have mainly organic or systemic manifestations have been described with the organs or systems manifesting the disturbances In this part of the text viral infections which were not conveniently described with a system are discussed.

Smallpox (Variola). Smallpox is a disease of viral origin and always potentially epidemic in nature. However, the disease can be entirely controlled by means of vaccination The lesions of smallpox often heal with scarring

Variola virus is stable and confers a solid immunity.

Immunologic and serologic studies indicate an extremely close relationship between the viruses of variola and vaccinia The presence of common antigens and antibodies, demonstrable by in vitro technics, in variola and vaccinia has been studied in great detail

The characteristic essential lesion of smallpox consists of degeneration of the cells of the deep layers of the epidermis, accompanied by exudation. The exudate increases in amount, and the spaces of the reticulum enlarge until its fibers rupture and the lesion becomes a distended pustule

The subsidence and the healing of the lesions are accomplished by absorption and by drying of the vesicular fluids, and by the regeneration of the epidermis, in the course of which the residual mass of degenerated epithelial cells, leukocytes, and debris is exfoliated.

SYMPTOMS. Twelve days (9 to 20 days) after exposure of a susceptible person to variola virus there are chills, prostration, headache, severe backache, vomiting, and fever up to 103 F (39.4 C) or higher. The aching is deep seated and often most intense in the back and legs. After 3 or 4 days of the fever and aching the temperature recedes and the rash characteristic of smallpox begins

During the course of smallpox, symptoms of pyogenic infections of various types may occur at any time. Terminal bronchopneumonia or bacteremia occurs in practically all cases of fatal smallpox

EXAMINATION The developmental stage is attended by a rash. In some instances this rash resembles both in appearance and distribution that of scarlet fever while in others the rash is macular in form resembling that of measles Both of these skin manifestations tend to be present on glabrous skin over the lower abdomen, medial aspects of the thighs and the lateral thoracic regions.

The macule, 2 to 3 mm in diameter, discrete and fading on pressure, is the common characteristic initial lesion of smallpox The lesions are apparent on the third or the fourth day after the onset of the fever. On the second day after the appearance of the macule the eruption becomes papular. On the third day vesicles form at the apex of the papules. The vesicles are umbilicated On the fifth day the vesicles change to pustules. The fever rises again to 101 to 103 F (38 3 to 39 4 C). This rise of fever attends the development of pustules It lasts but one day.

The swelling about the lesions is attended by pain. The eyes may be swollen shut. Lesions in the mouth and throat may be painful and aphonia is common.

Other lesions of smallpox are the confluent, hemorrhagic (black smallpox); sometimes urticarial lesions are present. Hemorrhagic smallpox is a serious form of the disease which is commoner in those who are strong and robust. On the third or fourth day the usual rash becomes hemorrhagic and ecchymoses appear on the

occur in a subclinical as well as a clinically apparent form in the same type of hos and still others in an apparent form in one type of host and an inapparent one i another

Viral infections are characterized by their ability to confer solid and durab immunity The immunities which follow natural infections are commonly associate with antibodies that appear in the blood. It is generally held that the initial stimulu leading to their formation of antibodies is not entirely responsible for the immunity It seems likely that immunity is due to the virus living and persisting in the tissue and thus serving to keep the immunity alive, for viruses are ordinarily intracellula and antibodies do enter the cells

It has long been believed that well-nourished persons are more resistant to an kind of infections than those who are undernourished or wasted. This belief, how ever, has been challenged repeatedly, particularly in regard to viral infections River has suggested a theory to explain "malnutritional immunity" based on the assump tion that undernourished cells are lacking in biotin or other stored food material necessary for the proliferation of viruses.

Sprunt observed that prolonged fasting may cause a tenfold increase in the nor mal antiviral resistance of rabbits, provided the animals have free access to drinkin water during the fasting period He obtained data which might be construed as proo that a reduction in the amount of local nutritional reserves in dermal tissues prevent viral proliferation That other factors are also operative, however, is indicated from the observation that blebs raised by the intradermal injection of the viral suspen sions subside much more slowly in the fasted animals than in well-nourished controls

Sprunt found that the failure of virus to spread normally in starved animals i due to increased amounts of interstitial fluid, since fasting animals tend to increase the amount of their interstitial fluids if allowed free access to drinking water

Assuming that viral particles are autonomous biologic entities, Rivers postu- lated that depletion of tissue biotin and other nutritional factors might possibly con- tribute to localization of a virus

The laboratory procedures that aid in the diagnosis of viral diseases are highly specialized and not of the kind which can be performed by the ordinary clinical laboratory In some instances a complement-fixing or agglutinating antibody may have been developed. The agglutinating antibody is based on inactivation of virus and the test is therefore partly an in vivo test carried out with susceptible experi- mental hosts. In vitro tests, such as the complement fixation test, are more con- venient and more economical than neutralization tests, but they are not uniformly applicable to the diagnosis of viral diseases A certain minimal amount of viral material must be present in the antigen that is used in such a test, and this is some- thing not easily realized with materials representing all kinds of viral infections However, the complement fixation test, which is the more sensitive of the two in vitro tests, has proved its value in the diagnosis of several viral diseases. In the generally serviceable neutralization test it is important to know that antibodies often do not make their appearance in the patient's blood until late in the disease or after recovery. A large part of the value of these tests lies in the identification of a past infection rather than in that of a current illness In any case it is important to procure a specimen of serum early during the course of a patient's illness, for com- parison with later specimens.

Effective immunization requires the use of active virus. Vaccinia virus, fixed rabies virus and strain 17D yellow fever virus are the three notable examples There are available a few vaccines, consisting of suspensions of inactivated viruses, which will establish immunities of short duration against some viral diseases. Influenza and equine encephalomyelitis are examples

All forms of life, even bacteria, seem to have their special forms of viruses and viral diseases.

varies from one to several dozen and all are situated on the hands and fingers. There is little discomfort, only slight pain and mild itching

According to Kummer there have been reports of 12 cases in which a generalized eruption has occurred. These disseminated lesions are multiform in type, being either umbilicated papules, urticarial wheals, or macules, any of which may become vesicular or hemorrhagic. This generalized outbreak subsides within a week, and the eruption has been considered as being either toxic or produced by hematogenous dissemination of the infection

Examination. The lesions may be seen to develop from erythematous papules which slowly increase in size, becoming firm, elastic, bluish red nodules from 1 to 2 cm. in diameter. The lesions often are surrounded by inflammatory areolas and may be found in various stages of development. Each nodule becomes semiglobular with a central depression; the surface becomes flat, and when the grayish loose epidermal covering is removed, a reddened, granulating base remains. On healing, the entire nodule flattens and softens and the lesion is gone in from 4 to 6 weeks without formation of scars The regional lymph nodes are occasionally enlarged and secondary pyogenic infection with lymphangitis may occur. There is little constitutional reaction except in unusual instances, when the eruption becomes generalized or secondary infection ensues.

Diagnosis. The history of contact with an infected cow, the spontaneous resolution of the nodule, and microscopic examination of the biopsied nodule seem to be the diagnostic criteria.

Measles. Synonyms for measles are morbilli, rubeola, and Masern.

Measles is usually a mild disease of viral origin. The complications of measles which are of bacterial origin are varied and often of a serious nature The disease occurs both sporadically and epidemically but usually in epidemics during the winter and spring months An attack confers a good immunity

The virus is present in the blood and in the nasopharyngeal secretions probably during the whole of the prodromal period and up to 24 or 30 hours following the appearance of rash and it may persist to confer immunity.

Symptoms The incubation period of measles up to the appearance of the exanthem is from 12 to 19 days The average period is 2 weeks The skin rash is preceded by 1 to 5 days of prodromal symptoms consisting of catarrhal manifestations in the upper part of the respiratory tract There are sneezing, coryza, redness of the eyes, cough and fever In some instances a chill occurs and, in most, there are chilly sensations. The characteristic diagnostic lesions are the Koplik or buccal spots when they can be found These appear from 1 to 4 days prior to the onset of rash The fever and cough become steadily worse until the appearance of the rash.

The symptoms of measles are mild and usually insignificant. The symptoms of the frequent complications often are those of serious disease Otitis media, bronchopneumonia and encephalitis are the more common complications, and are due to bacterial invasions, often by the streptococci, pneumococci, or *Hemophilus influenzae*. Appendicitis is a definite but a rare complication of measles.

The symptoms of otitis media and bronchopneumonia occur early, often during the course of the active disease

The symptoms of involvement of the central nervous system (measles encephalitis) appear usually some days after the appearance of the rash, perhaps after the rash has faded The temperature rises again and the patient becomes drowsy and may have convulsions.

Among the 13,037 cases of measles reported to the Philadelphia Health Department by Sawchuk during the 1946 epidemic there were 14 cases of measles encephalitis, a ratio of 1:1,000. Measles encephalitis is suggested by edema, engorgement of the superficial meningeal vessels and prominence of the smaller vessels in the white matter. In an occasional case perivascular staining indicates focal hemorrhages. The convolutions

conjunctivae and there is bleeding from the mucous surfaces. Death may (the fifth or sixth day.

The characteristic of smallpox is that all of the skin lesions in an area ar at the same stage of eruption. The pustules begin to dry and generally arc over by the end of the second week, the scabs dropping off about the en third week A mild leukopenia often occurs during the pre-eruptive stage moderate leukocytosis appears with pustulation.

In hemorrhagic fulminating smallpox, on the second or third day of diffuse, hyperemic rash appears, beginning as small punctate hemorrhage skin. The skin quickly assumes a purplish appearance and there are ecchyn the conjunctivae and sometimes hemorrhages from the mucous membranes. form of the disease there is never a characteristic smallpox eruption over t However, in some instances of hemorrhagic smallpox, bleeding may be delay the rash has appeared, in which case hemorrhage may occur into or betw lesions The blood manifestations in hemorrhagic smallpox are characteriz decrease in polymorphonuclear cells, thrombocytopenia, and a definite l cytosis The changes in the blood resemble those in leukemia.

A case of unrecognized hemorrhagic smallpox may be the means of dis tion and origination of an epidemic of this disease.

Diagnosis The history and the symptoms during the initial stage of sı may suggest influenza or the prodromal phase of many infectious disease eruption of smallpox is usually characteristic. As stated, all the lesions in are in the same stage of eruption at the same time. The cutaneous lesions of sr are more plentiful on the extremities and the face than elsewhere. Severe rhagic forms of smallpox may resemble septicemia, particularly that occurri ing a meningococcal infection The diagnosis of smallpox on clinical evid generally possible The institution of preventive measures cannot wait for re laboratory tests

Reaction to the Paul test, which consists of introduction of the conten vesicle into the scarified cornea of a rabbit, is positive in one half of the The reaction is characterized by a papular keratitis which yields Guarnieri's on examination of the contents of a small umbilicated papule.

A specific precipitin test also has been described but is not in general use

Varioloid. The term varioloid is used to designate a mild variola which in a partially immune person who has been vaccinated successfully a num years previously. The prodromal symptoms are mild. The rash is scanty, bu ceeds through the appointed course of development at a more rapid rate, an or no secondary rise in temperature attends pustulation In some persons m atypical symptoms of the disease may occur and these are epidemiologically

ld

ne

oc

those recently vaccinated.

The diagnosis of varioloid and variola without exanthem has generally been on epidemiologic evidence In the absence of epidemiologic evidence and suspicion is held it is wise to seek the help of health authorities so that proper nostic laboratory technics can be employed to establish unequivocally the eti of the disease by isolation of virus or demonstration of rise in specific antib during convalescence.

Milkers' Nodules. Milkers' nodules occur in those employed as milkers of having udders crusted or ulcerated with the lesions of cowpox. The disease o during the latter part of the summer. One attack apparently confers immunit seems that the infection enters the skin through abrasions.

Symptoms. The incubation period is from 5 to 7 days. The number of le

monly observed are ocular defects, deafness, cardiac lesions, microcephalus, mental retardation and dental defects. Dental defects are severe in infants belonging to the mothers who had suffered from German measles between the sixth and the ninth weeks of pregnancy, considered to be the "critical" period of dental development. The main dental abnormalities comprised retardation of eruption, hypoplasia of enamel and dental caries. As would be expected the lens of the eye is affected in many of those who have dental malformations

Estimates of percentage involvement of the fetus from maternal rubella during the first three months of pregnancy range from 90 per cent (Australia) to 27 per cent (United States), with a graded decreasing expected anomaly rate from rubella infection in later pregnancy. A woman who contracts rubella during early pregnancy has approximately a 10 1 liability of subsequently being delivered of a congenitally defective child.

Fetal injury is believed to occur as a result of passage of rubella virus through the placenta, thereafter exerting a direct effect on early somatic fetal development. Paradoxically, rubella produces the same result when it occurs and subsides even before conception. Retention of the virus in maternal tissues and its later passage through the placenta to the fetus could account for this as well as the maternal immunity. Other diseases occurring in early pregnancy and in the immediate preconception period, particularly infectious mononucleosis, are also stated to result in congenital defects

The observations of Gregg and associates on the relationship between maternal rubella infection and developmental defects in offspring do not diminish the absolute importance of gene influences, but emphasize the relative importance and scope of environmental factors in human development.

Symptoms. After an incubation period of 10 or 12 days the symptoms commence with sore throat, fever (temperature 99 to 100 F, or 37.2 to 37.8 C), chilliness, headache, coryza and perhaps aching in the back and legs if fever is present

Examination. The throat is somewhat reddened, often there is present irregular areas on the mucous membranes which resemble the skin rash On the second day the skin rash appears on the face, and then it spreads rapidly over the chest and limbs. The eruption consists of erythematous macules which may become slightly elevated and are of varying sizes The rash fades rapidly and is gone in from 3 to 5 days, leaving a moderate brownish desquamation of the involved areas of skin Characteristically there is enlargement of the cervical lymph nodes.

Diagnosis. Rubella often resembles measles and infectious mononucleosis (glandular fever). Differentiation from measles is best established by the absence of Koplik spots and the enlarged cervical nodes. Infectious mononucleosis is characterized by an increase, up to 75 or 85 per cent, of lymphoblastic mononuclear cells in the blood and on the rise in the titer of heterophil antibodies The cervical lymph nodes and the spleen are often palpable in infectious mononucleosis

Pretibial Fever. It seems that the cause of this disease, according to Daniels and Grennan, is a filtrable virus which has been transmitted to guinea pigs and to human beings. The incubation period is from 10 to 15 days.

Biopsies of the cutaneous lesions reveal a diffuse edema and a slight to moderate perivascular infiltration

There may be a mild sore throat, cough and coryza. In some there are frontal headache, postorbital pain, backache, malaise, chills or chilliness and fever. The irregular fever lasts from 4 to 8 days.

On the fourth day of the illness there is present a raised, erythematous eruption of the skin, the lesions being of irregular outline, often 2 to 5 cm in their largest diameter. The eruption is often bilaterally symmetric and limited to the pretibial areas Occasionally the eruption may appear over the entire body. This eruption fades away in 2 days The spleen is palpable. The pulse rate is slow. The leukocyte counts are *equivocal*.

A presumptive diagnosis may be made on the basis of the presence of the fore-

are flattened as a result of edema A cerebellar herniation cone may be present and may account for central cardiorespiratory failure. However, these changes are not specific, since they may be observed in any of the encephalitides.

Neurologic and psychologic examinations were made on 19 of the 34 surviving patients out of 50 patients who include the 14 previously mentioned. Only 2 of the 19 appeared normal. The greatest number of neuromuscular disorders involved the extremities, most of the others involved the cranial nerves Of electro-encephalograms made of 4 of the mentally defective patients, 3 were interpreted as abnormal.

Studies of spinal fluid indicated that a low cell count (fewer than 50 cells per cubic millimeter) in measles encephalitis indicates a grave prognosis.

EXAMINATION Photophobia often is present. On examination the Koplik spots, if definitely manifest, are diagnostic They are usually bilateral and occur at the level of the premolars and around the papilla of the parotid duct; frequently they appear on the mucous membrane of the lower lip. They have a white or bluish white center set on an erythematous base, and are best seen by daylight.

The rash appears on the forehead and behind the ears. It spreads over the neck, body and extremities and usually is fully developed in 2 or 3 days. The first stage is a macular eruption which becomes maculopapular, and the lesions often join to form irregular areas The face usually is swollen and congested and with the catarrhal features has a characteristic appearance The rash may become confluent over the greater part of the body It usually persists for 2 or 3 days after the temperature subsides and then fades rapidly, but instances of longer duration are common. The rash is a hyperemia and disappears on pressure, but in the malignant form of measles it may become red in color Among peculiarities of the rash are the occurrence of numerous miliary vesicles and of petechiae, present occasionally even in cases of moderate severity A sudden recession of the rash may be due to a failing circulation which causes the rash to fade.

At the height of the disease there is often leukopenia until a complication ensues

DIAGNOSIS During an epidemic the diagnosis of measles is easy. The Koplik spots, if they can be seen in the mouth, are diagnostic In sporadic instances of measles, when the progression of the [illegible]
from this. Without Koplik spots and [illegible]
tion from rubella may not be made [illegible]
does not occur in measles Occasionally, under certain circumstances, it may be well to distinguish early smallpox, rubella, scarlet fever and rashes due to drugs from measles.

A detectable diazo substance often occurs in the urine of those who have measles This substance is absent in rubella.

When nervous symptoms are present, the protein and cells of the spinal fluid are increased.

Ford has observed that as high as 65 per cent of the survivors who have had [illegible] and physical impairment.

[illegible] rubella are German measles, rubéola,
[illegible] le
[illegible] n. In adults it is a little more serious. Serious effects are often rendered to the fetus should the mother have the disease during pregnancy

RUBELLA IN HUMAN VOLUNTEERS Experiments carried out on 40 women volunteers demonstrated that typical rubella could be produced by introduction of the virus into the upper part of the respiratory tract The virus can be obtained from nasopharyngeal washings taken on the first day of the rash.

There is evidence that infection provides good immunity for at least 9 years

CONGENITAL DEFECTS. Gregg and his associates presented evidence that maternal rubella infection in early pregnancy appears to be responsible for the frequent development of congenital anomalies in infants subsequently born. The anomalies most com-

SYMPTOMS. In severity the disease varies from an almost symptomless infection to a severe, rapidly fatal one in which death occurs usually within 10 days of onset. Recovery leaves a lifelong immunity. There are no sequelae. The incubation period is 4 to 10 days

There are usually no prodromes The patient becomes ill suddenly. The clinical course in severe instances of the infection is divided into the stages of active congestion and stasis

The onset of the stage of active congestion is acute and characterized by fever, chill, headache, and backache. The temperature rises rapidly to reach its maximum on the first or second day. The initial temperature is continuous and seldom exceeds 103.5 F (39.7 C).

During the stage of congestion the patient is intensely ill and restless. Nausea and vomiting are common. The face is flushed, lips are swollen, and eyes injected. The tongue is bright red A tendency to bleeding may be apparent early. The period of active congestion lasts 3 or 4 days, at the end of which the temperature subsides.

At the onset of the stage of stasis the temperature rises again but seldom reaches its previous maximum The whole aspect of the illness changes during this period The active congestion fades, to be replaced by a venous stasis. The face is no longer swollen, and a dusky pallor replaces the bright red of the first stage. The gums become swollen and spongy and bleed spontaneously or on light pressure. Nausea and vomiting are common. The vomited matter usually contains some altered blood, this is the so-called black vomit. The tendency to hemorrhage is marked; ecchymoses may develop, melena is common

The two stages may coalesce without any drop in temperature. However, in most instances there is a definite rise-fall-rise appearance to the temperature curve

EXAMINATION The appearance of the patient depends on the stage and the severity of the infection. During the stage of congestion the face is intensely reddened, while during the stage of stasis the face is pale.

Prostration may be present and is usually out of proportion to the symptoms The pulse rate is markedly slow in relation to the temperature. The blood pressure is low Jaundice of a mild degree may be present during the second stage of stasis, or it may not appear at all It is more marked in those in whom convalescence is prolonged

Evidence of severe hepatitis and insufficiency may be present and revealed by tests of hepatic insufficiency.

There is a constantly progressive decrease in the number of leukocytes beginning with the onset of the disease The leukopenia reaches its maximum on the fifth or sixth day and is chiefly due to a decrease in the number of neutrophils Leukopenia is characteristic of yellow fever

In the terminal stages formation of urea is diminished. There may be a terminal anuria.

Most deaths occur on the sixth or seventh day, and seldom later than 10 days after onset Complications are not frequent. When recovery occurs, it is rapid and complete.

DIAGNOSIS. During an epidemic, a diagnosis of yellow fever can often be made on the basis of the clinical findings. The laboratory procedures for the establishment of a diagnosis are the isolation of the virus, demonstration of the development of specific antibodies during the course of the disease, and pathologic findings in the liver in fatal instances

The facilities for animal inoculation are usually not available The diagnosis may be established by the examination of two specimens of serum in the protection test. The first is obtained as soon as possible after the onset of the disease and the second during convalescence. If the first specimen is without antibodies, whereas specific antibodies are present in the second, the patient had yellow fever.

going symptoms if influenza and overexposure of the pretibial regions to hot stoves or an open fire are ruled out.

Colorado Tick Fever. This fever is called also mountain fever, tick fever, mountain tick fever, nonexanthematous tick fever, and American mountain fever.

Colorado tick fever is caused by a tick-borne virus. It is a nonexanthematous tick fever as contrasted with Rocky Mountain spotted fever caused by a rickettsia. The virus confers, apparently, a solid immunity since second attacks are unknown.

SYMPTOMS The symptoms commence with chilly sensations and aching of the body Headache, pain in the eyes and lumbar backache attended by anorexia, nausea, vomiting, photophobia, and hyperesthesia of the skin rapidly ensue. The pulse rate increases The temperature rises and is sustained at from 102 to 104 F (38 9 to 40 C) for about 2 days. A remission of the symptoms then occurs, lasting 2 or 3 days during which the patient is somewhat weak. At the end of this period there is usually a recrudescence, and this time the symptoms last for 3 or 4 days. More than one relapse may occur.

The convalescent period of weakness seems unusually long considering the relatively short duration of fever. Complications and death have not been recorded.

EXAMINATION Physical examination reveals only a skin rash and slight hyperemia of the throat and conjunctivae The rest of the findings if any are present are not due to mountain fever. The leukocyte count falls to 2,000 or 3,000 cells per cubic millimeter, the lowest count usually being found during the first relapse. The reduced number of leukocytes is due to the decreased numbers of granulocytes.

DIAGNOSIS. History of exposure to ticks, the recrudescence of the symptoms, and leukopenia suggest a diagnosis of Colorado tick fever Specific diagnostic complement-fixing antigens for Colorado tick fever which give no false positive reactions have been prepared from infected mouse brains The complement-fixing and neutralizing antibodies apparently appear in the blood of human beings about the ninth to the fourteenth day after the onset of the illness.

Yellow Fever. Yellow fever is known also as fièvre jaune, fiebre amarilla, febre amarela, Gelbfieber.

Yellow fever is an acute infection caused by a virus, *Charon evagatus*. Man acquires the infection by the bite of an infected mosquito (see Mosquitoes, Chapter 20). The disease occurs in two main epidemiologic varieties. In the first the virus is transmitted from man to man by certain species of mosquito belonging to the genus *Aedes* of domestic nature, the virus cycle being man—*Aedes aegypti*—man In the second variety the course of a viral cycle involves wild monkeys and forest mosquitoes. Yellow fever, at this moment, is present and is being maintained in large areas of continental South America and Africa.

Yellow fever viral infection gives rise to specific protective antibodies and confers a solid immunity.

VACCINATION The vaccine 17D as prepared by the Rockefeller Institute produces protective antibodies which can be detected after 10 days, and only 2 per cent of serums collected from adults 4 years after vaccination by Fox and Cabral failed to show protective power.

The directions for administration come with the vaccine No local reaction occurs after administration. A general reaction characterized by malaise, fever, and headache may ensue. A severe reaction, often with encephalitic symptoms, is possible but rare. Too, since the vaccine (17D) contains egg protein, an anaphylactic reaction is possible

Characteristically in the most severe instances of yellow fever there is an almost complete destruction of the parenchymatous cells of the liver and associated with these changes are the metabolic disturbances incident to extensive hepatic destruction. The changes in the kidneys account for the marked albuminuria present.

Evidence of erosion and hemorrhage is present in the mucosa at the pyloric end of the stomach. In very few cases is there a complete absence of altered blood in the gastric contents

DIAGNOSIS. Diagnosis is difficult in sporadic, atypical and primary instances of the disease, but is relatively easy during an epidemic.

In order to prove by serologic methods that a given infection was caused by dengue virus, it is necessary to demonstrate that antibodies were either absent or present in low concentration during the acute phase of the illness and developed or increased in amount during convalescence

Phlebotomus Fever (Sandfly Fever). Sandfly fever, pappataci fever, and three-day fever are commonly used names for phlebotomus fever.

The term sandfly fever, popularly used among English-speaking people, has not been accepted in international scientific literature. The term sandfly as used in the United States refers to a different fly belonging to the genus *Culicoides* which has nothing to do with sandfly fever. Pappataci fever, the popular name for the disease in Italy and the Balkans, has also failed to find general acceptance The name phlebotomus fever, which stresses the relationship of the disease to its specific insect vector (the genus *Phlebotomus*), seems acceptable. The fever is of viral etiology.

Experiments on human volunteers residing in phlebotomus-free regions of the United States have shown that a solid immunity to reinfection with the same strain of virus is present for at least 2 years, according to Sabin, after a single experimental attack of the disease The incubation period, which averages from 3 to 4 days, may vary from two and a half to 6 days

SYMPTOMS. After an incubation period of 3 or 4 days the symptoms commence with headache, photophobia, pain in the eyeballs, backache, stiffness in the neck and back, pains in joints and extremities, anorexia, nausea, vomiting, abdominal distress, alteration or loss of taste, sore throat, epistaxis, chills or chilliness and profuse sweating, all of which occur in varying degrees Some patients may have only the general aching and fever. The aching may be severe. There is constipation during the first part of the illness to be followed by diarrhea during convalescence.

The fever ranges upward to 104 F (40 C) within 24 or 48 hours after onset, and the febrile period lasts from 2 to 9 days but usually terminates in 3 or 4 days Fevers of less than 1 day's duration and more than 9 days' duration may occur.

Marked but transitory mental depression occasionally is present during convalescence. Recurrences of the fever and symptoms during convalescence are occasionally observed

EXAMINATION. There are present an erythema of the face and exposed parts of the neck and chest, conjunctival injection which is occasionally limited to the exposed portion of the ocular conjunctivae, tenderness of the eyeballs, and congestion of the fauces, soft palate and posterior pharyngeal wall Urticaria or erythema multiforme may occasionally be observed, but a true rash does not occur

The pulse rate is increased in accordance with height of the fever but returns to normal after the first day or two of fever Bradycardia may be present at the end of the febrile period and during convalescence

On the first day of the disease according to Sabin, Philip and Paul the total leukocyte count is normal There is a relative and absolute decrease in the lymphocytes accompanied by a relative and sometimes absolute increase in the neutrophils which is due to an increase in immature cells During the second or third day of fever, the number of lymphocytes begins to return to normal and for a few days thereafter may constitute from 40 to 65 per cent of the total count. At the same time, the number of neutrophils begins to drop, and the immature cells increase to a point at which they usually outnumber the segmented cells The greatest drop in the total number of leukocytes may not occur until the end of the febrile period or after defervescence, but the marked shift to the left in the neutrophils and changes in the proportions of different types of cells at various stages of the disease are more important for diagnosis than is a single total leukocyte count. The urine is normal.

Dengue (Mosquito-Borne). Dengue has various designations, among which are breakbone fever, dandy fever, denguero, bouquet fever, giraffe fever, polka fever, five-day fever and seven-day fever

Dengue fever is a mosquito-transmitted viral infection. The existence of multiple immunologic types of dengue viruses is known There are at least three immunologic types in Hawaii, New Guinea, India and Japan It seems that all these viruses have at least one common antigen

Neutralizing antibodies for the homologous type of virus have been found in human beings infected by the Hawaiian strain as early as a week after the onset of illness and as late as 2 years. The usual incubation period is from 5 to 8 days, although it may vary from two and a half to 15 days, depending on the amount of virus introduced

SYMPTOMS In about half of those who have dengue fever the onset of symptoms may be gradual with headache, backache, fatigue, stiffness, anorexia, chilliness and malaise A skin rash may precede the fever or become manifested after the fever is present In the rest of the patients the onset is sudden with high fever attended by severe headache, pain behind the eyes, backache, pain in the muscles and joints and chilliness, but rarely a shaking chill. The fever persists for 5 or 6 days and terminates by crisis The temperature rarely exceeds 105 F (40 5 C) Occasionally the temperature will return to normal after 2 or 3 days but a febrile period will return again. The course of the fever may be changed by the administration of aspirin for the aches and pains.

The pulse rate at first increases proportionately to the temperature, but after the first day or two it is slowed An absolute bradycardia may be present during convalescence.

Digestive symptoms such as anorexia, abdominal discomforts, and altered taste sensations are common Diarrhea may be present at the onset, to be followed by constipation during convalescence

There are mild forms of the disease consisting of a febrile illness of from 1 to 3 days In these there is no skin rash Reinfection with a heterologous virus may be encountered in those who have previously had the disease

EXAMINATION On examination there is a flushed appearance of the face, neck and chest; and a punctiform rash, especially over points of friction as at the back of the elbows and front of the knees, may be present early in the disease The bulbar and the palpebral conjunctivae may be injected; the eyes are tender to pressure and painful on movement Photophobia may be obvious Lymph nodes frequently are enlarged, but rarely is the spleen palpable. There may occasionally be sufficient edema about the fingers to interfere with closure of the hand, skin paresthesias are present in some The large joints present no abnormalities even when there is a great deal of pain situated in them

The rash may be macular or maculopapular, commonly appears on the third to fifth day and lasts 3 to 4 days. It commences on the chest, trunk, and abdomen, and spreads to the extremities and face Itching, especially of the palms and soles, is common. Desquamation is rare The rash may not be apparent before the last day of fever or until soon after defervescence. This delayed rash consists of small petechiae over the extensor surfaces of the feet and legs, hands and fingers, and on the buccal mucosa and hard and soft palates. This petechial eruption fades after one to three days, leaving a transitory brownish discoloration.

Leukopenia is present. During the first 24 hours the total number of leukocytes may be normal, but the lymphocytes show an absolute and relative decrease, while the number of neutrophils is increased by the appearance of immature forms As the disease progresses, the total number of leukocytes decreases, sometimes to as few as 1,500 cells per cubic millimeter The lymphocytes toward the end of the febrile period and early in convalescence frequently constitute the major portion of the circulating leukocytes. The leukocyte count returns to normal within a week after defervescence.

persists throughout the illness and may be the chief complaint by the patient Generalized aching and soreness of the ocular muscles are often present. Nosebleed sometimes occurs Prostration and signs of cardiac weakness may be evident from the onset, usually becoming pronounced by the second week of the illness. Constipation may be troublesome throughout the illness The general feature of prostration, tending toward stupor and delirium, becomes graver in the second week. In severe disease with definite cardiac weakness there is a tendency toward development of gangrene of the extremities, more frequently of the toes Mental disturbance is common. This may vary from confusion, disorientation, restlessness, insomnia and irritability to delirium.

In cases of severe involvement which end in recovery there is often a sharp change toward the end of the second week. If the disease is uncomplicated, the temperature falls and the stuporous condition disappears about the fourteenth day. Prostration and cardiac weakness continue for a varying length of time after defervescence, depending to a great extent on the age of the patient, those in the younger age groups recovering more quickly than older persons In instances which proceed to a fatal outcome the prostration and the mental cloudiness increase and coma ensues.

Delirium may be present from the onset During the febrile period or during convalescence, hemiplegia, hemiparesis, aphasia and other focal cerebral symptoms are often present. Jacksonian convulsions or generalized muscular twitchings occur Bulbar palsy is common. Optic neuritis followed by optic atrophy, and neuritis of the facial, auditory and oculomotor nerves are observed. Lesions of the spinal cord causing paraparesis and incontinence are mentioned During convalescence neuritis involving a single nerve or groups of nerves, or of a generalized toxic type, occurs Often the brachial plexus or the sciatic, median, ulnar, axillary or musculocutaneous nerves are affected

Some evidence of involvement of the respiratory system is usually present. This varies from a mild cough, which may never be troublesome, to definite bronchopneumonia The pneumonic process may be the presenting symptom.

Among the complications which may be encountered are bronchopneumonia, parotitis, otitis media, mastoiditis and thrombosis of various veins.

The fatality rate varies in different epidemics In all epidemics the rate is less in children than in adults More than 80 per cent of those more than 50 years of age may succumb In sporadic cases in interepidemic periods the death rate is much lower.

EXAMINATION. Aside from the fever and prostration the most characteristic observation on examination is a skin rash which appears on the fourth to sixth day after onset of the illness It may appear as early as the third day or as late as the ninth day The rash consists of rose red macules and papules. These lesions at first disappear on pressure but become petechial and darker as the disease progresses. In severe involvement coalescence of the lesions occurs The eruption appears first on the medial surfaces of the proximal portions of the arms or on the sides of the thorax and the upper part of the abdomen and spreads to the rest of the thorax, the back and arms and legs, usually being less pronounced on the extremities The palms and the soles may be involved, while the neck and face are seldom included in the area of distribution. The rash becomes brownish as recovery ensues, usually disappearing during defervescence In some cases the remnants of the rash may be discernible for several weeks.

The pulse rate often remains below 120 or even 100. A rate of more than 130 indicates severe involvement with a doubtful prognosis. In some patients there is a decrease in pulse rate (50 to 60) during convalescence, the pulse gradually regaining the normal rate as strength returns. On recovery from a severe attack, shortness

DIAGNOSIS The disease is suspected when outbreaks of an illness with fever of short duration occur during the hot, dry season, especially among the newcomers in countries known to harbor *Phlebotomus papatasii*. In other words, the diagnosis of phlebotomus fever is generally based on clinical and epidemiologic data.

THE RICKETTSIAL DISEASES

Rickettsias are gram-negative microorganisms, coccoid or bacillary, which are parasitic in the arthropods and are highly adapted to their hosts. They sometimes infest man and higher animals, and are grown with difficulty on artificial mediums Those known to be pathogenic for man occur intracellularly in the tissues of their vertebrate and arthropod hosts With the exception of the rickettsia of Q fever, they do not pass filters that retain pathogenic bacteria

A characteristic of this group of diseases, with the exceptions of Q fever and rickettsialpox, is the production in patients of agglutinins for the X strains of *Proteus vulgaris (Bacillus proteus)*. This agglutination of Proteus X (Weil-Felix reaction) has been of great assistance in distinguishing the tsutsugamushi group f[illegible] typhus and spotted fever groups, since with tsutsugamushi agglutinins for [illegible] are typically produced, while the serums of [illegible] OX2 strains There [illegible] immunity, which separate the subdivisions [illegible]

Epidemic Typhus (Louse-Borne Typhus Fever, [illegible] the name epidemic typhus are spotted typhus, petechial fever, jail fever, ship fever, camp fever and exanthematous typhus

Epidemic typhus is an acute infectious disease caused by *Rickettsia prowazekii.* Persons of all ages are susceptible

The disease is transmitted from person to person by body lice. Rickettsias are present in the feces of typhus-infected lice in great numbers, and it is probable that from deposits of such feces they gain entrance to the body through abrasions in the skin. The high morbidity rate among doctors and nurses in epidemics of typhus suggests that the inhalation of dried, infected louse feces or the deposition of air-borne infected material on the mucous membranes may be responsible for some instances of the disease.

The chief epidemiologic characteristics of epidemic typhus are as follows: (1) It occurs among populations disorganized by war, famine or social revolution (2) It occurs first and most commonly in the destitute, in concentration camps and in prisons (3) It is transmitted from person to person through the agency of the body louse (4) The epidemics occur in the winter and spring One attack usually confers immunity which may not be permanent

Often there are present splenic enlargement and bronchopneumonia The essential lesion is focal injury of capillary and precapillary vessels, characterized by endothelial swelling, proliferation and necrosis with thrombosis, and by nodular perivascular exudations Such lesions are most frequent in the skin, heart, great vessels, kidneys, adrenal glands, testes, epididymides and especially the cerebral cortex Splenic hemorrhages and thrombi may be present These findings are essentially the same in all rickettsial infections

SYMPTOMS. The incubation period is between 5 and 15 days, the usual time is 8 to 12 days. The prodromes include 1 or 2 days in which the patient experiences malaise, headache, anorexia and at times nausea In the majority of cases the disease begins abruptly with rapidly rising fever, repeated chills and headaches.

The fever rises steadily, usually reaching its maximum by the end of the first week. Morning remissions of fever occur These remissions may be slight during the second week. The fever falls usually by rapid lysis after about fourteen days, patients who have uncomplicated typhus ordinarily being afebrile by the sixteenth day after the onset

Headache is a prominent symptom, being severe and difficult to relieve It often

where cases of Rocky Mountain spotted fever or of tsutsugamushi may be encountered also. It is practically impossible to make a differential diagnosis prior to the appearance of the rash. Other diseases which typhus resembles are measles, meningococcemia and typhoid fever. Drug rashes also may be confusing

The final diagnosis in the sporadic case depends on the presence of the Weil-Felix reaction The standard Weil-Felix reaction may show some agglutination in dilutions of 1:25 beginning on the fourth day of the illness The important positive diagnostic observation is a rise in the agglutination titer, which may rise to dilutions of 1:30,000 toward the end of the second week of the fever.

The complement fixation test may serve to distinguish typhus from spotted fever and from Q fever. The complement fixation persists for many months.

The rickettsial agglutination test may be employed in the diagnosis of typhus and related fevers.

The injection of endemic typhus blood into a guinea pig causes scrotal swelling and fever.

The case fatality rate is less than 5 per cent in murine typhus, with most of the deaths those of patients more than 45 years of age. The fact that the case fatality rate is much lower in murine typhus than in epidemic typhus has usually been considered to be due to a difference in the virulence of the flea-borne as compared with the louse-borne strains Endemic or murine typhus occurs among populations in which the element of human distress is not paramount

Scrub Typhus (Tsutsugamushi Disease) (Mite-Borne). Scrub typhus is known also as tsutsugamushi, Japanese river fever, flood fever, Kedani mite fever, pseudotyphus of Deli (Sumatra), and coastal fever or Mossman fever of North Queensland (Australia)

Scrub typhus is a typhus-like malady which is widely distributed in the Orient and islands of the Pacific. The disease is acquired on exposure to certain types of vegetation in areas of open country which is overgrown with weeds Ordinarily scrub typhus occurs sporadically or in small outbreaks

The causative organism of scrub typhus is *Rickettsia tsutsugamushi* (*Rickettsia orientalis*). *Rickettsia tsutsugamushi* does not invade the nuclei of mammalian cells, and in this respect it differs from rickettsia of Rocky Mountain spotted fever.

The usual vertebrate host of the virus of scrub typhus in Japan is the field vole *Microtus montebelloi* Certain species of wild rats which are commonly infested by mites probably are the principal reservoirs of the organism of scrub typhus in the Philippine Islands, Formosa, Sumatra and New Guinea

The common vector in Japan is the kedani mite, *Trombicula akamushi* (*Trombicula fletcheri*). In the Philippines, Sumatra, Malaya, India, and Queensland (Australia) *Trombicula deliensis* is thought to be the vector, in New Guinea the rickettsia has been recovered from *Trombicula fletcheri*

PATHOLOGY. Scrub typhus is characterized by a disseminated perivasculitis associated with edema and passive hyperemia These changes are advanced in the heart, lungs, regional lymph nodes, testes and brain Other organs show variable degrees of involvement The necrosis of the skin at the site (eschar) of the primary lesion and the necrosis of the regional lymph nodes are the only histologic evidence of "toxemia" In all cases there is sufficient cardiac involvement to produce impairment of heart function and, in addition, an interstitial pneumonitis of sufficient severity to alter the normal gaseous exchange

SYMPTOMS The incubation period is from 7 to 21 days. The onset of the symptoms may be abrupt, or prodromes may be present Early symptoms usually include chilly sensations or chills, headache, anorexia, orbital pain, and rise of temperature There may be severe malaise, vomiting and prostration. During the first week the patient is alert but during the second week the typhoid state is present There may be partial deafness and generalized hyperesthesia. Coma may be present in the critically ill.

of breath may be present for several weeks. Recovery, once assured, is usually complete and sequelae are absent

In many instances albuminuria is present at the height of the illness. It clears with subsidence of the fever.

Azotemia in epidemic louse-borne typhus is found to occur in more than half of the cases, as indicated by increased concentrations of blood urea and creatinine. The correlation between clinical severity and azotemia is constant. Increased concentration of blood nonprotein nitrogen is present in every instance of the fatal disease. Azotemia appears to be closely associated with excessive destruction of body protein and increased nitrogen excretion, with dehydration and a reduced output of urine in the presence of otherwise normal renal function, and in severe typhus with a sudden rapid fall in blood pressure associated with evidences of renal insufficiency The appearance of renal insufficiency as a complicating condition in the disease is in nearly every instance the earliest indication that the patient's course is severe or may end fatally

The leukocyte count varies from 5,000 to 12,000 or 15,000 per cubic millimeter

The Weil-Felix reaction may become positive during the first week but usually it becomes positive during the second week of illness, reaches its height about the time convalescence is established and disappears rather rapidly. It is advisable to test at least two samples of serum, one taken early in the illness and a second late in the second week. With a sensitive antigen the serums of patients with typhus often reach a titer between 1 10,000 and 1:100,000 The OX19 strain of *Proteus vulgaris* is more commonly agglutinated than OX2 and is the strain customarily employed. The serums of patients who have Rocky Mountain spotted fever also show the Weil-Felix reaction in high titers and consequently this reaction is of no practical value in differentiating between the two diseases Serums from persons suffering from other illnesses not related to the rickettsial diseases may show the Weil-Felix reaction in dilutions as high as 1 320 and occasionally 1 640

The complement fixation can be utilized in the diagnosis of typhus The reaction to this test, with typhus rickettsias used as an antigen, becomes positive during the second week of the disease and may remain positive for many years It is of value in differentiating typhus from Rocky Mountain spotted fever

Endemic Typhus (Murine Typhus, Brill's Disease) (Flea-Borne and Mite-Borne) The difference between the epidemic form and the endemic or murine type is largely epidemiologic, with some variations, not entirely explained, in the immunologic observations

The causative organism of endemic typhus has been named *Rickettsia typhi.*

EPIDEMIOLOGY. The chief epidemiologic characteristics of endemic typhus are as follows. (1) Human cases are associated with rat harbors (2) The disease occurs most commonly among workers in food-handling establishments (3) There is no predominance of cases among the poorer sections of the population (4) Transmission from person to person through contact or by rat fleas has not been observed (5) The peak of prevalence is in late summer and fall

SYMPTOMS. The symptoms of the endemic form of typhus are identical with those of the epidemic form with the exception that on the average they are much less severe. [illegible]

may compri [illegible]

The lab [illegible]

that leukop[illegible]

DIAGNOSIS. Epidemic and murine typhus fever have the same diagnostic requirements

When typhus is present as an epidemic, little difficulty should be experienced in making the diagnosis Sporadic cases, whether of the epidemic or of the endemic form of the disease, give more difficulty. This is true particularly in those regions

patients ill with the disease a rickettsia, *Rickettsia akari*, has been isolated. This strain is antigenically distinct from the organisms causing typhus, tsutsugamushi and Q fever.

SYMPTOMS. The initial lesion appears about one week before any other symptoms are present The patient does not appear ill and continues with a normal intake of food and drink. The onset is sudden, with chills, fever, sweats, backache and lassitude Chills frequently precede the fever. Two or more chills may occur each day. Occasionally there are chilly sensations rather than chills.

The temperature rises rapidly to reach 103 to 104 F (39.4 to 40 C). There are morning remissions. Defervescence is finished in from 2 to 10 days. Sweats follow the chills and the subsidence of the fever during the early morning hours.

Headache is severe. There may be pain back of the eyeballs. Photophobia and occasionally a mild conjunctivitis are present. Backache, myalgias, and general soreness of the muscles are common early in the disease. Lassitude and a feeling of fatigue are common.

EXAMINATION. The initial lesion, or papule, often occurs on an unexposed part of the body. However, it may appear on the neck, the face, or the dorsum of a hand The surrounding skin is normal. As the papule increases in size, the center becomes vesiculated but soon shrinks and becomes a black eschar. The surrounding skin when the eschar has formed is erythematous but without induration. The regional lymph nodes enlarge and may be slightly tender. The initial lesion heals in approximately 3 weeks with formation of a scar.

About 1 week after the appearance of the initial lesion, usually synchronously with the onset of the fever or occasionally from 1 to 6 days later, examination reveals a maculopapular skin rash which is often discrete, but there may be too an accompanying erythematous reaction The papules are firm to the touch and small (2 to 8 mm) Some of the papules become vesicular in 1 to 3 days Drying of the vesicles leaves firm eschars The rash is irregular in distribution over the arms, legs, back, thorax and face The palms and soles are not involved, the mucous membranes rarely The rash is without discomfort and heals without formation of scars

The pulse rate varies with the temperature The spleen rarely is palpable.

Leukocyte counts often reveal a moderate leukopenia The differential smear may confirm the presence of a relative lymphocytosis The leukopenia is gone in about 2 weeks after the onset of fever There is a transient febrile albuminuria Agglutination reactions with Proteus OX19, OX2 and OXK are essentially negative.

DIAGNOSIS. Diagnosis is made by testing with a specific antigen of rickettsialpox or by recovery of an organism possessing the characteristics of a rickettsia from the tissues of a mouse inoculated with blood drawn from a patient who has the disease.

The vesicles in *chickenpox* are superficial, thin and easily broken, while in rickettsialpox they are deep-seated and firm

The pock in the early stage of *smallpox* resembles that of rickettsialpox, but heals with formation of scars. The smallpox rash has a more selective distribution, [illegible] lesion, [illegible] ecchymotic. No initial lesion is present Nearly all patients give a positive agglutination reaction with Proteus OX19 and a positive reaction to the complement fixation test with homologous rickettsial antigens

The lesions of *Rocky Mountain spotted fever* are not so discrete as those of rickettsialpox and they are often ecchymotic and are never vesicular Patients who have Rocky Mountain spotted fever give a positive agglutination reaction with Proteus OX19 or OX2 whereas these reactions are not present in rickettsialpox.

The rash in *scrub typhus* fever is macular or maculopapular and not vesicular. The course of the disease is severer and pulmonary signs are common Serum

The average duration of the fever varies from 3 days to a month. The fe shows morning remissions. There may be afebrile periods lasting as long as 2 t days Defervescence takes place by lysis.

As a rule, the pulse rate rises and falls with the temperature during the f week of illness. In the second and third weeks the pulse tends to become wea and more rapid. The blood pressure usually falls gradually during the second w of illness Circulatory collapse or congestive heart failure may develop

EXAMINATION The rate of the respiration varies from 20 to 30 per minu When pulmonary or cardiovascular complications supervene, the respiratory r may rise to 40 or even 60 per minute

A primary lesion is present in most instances. This lesion begins as an erythe atous macule, becomes a papule, and subsequently ulcerates. The ulcer is shar defined, is surrounded by a red areola, and subsequently a black eschar ensues. T lymph nodes of the drainage area are enlarged The primary lesion appears bef the onset of fever It is most frequently on the ankles and lower parts of the l or on the thighs. Usually this lesion is single, but two primary lesions may oc on different parts of the body

There are redness of the throat and unproductive cough in the early stage scrub typhus Passive congestion of the bases of the lungs is present Bronchitis bronchopneumonia is common

A rash usually develops between the fourth and the seventh day It may app first on the sides of the chest and abdomen. It sometimes appears on the fa rarely on the palms and soles The rash is maculopapular at first. In the beginni the color disappears on pressure The lesions are often discrete and rare petechial

The superficial lymph nodes are enlarged. Greater enlargement, pain, a sensitiveness may be found in the group of nodes draining the region in which t primary lesion is situated than in other nodes.

The spleen is palpable and tender

Subconjunctival hemorrhage may occur Edema of the optic disk and of t retina may be observed during the second and third weeks Retinal hemorrhag occur rarely

The urine usually contains some albumin Slight anemia is present In the ear stages of illness the leukocyte count is normal. Later there may be a slight increa of polymorphonuclear cells followed by an absolute lymphocytosis which persis during convalescence. The leukocyte count varies from 1,500 to 19,500 per cub millimeter of blood The lymphocytes range above 40 per cent

DIAGNOSIS Scrub typhus differs from typhus in that the eruption is mor frequently absent and seldom becomes petechial A presumptive diagnosis ca often be made by finding the characteristic primary lesion and a regional or genera adenopathy.

Reaction to the Weil-Felix test becomes positive with Proteus OXK about th twelfth or fourteenth day of illness in most cases The causative organism, Rick ettsia tsutsugamushi, can be recovered readily from the blood of patients durin the acute stage of the disease by the intraperitoneal inoculation of 0.2 to 0.3 ml of blood in white mice When the reaction is positive, both of these laborator procedures establish the diagnosis, but the disease is not excluded by a negative Weil-Felix reaction with Proteus OXK The complement fixation test gives reac tions which are specific.

In mild instances of scrub typhus prognosis is excellent When cyanosis or bronchopneumonia appears, the outlook is grave.

Rickettsialpox (Mite-Borne). Rickettsialpox, also called Kew Garden fever, is an acute, febrile disease occurring in areas infested with mice and rats. Because of some similarity to chickenpox the name rickettsialpox has been assi ned From

The Weil-Felix reaction gives no aid in differentiating spotted fever from typhus. In a large number of cases it has been noted that agglutinins for Proteus OX2 occur more frequently in the serums of patients with spotted fever than in those of patients with typhus, but since they do occur in some of the latter the stated difference is of no help in the individual case. When agglutinins for both strains are present, those for OX19 are usually higher than those for OX2. The agglutinins for OX19 usually appear toward the end of the second week of the disease At times they are delayed until early convalescence. In some proved cases of spotted fever no agglutinins for Proteus X are produced The curve of agglutinins in its rise and fall is similar to that seen in typhus. As in typhus, it has been found that complement fixation with the rickettsias of spotted fever used as an antigen becomes positive in the second week of illness.

DIAGNOSIS. The diagnosis depends on the laboratory findings as enumerated Generally, spotted fever differs from typhus chiefly in two respects: (1) In spotted fever the rash appears first on the extremities and spreads centripetally. (2) Gangrene of the genitalia is common in spotted fever but is very rare, if it occurs at all, in typhus. Cutaneous and subcutaneous hemorrhages seem to be commoner in spotted fever than in typhus

In typhus fever the pulse rate usually rises and falls with the fever and is proportional to the elevation of temperature. In spotted fever the pulse may be relatively slow early in the disease or throughout the course of the fever. In typhus fever the eruption very rarely occurs on the face.

A vaccine made from infected ticks for use against spotted fever was elaborated and is prepared by the United States Public Health Service at Hamilton, Montana. There is no good evidence that the vaccine is of value after the infection has been acquired, nor is it of any value in treatment It may offer some protection during sojourn in infested areas. According to reports, chemotherapy has given good response in some instances

Boutonneuse (Tick-Borne) Synonymous names for boutonneuse are Marseilles fever, fièvre exanthématique, and escarro-nodulaire

Boutonneuse is caused by *Rickettsia conorii* and is closely related to Rocky Mountain spotted fever. It has an extensive distribution in Rumania, Portugal and the countries bordering the Mediterranean.

The infection is transmitted by the brown dog tick *Rhipicephalus sanguineus.*

SYMPTOMS. The incubation period is 5 to 7 days, although in occasional cases it may be as long as 18 days

As in other rickettsial infections, the onset is usually abrupt, with fever and repeated chills or chilliness The temperature rises rapidly and may reach 104 F (40 C) in a few hours Headache and pain in the muscles and the joints are common complaints. Prostration is usually not a prominent feature of this disease The febrile period is from 8 to 14 days, defervescence taking place by rapid lysis

Insomnia is common throughout the febrile period As the disease is seen in Marseilles and Italy, mental disturbance is less severe than in other rickettsial infections, although patients who have severe involvement may show moderate delirium The case fatality rate is low, being less than 3 per cent

EXAMINATION A papular or maculopapular rash appears on the second to fourth day of illness It begins on the trunk, legs and arms and extends rapidly over the entire body, usually appearing on the face last The palms and the soles are commonly involved The rash may be less pronounced on the abdomen than elsewhere It may be found on the soft palate as small round red spots which persist only a few days

The individual lesions comprising the rash may become hemorrhagic, especially those on the legs, but there is little tendency to coalescence The rash usually disappears with convalescence.

Frequently a small ulcer about 2 to 5 mm in diameter, showing a black necrotic center surrounded by a red areola, is found at the onset of illness This has been

agglutination with Proteus OXK occurs about the second week in a majority of cases. Specific complement fixation antigens are also available for differentiation

The rash in *boutonneuse fever* is papular or maculopapular and frequently involves the palms and soles. Serum agglutination of Proteus OX19 occurs late in the disease or in the convalescent stage. There is a history of a tick bite.

Rocky Mountain Spotted Fever (Tick-Borne) The causative agent is *Rickettsia rickettsii (Dermacentroxenus rickettsi)*

The usual vectors for the transmission to man of Rocky Mountain spotted fever are the wood tick of the Northwest (*Dermacentor andersoni*) and *Amblyomma americanum* and the American dog tick (*Dermacentor variabilis*).

Rocky Mountain spotted fever is a severe rickettsial disease which occurs when a human being is bitten by an infected tick The important endemic foci in the United States are Wyoming, Montana, Colorado and the Southern Atlantic states (Virginia, Maryland and North Carolina) In the West the majority of cases appear between April and June, and in the East, during July and August A greater number of victims of spotted fever show focal lesions in the midbrain, pons, medulla and cerebellum than do those of typhus

SYMPTOMS. The incubation period is from 2 days to 12 days The average is about 1 week

The symptoms of Rocky Mountain spotted fever resemble those of epidemic typhus fever There are prodromes consisting of loss of appetite, listlessness and headache The onset is usually sudden, with a chill or chilly sensations and rapidly rising fever. Prostration is usually pronounced In the severer type of the disease nosebleed may occur early. Soreness of the muscles and the joints is commonly present. The temperature rises rapidly, reaching its highest point usually in the second week. Morning remissions of 1 to 3 F occur. The termination of fever is by rapid lysis occurring usually about the twenty-first day, although patients who have mild disease may be afebrile before the end of the second week

Nervous and mental symptoms are common. restlessness, insomnia, disorientation and in severe instances delirium In fatal spotted fever, coma usually precedes death, which occurs about the end of the second week.

Convalescence of patients who have severe involvement is likely to be slow and may be complicated by visual disturbances, deafness or mental confusion Although recovery may be delayed, it is usually complete. The case fatality rate, as in typhus, varies directly with age, it is about 1 in every 5 who have this fever

EXAMINATION The most characteristic finding on physical examination is the rash. This appears between the second and fifth days, usually on the third or the fourth day The rash may be preceded by a suggestive mottling of the skin, and this resembles the early rash of measles. This introductory rash disappears in a few hours to be replaced by the maculopapular lesions The lesions are erythematous at first and become fainter, almost disappearing during the morning remissions of fever early in the disease They become more distinct each day until they are definitely petechial in all but the mildest forms of infection. In severe involvement the spots become deep red or purplish and confluent Necrosis may develop. The rash usually persists throughout the febrile period and into convalescence, becoming brownish Often a branny desquamation occurs over the areas where the rash was thickest. The site of first appearance and the spread and final distribution of the rash are important in the diagnosis of the disease. Usually the rash appears first on the wrists and the ankles, spreading rapidly in the first 24 to 48 hours to the back, then to the arms, the legs and the chest, and last to the abdomen, where it is least pronounced. The palms and the soles are frequently involved, often the face and occasionally even the scalp

The leukocyte count is increased in cases of Rocky Mountain spotted fever, usually being about 12,000 per cubic millimeter, although it may be as high as 30,000.

The Weil-Felix reaction gives no aid in differentiating spotted fever from typhus In a large number of cases it has been noted that agglutinins for Proteus OX2 occur more frequently in the serums of patients with spotted fever than in those of patients with typhus, but since they do occur in some of the latter the stated difference is of no help in the individual case. When agglutinins for both strains are present, those for OX19 are usually higher than those for OX2. The agglutinins for OX19 usually appear toward the end of the second week of the disease. At times they are delayed until early convalescence. In some proved cases of spotted fever no agglutinins for Proteus X are produced. The curve of agglutinins in its rise and fall is similar to that seen in typhus. As in typhus, it has been found that complement fixation with the rickettsias of spotted fever used as an antigen becomes positive in the second week of illness.

DIAGNOSIS The diagnosis depends on the laboratory findings as enumerated. Generally, spotted fever differs from typhus chiefly in two respects: (1) In spotted fever the rash appears first on the extremities and spreads centripetally (2) Gangrene of the genitalia is common in spotted fever but is very rare, if it occurs at all, in typhus. Cutaneous and subcutaneous hemorrhages seem to be commoner in spotted fever than in typhus.

In typhus fever the pulse rate usually rises and falls with the fever and is proportional to the elevation of temperature In spotted fever the pulse may be relatively slow early in the disease or throughout the course of the fever In typhus fever the eruption very rarely occurs on the face

A vaccine made from infected ticks for use against spotted fever was elaborated and is prepared by the United States Public Health Service at Hamilton, Montana There is no good evidence that the vaccine is of value after the infection has been acquired, nor is it of any value in treatment It may offer some protection during sojourn in infested areas According to reports, chemotherapy has given good response in some instances

Boutonneuse (Tick-Borne) Synonymous names for boutonneuse are Marseilles fever, fièvre exanthématique, and escarro-nodulaire

Boutonneuse is caused by *Rickettsia conorii* and is closely related to Rocky Mountain spotted fever It has an extensive distribution in Rumania, Portugal and the countries bordering the Mediterranean.

The infection is transmitted by the brown dog tick *Rhipicephalus sanguineus*

SYMPTOMS. The incubation period is 5 to 7 days, although in occasional cases it may be as long as 18 days

As in other rickettsial infections, the onset is usually abrupt, with fever and repeated chills or chilliness. The temperature rises rapidly and may reach 104 F (40 C) in a few hours Headache and pain in the muscles and the joints are common complaints Prostration is usually not a prominent feature of this disease The febrile period is from 8 to 14 days, defervescence taking place by rapid lysis

Insomnia is common throughout the febrile period As the disease is seen in Marseilles and Italy, mental disturbance is less severe than in other rickettsial infections, although patients who have severe involvement may show moderate delirium. The case fatality rate is low, being less than 3 per cent.

EXAMINATION A papular or maculopapular rash appears on the second to fourth day of illness It begins on the trunk, legs and arms and extends rapidly over the entire body, usually appearing on the face last. The palms and the soles are commonly involved The rash may be less pronounced on the abdomen than elsewhere. It may be found on the soft palate as small round red spots which persist only a few days.

The individual lesions comprising the rash may become hemorrhagic, especially those on the legs, but there is little tendency to coalescence. The rash usually disappears with convalescence

Frequently a small ulcer about 2 to 5 mm in diameter, showing a black necrotic center surrounded by a red areola, is found at the onset of illness. This has been

named tache noire (black spot) and is similar in appearance to the ulcer often seen in *tsutsugamushi* The *tache noire* may be found on any part of the body, usually on a part covered by clothing, this is supposed to be the site of the infecting tick bite. Sometimes the regional lymph nodes become enlarged and tender.

DIAGNOSIS. The Weil-Felix reaction with the OX19 strain of *Proteus vulgaris* used as an antigen becomes positive late in the disease.

There is no specific treatment for boutonneuse, and no vaccine is available at present.

Q Fever (Air-Borne and Food-Borne). The cause of Q fever is *Coxiella burnetii* (*Rickettsia burnetii*), and ticks infected with this organism have been found in many parts of the United States. The epidemiologic investigations of the occurrence of Q fever have revealed a close association with animal life, such as pigeons, rats, mice and cattle. Contamination of the environment with excreta or secreta of infected animals has been suggested as a means of dissemination of the rickettsia from animal to man. Evidence concerning the portal of entry is not conclusive but suggests that human infection may occur through ingestion or inhalation of the rickettsia

A minimal incubation period of 13 days is postulated, with a mean which is probably somewhat longer. The exact course of infection and mode of transmission cannot be ascertained, but the epidemiologic data point to the existence of an extra-human source and an intermediary host

SYMPTOMS. The onset may be sudden; many patients are able to state the hour at which they became ill. As a rule the onset is accompanied by chilly sensations, sweats, a feeling of general malaise with weakness and sometimes muscle aches, frontal headache and anorexia Thoracic pain is common, and this varies from vague aching to a pleuritic type of pain. Occasionally gastrointestinal symptoms consisting of diarrhea or mild abdominal cramps are present.

In other patients the onset of the symptoms commences with headache which is not severe Fever and chills and chilliness may be present, though a real chill is rare Muscle aches and pains and symptoms referable to the respiratory tract are common, as are mild gastrointestinal symptoms.

The average period of illness is 4 days In 1 in 10 the illness lasts longer than a week. In all patients the course of the disease is mild There is little prostration, and the patients are not any more incapacitated than they would be with a mild fever from any cause

EXAMINATION. The results of general examination are negative except for the fever.

DIAGNOSIS Specific diagnosis can be established only by special laboratory procedures Tests by complement fixation and agglutinin absorption are required.

Trench Fever (Louse-Borne). Trench fever, also known as five-day fever, Volhynia fever, His-Werner disease, skin fever and shank fever, is a febrile disease transmitted to man by the body louse Extracellular rickettsias have been found in lice fed on patients with the disease and are present in the feces of such lice

The incubation period varies from 5 to 20 days The onset is sudden with headache and pain in the legs, most noticeable in the region of the tibia There is a sudden onset of fever which may last 1 week Three or four episodes of fever of a few days' duration are common.

A macular rash is present at the height of the fever in the majority of cases Occasionally papules will be present. This rash may occur as early as the second day of the initial attack of fever or during one of the relapses. It is most commonly observed on the trunk and may disappear in 24 hours.

There is no report of agglutination of any of the X strains of *Proteus vulgaris* by serums from these patients.

Death or permanent sequelae do not occur as the result of trench fever.

The Spirochaetaceae are a family of the order Spirochaetales containing protozoon-like organisms which occur in the form of coarse flexuous spirals This family includes the genera *Spirochaeta*, *Saprospira*, and *Cristispira*

The genus *Spirochaeta* embraces slender, nonflagellated, wavy, nonpathogenic forms which inhabit sewage and foul water.

Several species of organisms which were formerly termed *Spirochaeta* have been transferred to other genera. Their names and their present classification follow *Spirochaeta carteri*, *Spirochaeta duttoni*, *Spirochaeta gallinarum* (*Borrelia anserina*), *Spirochaeta novyi*, *Spirochaeta obermeieri* (*Spirochaeta recurrentis*), *Spirochaeta refringens*, *Spirochaeta theileri* and *Spirochaeta vincentii*, retaining their original species names, are now with the genus *Borrelia;* for example, *Spirochaeta vincenti* is now *Borrelia vincenti* Likewise *Spirochaeta hebdomadis* and *Spirochaeta icterohaemorrhagiae* are now *Leptospira*, losing their spirochetal cognomen *Spirochaeta icteroides* is now *Leptospira interrogans*. Again, *Spirochaeta morsus muris* is now *Spirillum minus*. *Spirochaeta pallida* is now *Treponema pallidum*, and *Spirochaeta pertenuis* is *Treponema pertenue*.

The Treponemataceae are a family of the order Spirochaetales containing protozoonlike organisms which occur in the form of coarse or slender spirals The family includes both genera nonpathogenic to man and genera pathogenic to man.

Three genera which are pathogenic for man are (1) *Treponema*, of which *Treponema pallidum* is the cause of syphilis; *Treponema pertenue*, the cause of yaws; and *Treponema carateum*, the cause of pinta; (2) *Borrelia*, several species of which cause relapsing fever, and (3) *Leptospira*, several species of which cause spirochetal jaundice (Weil's disease)

Treponema pallidum is present in the blood in syphilis, especially during the primary and secondary stages, but is not detectable except by the inoculation of the testicles of rabbits with blood. This diagnostic method does not prove to be a practical diagnostic procedure. Spirochetemia occurs frequently and early in relapsing fever. For this reason examinations of fresh blood for the spirochetes by darkfield microscopy, or examinations of stained smears (preferred), as well as the inoculation of mice, are valuable diagnostic aids Likewise in rat-bite fever darkfield examinations of fresh blood may reveal the presence of *Spirillum minus* but since errors may occur due to artefacts, examinations of stained smears are preferred, although for diagnostic purposes they are inferior to intraperitoneal inoculation of mice or guinea pigs with blood, exudate or tissue removed from the primary lesion or material aspirated from lymph nodes Infection of the blood with the fusiform bacilli and spirochetes associated with Vincent's angina, gingivitis and gingivostomatitis (fusospirochetosis) is rare. Nevertheless, metastatic lesions occur and positive blood cultures, if made and cultivated under anaerobic methods, may be obtained

In leptospirosis of infectious jaundice (Weil's disease), *Leptospira icterohaemorrhagiae* can be found by darkfield examinations of the blood, but the procedure is not recommended for diagnostic purposes. Cultures of the blood are more valuable. However, most valuable for diagnosis is the inoculation of guinea pigs with infected blood and urine Serum agglutination tests are the most practical and reliable for diagnostic purposes, in all forms of the disease.

The Treponemas. The treponemas are extremely slender spiral rods which are motile by means of flexuous bending of the body

***Treponema pallidum* and Syphilis.** *Treponema pallidum* is actively motile, rotating on its long axis at a fairly constant speed This treponema is difficult to stain with the ordinary aniline dyes, but reduces silver nitrate to form a black surface deposit which permits its demonstration in tissues. It has been suggested that *Treponema pallidum* may have a cyclic development, in one phase of which it is present in a granular and microscopically invisible form, but this is probably a distortion of facts by protagonists of certain poorly conceived theories

IMMUNITY Immunity exists in a syphilitic patient, but it is never at any stage of the disease more than relative. It is doubtful that any degree of immunity is conferred by having had this disease. Intensive treatment of early syphilis with arsenic, mercury, iodides and such drugs may cure the patient if administered in adequate doses, but such treatment simultaneously abolishes all immunity which has developed The effects of penicillin treatment on immunity have not been determined. If antisyphilitic therapy is inadequate, the patient's natural defensive mechanism is seriously impaired. This means, as Chesney has stressed, that the patient is left both without cure and without defense, a situation often leading to neurorecurrences, therapy-resistant cutaneous relapses and precocious tertiarism A patient may be completely cured and yet remain refractory to natural reinfection Even in patients treated early, reinfection does not necessarily mean that the first infection has been completely eradicated, theoretically, at least, superinfection may have occurred because, as Moore pointed out, adequate methods of differentiating between the two are not available.

Urbach and Beerman stated that *immunity in syphilis is a special aspect of allergic* hypersensitiveness The entire course of syphilis may be explained on the basis of allergy The reaction of the organism to reinfection also suggests an allergic mechanism Chesney expressed the belief that the destructive character of tertiary lesions is due to hyperreacting defensive mechanisms of the patient toward the spirochetes, and thus *minimal numbers of spirochetes are capable of initiating tissue reaction and thus increasing* the injury by the infection Attempts to determine the presence of the allergic state, mechanism of the defensive reaction, existence of antibodies, the relationship of the positive serologic reaction to the organism's capacity to produce antibodies against spirochetes, and attempts to induce active or passive immunization against syphilis have failed

Agglutinins, precipitins and complement-fixing antibodies are present only in a sufficient concentration to combine with a lipid present in the tissue to give positive results of complement fixation and flocculation tests with aqueous suspensions of that lipid In ancient syphilitic infection these lipid antibodies often disappear from the serum but may still remain in the spinal fluid

The symptoms, the physical findings, and the diagnosis of syphilis of the various organs and systems are described in special sections of this text

THE CHANCRE The infection caused by *Treponema pallidum* is transmitted by intimate human contacts such as coitus That is, 9 of every 10 primary lesions are situated on the genitalia, while 1 of every 10 has an extragenital situation. All primary lesions are on mucous membranes or on the thin infolding skin about the genital orifices, for it is doubtful that the organism can penetrate the intact glabrous skin Extragenital lesions are usually on a lip, in the mouth, and rarely on a tonsil The incubation period for chancre development is from 10 to 90 days.

The hard chancre is the primary lesion of syphilis Its appearance depends on its stage of development and secondary infection which may be present A chancre commences as a reddened, nontender papule Four or five days later it is indurated. Induration progresses, but if there is no trauma or manifest secondary bacterial infection, erosion does not necessarily ensue However, almost always there are enough trauma and infection so that by the end of 2 or 3 weeks there is a circumscribed, round or oval, raised, eroded, moist, cyanotic, hard, indolent lesion surrounded *by an inflamed border The lesion bleeds easily on slight trauma* If the lesion is situated on the uterine cervix, profuse exsanguinating hemorrhages may occur.

Regional, and soon a generalized, lymph node enlargement ensue

In from 2 to 8 weeks the lesion heals If there has been no ulceration, a scar *is not present.* The usual ulcerating chancre heals with scar formation. The scar of a healed chancre may be of diagnostic importance for the rest of the life of the patient.

SECONDARY LESIONS. Two to 12 weeks after the appearance of the chancre a noticeable, generalized cutaneous rash often appears (secondary syphilis). This

stage of syphilis, characterized by a cutaneous eruption, may also involve the mucous membranes, eyes, osseous system, and the central nervous system. This so-called secondary syphilis results from a generalized dissemination of the organisms and their multiplication. The secondary lesions, as has been mentioned, indicate the development of antibodies and an allergic response to the products of infection.

The secondary lesions of the mucous membranes in syphilis occur on the buccal surfaces as grayish indistinct lesions The secondary macular cutaneous lesions appear on the palmar surfaces of the hands, on the wrists, and on the medial aspects of the knees and legs below the knees. The papular eruption is most commonly observed on the face, trunk, and abdomen These lesions are reddish brown. These have been described more fully in Chapter 8

More important here are the general symptoms consisting of lassitude, and pains through the body, more especially affecting the large bones near their joints. Headaches may be more severe at night than in the daytime The temperature may rise to 100 or 101 F (37 8 to 38.3 C) during the evening. In susceptible persons these symptoms may be severe enough to confine the patient to the bed.

The subsequent course of syphilis after the secondary stage depends on the particular tissue involved. The *Treponema pallidum* may involve almost any of the body tissues However, a syphilitic infection does not necessarily mean that generalized or localized disease will ever occur Twenty-five per cent of those who have syphilis recover spontaneously, another 25 per cent do not recover, but the disease remains without clinical manifestations. Of the remaining one half who have been infected with syphilis, an indefinite number are cured by adequate treatment. No percentage can be assigned to those who are cured by treatment In those left uncured by treatment, syphilis develops which becomes manifest. Some recover after inadequate treatment. There is left, then, an indefinite number in whom there develop complications varying in severity and prognosis. The less susceptible persons have benign gummas In the more susceptible, there develops serious disease of either the cardiovascular system or the central nervous system

Diagnosis of Syphilis The diagnosis is established by (1) clinical manifestations and observations, (2) the demonstration of *Treponema pallidum,* usually by darkfield examination of the exudate from an open or abraded primary or secondary lesion and (3) serologic changes in the blood and spinal fluid

The routine diagnostic employment of the darkfield examination is not practical for general use.

The serologic diagnosis of syphilis is based on the demonstration in the serum or in the spinal fluid of the lipid substance which combines to give positive complement fixation, and on flocculation tests In practice many complement fixation and flocculation tests of serum have been developed for the diagnosis of syphilis, all of which use as antigen suspensions of tissue lipids in an aqueous medium. In both the Wassermann and flocculation tests the degree of positivity may be expressed as the highest dilution of serum which gives a positive result Alternatively, in the Wassermann test it may be expressed as the amount of complement which can be fixed under standard conditions by a given amount of serum However, the reactions are reported from the laboratory as +− doubtful, + weakly positive, ++ and +++ moderately positive and ++++ strongly positive

The lipid substance demonstrated in the serum of syphilitic patients does not pass into the spinal fluid In patients who have syphilis of the central nervous system, the antibody apparently is elaborated locally and appears in the spinal fluid, sometimes in dilution titers exceeding that of the blood. A positive result of complement fixation or flocculation test in the spinal fluid is indicative of involvement of the central nervous system The Wassermann or flocculation titer of the fluid, associated with its cell content and protein content, and their response to antisyphilitic treatment, provide information of diagnostic and prognostic value

INTERPRETATION OF SEROLOGIC REACTIONS When diseases giving biologic nonspecific or falsely positive reactions are excluded, *positive serologic reactions* are almost invariably indicative of *syphilis, yaws, pinta or bejel.*

The incidence of positive reactions in the different stages of syphilis varies according to the sensitivity of the test or tests employed. The incidence in primary syphilis is about 75 per cent, in untreated secondary syphilis the incidence is 100 per cent; in early latent syphilis, late latent syphilis and cardiovascular syphilis about 85 per cent; in neurosyphilis about 95 per cent and in congenital syphilis 90 to 100 per cent It is much better to conduct the test 2 weeks after birth than to try to use cord blood for the test

The interpretation of *unexpectedly positive reactions*, especially when the tests are weakly positive or doubtful, or when one test gives a positive and another a negative reaction, or when the reactions fluctuate from positive or negative, or the reverse, may be difficult. If the patient is known to have syphilis, the results are to be regarded as positive If syphilis is not suspected clinically, the test is repeated one or more times In the meantime, to avoid iatrogenic syphilis the patient is not told of the serologic reaction. However, to disregard a positive reaction because it was unexpected is reprehensible

When doubtful reactions are recorded, the patient should not be informed of the results until a final conclusion is reached on the basis of history, physical examination and a repetition of the tests in the same and in another laboratory.

Falsely positive reactions due to errors in technic occur more frequently in flocculation tests than in complement fixation tests However, there are not more than 1 per cent falsely positive reactions, and these can be checked by repeating the serologic tests

A more important consideration concerns those biologic nonspecific or falsely positive reactions that may occur with the serums of normal persons. The serums of normal persons may contain reagin or reagin-like substances capable of giving falsely positive flocculation reactions

It is known that positive complement fixation and flocculation reactions often occur in cases of yaws, pinta and bejel, since these diseases are caused by spirochetes closely related to *Treponema pallidum*. Positive reactions may occur in the relapsing fevers, rat-bite fever due to *Spirillum minus* and the leptospiroses, but the incidence is variable

In leprosy of all types and in malaria falsely positive complement fixation and flocculation reactions may be observed

Positive serologic reactions are occasionally observed in vaccinia and vaccinoid, infectious mononucleosis, viral (atypical) pneumonia including viral pharyngitis and bronchitis, and other infections of the upper part of the respiratory tract. Positive reactions occur in trypanosomiasis and especially in Chagas' disease, lupus erythematosus, epidemic and murine typhus fever, subacute bacterial endocarditis or any febrile state

It is justifiable to suspect positive reactions as being false or nonspecific when *occurring in virgin girls or women with no history of what may have been an extragenital chancre* as well as, sometimes, in the case of boys or men who deny sexual exposure, also in patients thought to be truthful, and who in the past have had negative reactions and deny sexual exposure, likewise in married persons who, since marriage, have had one or more negative reactions preceding the positive one ... marital partners are found seronegative In a final analysis the conclu-

infectious mononucleosis, along with repeated serologic ...
tories and by different procedures, including quantitative tests over a period of at least 3 to 6 months. If persistently positive reactions are observed in the absence of

any of the foregoing enumerated conditions, it is advisable to regard chronic asymptomatic syphilis as present and to institute treatment for this disease. Examinations of spinal fluid are also helpful in the sense that positive reactions would be indicative of the presence of syphilis; negative reactions, however, would not exclude syphilis.

Positive serologic reactions may occur in well-treated syphilitic individuals after a period of negativity. These *serologic relapses* are interpreted in practice as indicative of renewed activity of persistent foci of infection or a reinfection and indicate the resumption of treatment in order to prevent clinical relapse or progression of the disease.

Seroresistance, Wassermann-fastness, is failure of the titer to fall satisfactorily after treatment, that is, persistently positive serologic reactions despite treatment It is present in late syphilis, in which the serologic reactions fluctuate back and forth from negative to positive.

Wassermann-fastness is encountered more frequently at present than when the Wassermann test alone was employed. The present complement fixation and flocculation tests are more sensitive. The consensus is to the effect that seroresistance is due to the production of reagin in persistent foci of syphilitic infection Relapses of symptoms are 4 times more frequent among seroresistant than among seronegative persons. Seroresistant persons often have infection of the central nervous system.

Falsely negative reactions can occur in late syphilis in both the latent and active stages. In late untreated primary syphilis, falsely negative reactions may occur, although they are almost invariably absent in untreated secondary syphilis. [illegible] may occur in serums of cases of cardiovascular [illegible] venile and acquired paresis. And while positive [illegible] with manifest lesions of syphilis, falsely negative reactions may occur in older children. The serologic tests frequently fail to give positive reactions in late congenital syphilis even in the presence of stigmas A negative reaction and even repeatedly negative reactions should not be permitted to influence clinical judgment

Examinations of Spinal Fluid The cerebrospinal fluid may give positive reactions in both acquired and congenital syphilis when the serum reacts negatively. Whenever late syphilis is suspected, it is generally advisable to conduct an examination of the cerebrospinal fluid in the diagnostic survey, including not only the complement fixation or flocculation tests but a total cell count, a test for increase of protein and a colloidal gold or mastic test. Syphilis cannot be regarded as cured on the basis of negative serologic reactions without 1 or 2 complete examinations of the cerebrospinal fluid

The spinal fluid in acute syphilitic meningitis has a pressure of from 150 to 300 mm of water. It is clear or opalescent and the cell count ranges up to 2,000 lymphocytes. The globulin is increased and there are 45 to 450 mg of protein per 100 ml. The concentration of sugar is from 18 to 75 mg per 100 ml. of spinal fluid The Wassermann reaction is positive in the spinal fluid in one half of the cases

In juvenile paresis the spinal fluid is under normal pressure and is clear, lymphocytes vary from 10 to 150, globulin is increased and there is a normal sugar content. The Wassermann test is positive and the gold curve is paretic (5555432000).

In adult general paresis the findings are, for practical purposes, the same as those present in juvenile paresis. These are zone one reactions

In tabes dorsalis the spinal fluid findings are the same as those of paresis except the gold curve is tabetic. Characteristically there is a second zone reaction (1123210000).

In syphilitic meningitis there is a third zone reaction (0001234530).

Premarital Examination for Syphilis Laws have now been enacted in some 30 or more states requiring for issuance of a marriage license a clinical examination and a laboratory test for syphilis and certification by the examining physi-

cian that the applicants for license do not have syphilis in a stage that is actually or potentially communicable.

The law is not intended to prevent permanently the marriage of persons who have syphilis, but only to delay the marriage of those who have communicable or potentially communicable syphilis until the disease has been rendered permanently noninfectious.

The examining physician performs the necessary examinations to determine whether the candidate for marriage has syphilis, and if so, whether the disease is in a stage or form that is or may become communicable. Whether the candidate for marriage has syphilis or not is obtained from the history and clinical examination and confirmed by serologic tests for syphilis.

A negative blood serologic reaction for syphilis does not rule out the possibility of syphilis The serologic changes in the blood may be negative in the presence of the early stage of a chancre. However, a single positive serologic reaction, unsupported by clinical evidence or history of syphilis, should not be interpreted as diagnostic of syphilis A positive reaction to a serologic test is not evidence of communicability of the disease The blood reaction may be and often is positive though the patient is permanently noninfectious.

If a candidate for marriage has syphilis, the physician is obligated to form an opinion as to whether or not the condition is actually or potentially communicable.

Syphilis presenting open lesions, or an early stage of the infection even though there are no open lesions, if untreated, must be considered potentially infectious. Candidates who have late syphilis are not likely to transmit the disease to a marital partner For purposes of certification for marriage, congenital syphilis in a candidate may be considered noncommunicable.

A candidate for marriage who has a seropositive blood reaction should have an examination of the spinal fluid If a candidate for marriage has neurosyphilis, the decision whether or not marriage should be permitted is a difficult one to make. A state law that requires postponement of marriage of persons who have communicable syphilis does not forbid marriage of a person who has incapacitating and eventually fatal syphilis if the disease in such a patient is noninfectious

Should both applicants have syphilis, they cannot infect each other, and therefore the disease is not communicable from one to the other The risk in such cases is not to the marriage partner but to their children if there should be any

A candidate who has syphilis in a stage that is or may become communicable but who has not had adequate treatment should ordinarily be required as a minimum to meet the standard required treatment for early and early latent syphilis

If a woman who has syphilis is permitted to marry, the physician must warn such a woman to place herself immediately under medical supervision and usually under treatment for syphilis, preferably with penicillin, if she becomes pregnant.

Some state laws provide that if one candidate for marriage is found to have syphilis, the proposed marital partner must be informed of this fact, after which the certificate may be issued and they may marry.

There are to be considered many factors such as stage and duration of the disease, age and sex of the candidate, amount, kind and method of treatment, so that consultation with a syphilologist may be advised.

Details of operation of the premarital examination laws now in effect in the *United States* illustrate the difficulties which are in many cases imposed on those who cross state lines in order to marry These difficulties arise chiefly from the lack of reciprocity in the acceptance (1) of laboratory reports from out-of-state laboratories and (2) of examination certificates signed by out-of-state physicians

it is performed and a notarized statement of the findings on examination is made, and a copy placed in the hands of the patient. The notarized statement should also be signed by the director of the laboratory performing the serologic test. The patient is informed however, prior to the examination, that such statements may not be acceptable by the state where the nuptials are to be performed.

Treponema pertenue and Yaws. Yaws is known also as pian, frambesia, and perangi.

Treponema pertenue is morphologically indistinguishable from *Treponema pallidum* and, as with *Treponema pallidum*, it is susceptible to trivalent arsenicals and penicillin.

There appears to be no congenital yaws The disease is not transmitted to the fetus through the placenta Mucous patches are uncommon in yaws The disease is not venereal, but is acquired by direct, extragenital contact, more than two thirds of the patients being infected before the age of 15 years. Tabes, paresis, and aortic insufficiency occurring in yaws are often difficult to attribute to yaws.

The disease is transmitted by the organism entering a cut or an abrasion in the skin. The role of flies as vectors has been suggested by Kumm, who found that a fly (*Hippelates pallipes*), widely distributed in the West Indies, fed in large numbers on the open ulcerative lesions, and that *Treponema pertenue* could then be found in the foregut or the stomach, where it remained viable for about 7 hours.

In man one attack of yaws may confer protection against a second attack Immunity develops slowly, thus reinoculation in the first 3 years of the infection may result in a modified attack, but most infected persons are refractory to reinfection after 10 years

There is considerable evidence that yaws confers a measure of protection against syphilitic infection There is some evidence also that syphilis may protect against yaws, or at least modify its clinical course

The primary and secondary cutaneous lesions of yaws are papillomas the tops of which soon become encrusted Necrosis, miliary abscesses and diminution of pigmentation may be observed Tertiary yaws presents no constant features by which the disease can be distinguished from syphilis on histopathologic examination

After examining a large amount of postmortem material Choisser expressed the belief that yaws produces lesions of the heart, liver, adrenal glands, pancreas and testes which are like those produced by syphilis He was able to diagnose the disease only by clinical history The lesions of bone in yaws compare with those of syphilis

Three to 4 weeks after exposure the initial lesion appears. Prior to the appearance of the initial lesion there may be experienced weakness, headaches, pains in the joints and arthralgias These symptoms attended by fever may persist for several weeks.

The primary lesion, the mother yaw, appears on an exposed surface of the body It is a painless and yellow-red papule surrounded by an erythematous zone. The papule increases in size, erodes and ulcerates, the dried exudate forming a dark crust

Six weeks to 3 months later, generalized secondary lesions develop which resemble the primary lesion These secondary lesions are attended by a more severe grade of general symptoms than those present with the mother yaw A localization of a secondary lesion in mucocutaneous junctions of the mouth, nose, or perineum originates a lesion which resembles a syphilitic condyloma Successive exacerbations of more of these same lesions may continue to appear for months to several years

The late sequelae of yaws generally affect the skin and bones. Gummatous nodules and deep, chronic ulcerations or crippling lesions of bones and joints may develop. A destructive ulcerative mutilation of the rhinopharynx (gangosa), a proliferative exostosis of the upper maxilla (goundou), and juxta-articular nodules may occur during the course of yaws

The findings on examination of a patient who has yaws depend on the stage the disease and on any or a combination of the many lesions present, all of whi *resemble those of syphilis.*

DIAGNOSIS. The diagnosis of yaws depends on the appearance of the lesior the history of exposure *in an endemic area, and the demonstration of the organisn* in early lesions either by direct darkfield examination or by contrast visualizatic with India ink or other staining methods

In patients who have yaws a positive response to Wassermann and flocculatic tests develops as regularly as in those who have syphilis.

Treponema carateum and Pinta. The disease pinta is called also mal de l pintos, carate, azul, boussarole or spotted sickness It has been erroneously terme Pinto's disease

Pardo-Castelló and Ferrer stressed the presence of atrophy of the epidermis in la lesions, the absence of pigment in the germinative layer, and the marked excess (pigment in the papillary layer of the corium They were able in all active stages t *demonstrate Treponema carateum in the malpighian layer of the epidermis.*

The incubation period of pinta varies from 5 to 12 months

The symptoms of pinta vary according to the stage of the disease. These stage are (1) the primary stage, (2) the secondary stage and (3) the tertiary stage.

Unlike syphilis and yaws general symptoms are not present in pinta.

On examination the initial lesion or the primary stage is a papule consisting c thickened and degenerated epidermis devoid of the normal amount of skin pigmen The papule is observed to slowly increase in size and in about 2 months it begins t appear reddened and covered with thin scales Smaller but similar lesions appea around the primary lesion These lesions itch At this stage of development th lesions may resemble those of lichen planus.

From 6 to 18 months or longer secondary lesions or pintids appear over bod and limbs These lesions are irregular in size and shape They may be ovoid and 1(*to 15 cm in diameter As time passes larger lesions are formed by the merger o* small ones The surface of the pintid is scaly and the base erythematous an hyperpigmented

The tertiary lesions of pinta are advanced secondary lesions characterized b more profound pigmentary changes. In the skins of lighter color a pink hue may be visible in the areas of depigmentation. Colors of a bluish tint may be observed Black pinta may be present in the skins of the colored races White pinta is observed in the lesions devoid of pigment White pinta represents the mature skin lesion of pinta These mature lesions are attended by atrophy of the skin These mature lesions are commonly present over the exposed extensor surfaces of the hands, arms and over the legs Less commonly do these lesions occur on the face and neck *Cuban pinta is characterized by lesions of the palms of the hands and* soles of the feet

Examination may reveal enlargement of the heart due to valvular lesions of which aortic insufficiency is common The aortic arch may be dilated as with syphilitic aortitis Aneurysms may ensue

Lesions of the central nervous system are uncommon.

Juxta-articular lesions may be present and resemble those of yaws The Charcot type of joint does attend pinta

Enlarged lymph nodes are present throughout the active stages of pinta.

DIAGNOSIS. The diagnosis is based on the appearance of the *cutaneous lesions.* The serologic reactions are not positive during the initial stage; they become positive only during the *early secondary stage in about two thirds of the cases,* and are positive in almost all cases in the late secondary stages

The *disease responds* to treatment with penicillin, arsenicals and bismuth as do yaws and syphilis.

The Borrelias. The borrelias cause a relapsing fever and are transmitted to man by bites of ticks of the genus *Ornithodoros* and the louse, *Pediculus humanus* var. *corporis*, the infection being caused by lice crushed on abraded skin.

***Borrelia recurrentis* and Relapsing Fever** (*Louse-Borne and Tick-Borne*). *Borrelia recurrentis* is a flexible spiral organism which takes the usual bacterial stains It is of widespread distribution. Louse-borne strains have been shown to be infective for argasid ticks, which can then transmit the disease to man; tick-borne strains have been similarly transferred to lice.

Infected ticks (*Ornithodoros turicata, Ornithodoros hermsi, Ornithodoros parkeri* and *Ornithodoros talaje*) have been found in Wyoming, Montana, Idaho, Texas, Oklahoma, Kansas, California, New Mexico, Colorado, Arizona, Utah, and Florida.

Agglutinins and other antibodies may be produced in high titer in the initial attack. However, the serologic activity may change in succeeding attacks The development of mutant strains not susceptible to the antibody previously elaborated may account for the relapse. After recovery from the disease takes place, immunity seems to be present from 3 to 5 years

PATHOLOGY Organisms are particularly numerous in the malpighian bodies of the spleen, which reveals miliary necrotic lesions Hemorrhagic lesions may be found in the gastrointestinal tract and in the kidneys

SYMPTOMS. The symptoms are the same, and are characterized by varying degrees of severity, in the African, Iranian, and American types of the disease. The illness begins with an acute febrile onset 3 to 10 days after inoculation by the louse or tick After 3 to 5 days the fever abates The afebrile period may last 3 to 10 days, and is followed by a second febrile attack during which organisms reappear in the blood, but in a smaller number. Three to 10 such recurring febrile attacks may occur A severe attack of relapsing fever may require weeks or months for convalescence. During convalescence neurologic complications may occur which consist of meningitis Other frequent complications are pneumonia, iritis, parotitis, abortion and retinal hemorrhages.

EXAMINATION On physical examination there are no characteristic findings except the fever During the initial febrile stage there may be large numbers of organisms in the blood, they may be found in the urine in approximately a fourth of the cases. After an average of 4 days the fever declines, coincident with the disappearance of organisms from the blood. As the organisms decrease in number, they become less motile, tend to assume bizarre forms and may agglutinate. During the afebrile period the blood is not infectious for lice

DIAGNOSIS The diagnosis is established by the demonstration of the organism in stained blood films, or by animal inoculation The mortality rate in the endemic infection varies between 2 and 5 per cent, but in epidemics it may be 50 per cent or higher.

***Borrelia vincenti* and Vincent's Angina.** Vincent's angina or infection, an ulcerative stomatitis, is present in association with a coarse, thick, gram-negative rod with tapered ends, the *Fusobacterium plauti-vincenti*, and *Borrelia vincentii*, acting in symbiosis There is no agreement as to whether these 2 organisms are the actual cause of the necrotic lesions, or only secondary invaders Thus Vincent's angina has been ascribed by some to a virus, and by others to a predisposing vitamin deficiency. Vincent's infection may be present in pulmonary disease—pulmonary spirochetosis

The disease is an ulceromembranous stomatitis Other than the presence of the stomatitis there are no characteristic features in Vincent's infection.

The Leptospiras. The leptospiras are characterized by minute elementary spirals running through the body, by the absence of flagella, and by great flexibility of the terminal portion of the organism

***Leptospira icterohaemorrhagiae* and Related Organisms.** *Leptospira icterohaemorrhagiae* is the cause of Weil's disease. *Leptospira grippo-typhosa* is

The findings on examination of a patient who has yaws depend on the stage of the disease and on any or a combination of the many lesions present, all of which resemble those of syphilis.

DIAGNOSIS. The diagnosis of yaws depends on the appearance of the lesions, the history of exposure in an endemic area, and the demonstration of the organisms in early lesions either by direct darkfield examination or by contrast visualization with India ink or other staining methods.

In patients who have yaws a positive response to Wassermann and flocculation tests develops as regularly as in those who have syphilis.

Treponema carateum and Pinta. The disease pinta is called also mal de los pintos, carate, azul, boussarole or spotted sickness. It has been erroneously termed Pinto's disease.

Pardo-Castelló and Ferrer stressed the presence of atrophy of the epidermis in late lesions, the absence of pigment in the germinative layer, and the marked excess of pigment in the papillary layer of the corium They were able in all active stages to demonstrate *Treponema carateum* in the malpighian layer of the epidermis.

The incubation period of pinta varies from 5 to 12 months.

The symptoms of pinta vary according to the stage of the disease. These stages are. (1) the primary stage, (2) the secondary stage and (3) the tertiary stage

Unlike syphilis and yaws general symptoms are not present in pinta.

On examination the initial lesion or the primary stage is a papule consisting of thickened and degenerated epidermis devoid of the normal amount of skin pigment The papule is observed to slowly increase in size and in about 2 months it begins to appear reddened and covered with thin scales Smaller but similar lesions appear around the primary lesion These lesions itch At this stage of development the lesions may resemble those of lichen planus

From 6 to 18 months or longer secondary lesions or pintids appear over body and limbs These lesions are irregular in size and shape They may be ovoid and 10 to 15 cm. in diameter. As time passes larger lesions are formed by the merger of small ones The surface of the pintid is scaly and the base erythematous and hyperpigmented.

The tertiary lesions of pinta are advanced secondary lesions characterized by more profound pigmentary changes In the skins of lighter color a pink hue may be visible in the areas of depigmentation Colors of a bluish tint may be observed Black pinta may be present in the skins of the colored races White pinta is observed in the lesions devoid of pigment White pinta represents the mature skin lesion of pinta. These mature lesions are attended by atrophy of the skin These mature lesions are commonly present over the exposed extensor surfaces of the hands, arms and over the legs. Less commonly do these lesions occur on the face and neck. Cuban pinta is characterized by lesions of the palms of the hands and soles of the feet

Examination may reveal enlargement of the heart due to valvular lesions of which aortic insufficiency is common The aortic arch may be dilated as with syphilitic aortitis. Aneurysms may ensue.

Lesions of the central nervous system are uncommon

Juxta-articular lesions may be present and resemble those of yaws The Charcot type of joint does attend pinta.

Enlarged lymph nodes are present throughout the active stages of pinta

DIAGNOSIS The diagnosis is based on the appearance of the cutaneous *lesions.* The serologic reactions are not positive during the initial stage; they become positive only during the early secondary stage in about two thirds of the cases, and are *positive in almost* all cases in the late secondary stages

The disease responds to treatment with penicillin, arsenicals and bismuth as *do* yaws and syphilis.

blood, their abundant excretion in the urine, and complete development of antibodies in the blood.

Mud Fever or Field Fever. Mud fever or field fever is caused by *Leptospira grippo-typhosa* and is carried by field mice. The infection in these animals is an intense one. Mud fever or field fever is less endemic than Weil's disease, and appears in short epidemics in summer or autumn when there is more chance of exposure to the foul water of swamps. The symptoms are those of a mild form of Weil's disease.

THE BARTONELLACEAE

The genus *Bartonella* of the family Bartonellaceae includes the species *Bartonella bacilliformis* which is infectious to man

Bartonellosis. *Bartonella bacilliformis* is a gram-negative, flagellated organism which stains a distinct red-violet with Wright's or Giemsa's fluid It is very polymorphous, and the maximal morphologic range is seen in the blood of man

The microorganism is transmitted by one or probably several species of *Phlebotomus* or sandfly indigenous to an endemic region It is not transmitted by contact

Bartonellosis is limited to northwestern South America, between latitudes 2 degrees N. and 13 degrees S, at altitudes less than 8,000 feet and more than 2,500 feet Transmission occurs by means of the night-flying and night-feeding *Phlebotomus verrucarum* (see Insects, Chapter 20)

The infection exhibits 2 successive clinical manifestations, of which the second, *verruga,* coincides with, and seems to be an expression of, immunity toward the first form, *Oroya fever* A patient who has had Oroya fever and who then has had verruga and has recovered is immune to further exposures

Oroya Fever (*Carrión's Disease*) The bartonellas in Oroya fever are present within the cytoplasm of cells lining the blood capillaries and the lymph capillaries Infected cells are present in lymph nodes, liver, spleen, bone marrow, kidneys, adrenals, and pancreas, and occasionally in the skin, heart and lungs

Verruga peruana is the nodular cutaneous eruptive stage of Carrión's disease, which differs much from Oroya fever in its clinical manifestations

The incubation period of Oroya fever is from 3 to 15 weeks The symptoms commence with malaise, anorexia and apathy followed by irregular fever and pain The pain is worse at night and disturbs sleep It is situated in the back and extremities. During the period of the fever in the ensuing months there are loss of weight and extreme exhaustion

On examination during the febrile stage of the disease there are extreme paleness and increase of the pulse rate and of the respiration. The superficial lymph nodes are enlarged Usually the liver is palpable, but not the spleen There may be an increase of tendon and superficial reflexes, hemiplegia, facial paralysis, amblyopia, hemianopsia and amaurosis. These are ascribed to vascular lesions of the brain Meningeal findings are common, consisting of meningism, Kernig's sign, headache and persistent vomiting There may be increased pressure of the cerebrospinal fluid and an excess of albumin and of cells in the fluid Frequently bartonellas are not present in the fluid.

The *verruga peruana stage* of Oroya fever is characterized by a nodular cutaneous eruption which usually develops during the period of convalescence. These small warty lesions appear on the face and the extremities, enlarge and become bleeding warty tumors which persist from 1 month to 2 years The eruptive lesions may be small (miliary), of moderate size (nodular), or larger and fungating (mular)

The lesions appear in successive exacerbations They are small (millimeters in size) and nodular, erythematous, and have a smooth, glistening surface. The lesions increase in size, some of them attaining a diameter of 1 cm. The lesions appear sym-

the cause of the disease known in Eastern Europe as mud fever, swamp fever and field fever, and for which field mice seem to be the natural vectors. *Leptospira hebdomadis* in Japan is the causative agent of a disease known as seven-day fever.

Leptospira can penetrate through the intact skin and mucous membranes as well as through these tissues after injury. Usually infection follows contact of the abraded or sodden skin with infected mud or water, but it may follow strangulation by water after one falls into a stream, or the bites of rats, dogs or ferrets. Infection in the United States of America occurs most commonly from contamination of a wound or food with the blood or urine of an infected animal. Mechanical transmission of the infection may occur, as illustrated by the bite of a dog or a ferret that has previously killed a rat Contact with infected dogs or pigs may transmit the disease.

Many human leptospiral infections originate from water or moist objects contaminated with infected urine from rats or dogs.

Weil's Disease. Weil's disease is the commonest form of leptospirosis in the United States of America Human infection occurs from the ingestion of food, and especially of water, contaminated by the urine of infected rats, or from the bite of rats The incubation period is from 6 to 12 days

The progress of the infection is characterized by stages. The first, febrile or septicemic, stage is manifested by chills, fever, headache, generalized muscle aching and pains, anorexia, vomiting, and prostration The fever reaches 102 F (38 9 C) or higher. There may be a lobular type of pneumonia Hemorrhagic herpes may be observed One definitely characteristic manifestation in association with the other symptoms is the presence of a severe conjunctivitis.

During this stage there are spirochetes in the peripheral blood but none in the urine. The leukocyte count varies from 10,000 to 25,000 per cubic millimeter of blood.

On the fifth to the sixth day the temperature recedes to normal limits and then jaundice is in evidence

The second stage of the disease begins on about the fifth or sixth day with the appearance of the jaundice if this occurs By no means do all of those who have Weil's disease have jaundice In those who have jaundice, petechiae, purpura and nosebleed are in evidence. Renal failure may occur in this stage of the disease as the result of a hemorrhagic nephritis In those who manifest failure of renal functional activity with increased concentrations of blood urea and bloody urine a diuresis often initiates the convalescence at about the end of the second week of the disease.

Relapses after recovery occur in many of the cases but are not serious. Meningitis may occur as a complication or independently as a meningitis leptospirosa A most severe leptospiral vegetative endocarditis may follow Weil's disease.

Serious complications of Weil's disease arise in the eyes. They consist of iridocyclitis, optic neuritis and blindness.

The diagnosis during the first 5 to 7 days depends on finding the leptospira in the blood of the patient The most convenient method demonstrating the leptospira is by means of intraperitoneal injection of guinea pigs from which a severe infection ensues; the leptospira can easily be demonstrated in the guinea pigs. In those who do not have jaundice, most commonly the disease goes unobserved by the patient or is not considered as anything that is of a serious nature Specific antibodies begin to appear about the fourteenth day By the end of the third week high agglutinins and lysin titers are demonstrable By the end of the third week the titer is frequently more than 1:10,000. Agglutination in a dilution of 1:300 is considered diagnostic of Weil's disease. This reaction is highly specific The third, or convalescent, stage is characterized by the disappearance of spirochetes from the

Malaria is a disease of the lowlands. It is called also paludism, intermittent fever, chills and fever, Roman fever, Chagres fever, marsh fever, tropical fever, coastal fever and ague. In current use are the English term malaria and the Spanish, paludismo. The malarial parasites of man belong to a class of endoparasites, the Sporozoa, which reproduce by sporulation and have no organs of locomotion. The class includes the following orders: the Gregarinae, the Coccidia, the Hemosporidia, the Sarcospiridia, the Microsporidia, and the Myxosporidia All of these form spores at some stage in their life cycle and are widely distributed in both vertebrates and invertebrates. Of the orders of Sporozoa the Hemosporidia contains the human parasites which are the cause of malaria The malarial parasites belong to the genus *Plasmodium* of the family Plasmodidae.

Four species of *Plasmodium* are parasites of man: *Plasmodium vivax*, the cause of tertian malaria; *Plasmodium malariae*, of quartan malaria; *Plasmodium falciparum*, of estivo-autumnal malaria; and the less known *Plasmodium ovale*, which produces also a tertian form of the disease

The term mixed infection refers to the coincidence of two or more species in the same patient. Mixed infections with *Plasmodium vivax* and *Plasmodium falciparum* are the commonest, next *Plasmodium falciparum* and *Plasmodium malariae*, and least frequent *Plasmodium vivax* and *Plasmodium malariae*. All three species have been reported in the same individual In mixed infections the species appear antagonistic, in patients who have general paresis, inoculated with *Plasmodium vivax* and *Plasmodium falciparum*, one species predominates Masked mixed infections are common In such instances, although only one parasite may be seen in the blood smear, the other may be transmitted by inoculation.

Infection may so arise that one generation of parasites may mature 24 hours before another, resulting in quotidian or daily chills or febrile attacks. Thus a double tertian infection may result with *Plasmodium vivax* and *Plasmodium falciparum* and double or even triple infections with *Plasmodium malariae* The quotidian type of infection may be present in the initial attack, but it tends to return to the tertian or quartan form in recurrent attacks through the decline of the supernumerary group of parasites.

Plasmodium vivax has a world-wide distribution in coastal regions extending from latitude 60 degrees N to latitude 30 degrees S It is the prevailing species in the temperate zones.

Plasmodium malariae is rare in most countries, though it is frequently found in eastern Asia and it has been reported in Mediterranean Europe, southern Asia, Africa, the Philippine Islands, New Guinea, the West Indies, Brazil, Panama and in the southern part of the United States of America

Plasmodium falciparum is commonly limited to subtropical and tropical regions. It is the prevailing species in most tropical countries, and is common in southern Europe. It is present only in the extreme southern portion of the United States of America

The distribution of *Plasmodium ovale* is unknown

The malarial parasites of man are host specific They pass their life cycle in man and an anopheline mosquito The cycle in man is known as schizogony (splitting up of the parasite); that in the mosquito is a phase of sporulation (sporogony).

The bite of an infected mosquito introduces the *sporozoites* into the skin. Eventually the parasites gain access to the erythrocytes. Inside of the erythrocyte the sporozoite develops into a ringlike *trophozoite* and undergoes schizogony Schizogony includes the development of the *schizont* and the division into *merozoites* The enlarging merozoites rupture the cell and are liberated They then penetrate other red blood cells and repeat the cycle. Succeeding generations of merozoites originate trophozoites and become sexually differentiated into *microgametocytes* (male) and *macrogametocytes* (female). This sexual differentiation is in preparation for the sexual cycle in the mosquito.

The morphologic changes of the several species vary, in the peripheral blood, in

metrically on the extensor surfaces of the lower part of the legs, on the forearms, or on the face In some instances the eruption may be present on the trunk, the genitalia, the scalp, the palms or the soles. The eruptions may be localized or general, discrete or confluent. The fully developed lesion remains unchanged in appearance for a long time and then spontaneous regression ensues Pigmented spots may persist for a time after disappearance of the lesions, but scarring does not result.

Bartonella bacilliformis is rarely found in blood before anemia has developed from heavy parasitization and destruction of the erythrocytes. The parasites will be found in normocytes, microcytes, macrocytes, reticulocytes, and normoblasts Disappearance of the visible infection usually coincides with cessation of blood destruction The serum bilirubin is increased, owing to destruction of blood Cultures of blood may be positive after the disappearance of visible parasitemia; visible parasitemia can recur

The diagnosis of Oroya fever requires demonstration of the presence of *Bartonella bacilliformis* in the blood of the patient who has Oroya fever or from the lesion in the verruga stage of the disease. The organism may be found in blood films from a few days after infection until the beginning of convalescence It can be isolated in blood cultures even after the visible infection has disappeared.

The possibility of Oroya fever is considered in a patient who has an acute febrile illness and who, during the 3 months prior to onset of the illness, has been to the regions in South America where the organism of this disease exists.

The mortality rate is more than 50 per cent of those who have severe infection or infection complicated by malaria or other infection. Death occurs in from 10 to 30 days after onset of the illness

STREPTOBACILLUS MONILIFORMIS

Among synonyms for *Streptobacillus moniliformis* are *Streptothrix muris ratti, Haverhillia multiformis, Asterococcus muris, Actinomyces muris ratti* and others

In human beings introduction of the organism into the skin or into the alimentary tract results in invasion of the blood stream with subsequent localization in various parts of the body, and frequently in the joints. In fatal instances ulcerative endocarditis or myocardial abscesses are the causative lesions

There are no characteristic symptoms or even physical signs of infections by *Streptobacillus moniliformis* One syndrome caused by this microorganism is known as Haverhill fever

Haverhill Fever. Haverhill fever begins within a few days after ingestion of infected milk. The onset is with an irregular fever which persists for weeks or months. With the onset of the fever there is a diffused erythematous macular eruption over the extremities, followed by a generalized arthralgia. Often a generalized arthritis ensues.

The diagnosis is made by isolation of the specific organism from the blood. Agglutinins appear in the blood about 10 days after the onset of the infection. Penicillin is a good therapeutic agent.

In all other instances of infection by *Streptobacillus moniliformis* the sickness often follows a rat bite by less than 10 days. There is an irregular and often a relapsing fever. At the beginning of the fever there is often a petechial type of skin eruption, and polyarthritis and leukocytosis are present This syndrome following the bite of a rodent by less than 10 days is highly suggestive.

The diagnosis cannot be made on the basis of clinical symptoms or findings. It is established by demonstration of the organism in cultures of the blood and joint fluid on the special mediums, by mouse inoculation, and by specific agglutination. An agglutinin titer of 1:80 or higher is considered specific for infection with this organism.

engorged with blood and the tubules are obstructed by deposits of hemoglobin and albumin.

The incubation period may be shortened by multiple exposures and lack of resistance, or it may be prolonged; duration of nearly a year has been observed in experimental infections with *Plasmodium vivax*. In the temperate zones tertian infection acquired in the summer or autumn may not cause a chill until the following spring.

SYMPTOMS The symptoms of malaria tend to progress from an acute to a chronic form as the disease progresses The severity and persistence depend on the species and strain of the plasmodium, the resistance of the patient, and the environment. The pernicious type is almost always caused by *Plasmodium falciparum*

The chill often has no recognizable prodromal symptoms When such symptoms are present, they comprise feelings of lassitude, lack of appetite, and deep aching but not severe pains in bones and limbs, and a slight fever. Characteristically each type of malaria is manifested by chills and fever which recur at definite intervals of from 24 to 72 hours.

In tertian malaria (*Plasmodium vivax* and *Plasmodium ovale*) the chills and fever come on alternate days (48 hours). In quartan malaria (*Plasmodium malariae*) the chills and fever occur each third day (72 hours). In malignant tertian malaria (*Plasmodium falciparum*) the chills may come daily or recur on alternate days; the course of this infection is often irregular. In multiple infections fever may recur at irregular intervals; for instance, daily in double tertian infections In low-grade infections and in chronic inadequately treated infections, chills may come at irregularly spaced intervals of days or weeks

In districts where the so-called benign tertian malaria is rampant in the latter part of September and October, at the onset of the malarial season, *the malarial chill is definitely characteristic* The chill usually occurs during the morning hours between 10 A.M and 12 M. The patient, having been active and well during the early morn- [illegible] photophobia. [illegible] rease to sharp [illegible] the hot sunlight increases the intensity of the chill. Soon there is headache, and often severe lumbar backache and deep pains in the thighs ensue. At this period during the chill the temperature reaches its maximum, and perhaps this is one reason for the patient retiring to the shade as soon as the chill commences The chill lasts from 5 minutes to half an hour Toward the end of the chill, sweating begins and lasts from half an hour to an hour and a half After the first few chills the patient often resumes work toward the midafternoon. On returning to work there is a degree of weakness and fatigue The following day there may be no more than a slight amount of weakness. Two days later the chill is often repeated, and so on until adequate treatment is administered, but often the chills cease spontaneously.

In the more severe chills the patient takes to his bed and covers himself with all available quilts or blankets He lies with the knees drawn up to the chest. At first there is shivering which may be superseded by shaking The shaking may be so violent that speaking is difficult or impossible During this stage children often have convulsions

During this stage the face is pale and the nailbeds and lips may be cyanotic. Soon the pale skin becomes flushed and sweating ensues The chill (cold), flushed skin (hot) and the sweating stages all last 4 or more hours

The severity of the chill and fever depends not only on whether it is an initial outbreak or a relapse, but also on the toxicity of the species, the number of parasites in the blood, and particularly, with *Plasmodium vivax*, on the number of generations.

The fever of the tertian and quartan types consists of a series of high elevations of temperature of short duration Temperatures higher than 105 F (40.5 C) are

their effect on the erythrocytes, and in their schizogonic cycle. They differ in incubational periods and in the pathologic reactions of the host. They also vary in ability to develop in different species of anopheline mosquitoes Different specie: show variable reactions to stains

EPIDEMIOLOGY Epidemiologically, malaria is a cosmopolitan disease. It will with any other known disease as a producer of suffering and disability and as a or an indirect cause of death. It is the most important parasitic disease of man be it lowers the health, vitality and physical development of a people; retards intelle social and national progress, reduces economic efficiency, renders useless exte territorial areas and often spreads over such vast areas of lowlands as to mak efforts of public health agencies disappointing.

The conditions that determine the distribution and prevalence of malaria deper the number of human carriers serving as sources of infection, the presence of anopl mosquitoes capable of transmitting the infection, the awareness of the danger mosquito bites, and the economic condition of the susceptible population

IMMUNITY There is some variation in individual susceptibility and resistan malarial infection The susceptibilities and resistances seem to depend somewhat on sex, occupation, and the degree of inherent and acquired immunity. Adults are resistant than children A few persons possess an innate immunity and remain fr the disease even in highly endemic areas. Differences in susceptibility have beer served in Negroes and whites Adult Negroes as well as Negro children from nonma districts show greater resistance than white children.

There is a concomitant immunity which seems to resist a new infection by the type of parasite. There is some residual immunity after the eradication of the par

There is a seasonal variation in the morbidity of malarial infection. For inst *Plasmodium vivax* infections are commoner in the spring and fall and *Plasmo falciparum* infections in the fall These seasonal outbreaks are associated with periodic prevalence of mosquitoes and with clinical relapses

PATHOLOGY The pathologic changes of chronic malaria are characterized by mentation of the cerebral cortex and kidneys, anemia, enlargement and fibrosis of spleen, and enlargement of the liver Capillary thrombosis, hyperemia, hemorrh emboli and pigmentation may be present in many organs which are not other seriously affected The discoloration of tissue is due to the deposition of degrada products of the hemolyzed blood and malarial pigment which occurs free as well a the parasites and phagocytic cells. Malarial pigment is believed to be closely relate hematin, although some investigators claim that it resembles melanin Malarial para commonly cause hemolytic anemia

The *brain* shows increased pigmentation of the capillary endothelium and reg of softening resulting from occlusion of the cerebral capillaries by thrombotic ma of free pigment, pigmented plasmodia (usually the sporulating forms of *Plasmod falciparum*), infected erythrocytes and phagocytes Numerous small hemorrhages produced by the rupture of the distended capillaries In prolonged cases foci of infl mation with proliferation of neuroglia cells, probably of toxic origin, may be pres

In early infections the *spleen* is soft, moderately enlarged, distended with blood, susceptible to rupture In chronic infections the spleen is enlarged, has a firm consiste from hyperplasia of the connective tissues, and is colored slate gray to chocolate pigment in the capillaries and sinusoids Hemorrhagic regions are frequent and schizo are abundant.

The *liver* is moderately enlarged and in chronic malarial infections is firm in text Its color varies from normal to chocolate brown or dark gray Pigment, parasiti erythrocytes, and phagocytic endothelial cells (Kupffer's cells) containing pigments a parasites may be observed. Characteristically there is a focal necrosis with the malar parasites embolic in the capillaries Cloudy swelling, infiltration with fat, and fa degeneration are present.

The *kidneys* are often congested and hemorrhagic owing to the rupture of thro botic capillaries. If death has resulted from the renal involvement, there is an act hemorrhagic glomerulonephritis as the result of embolic blocking of the capillaries the glomerular tufts In chronic disease there may be a secondary contraction of t kidney. The tubular epithelium may be pigmented In blackwater fever the kidneys a

Eosinophils decrease during the febrile attacks and increase in the afebrile intervals, producing a mild eosinophilia during convalescence.

In searching for the malarial parasites of uncomplicated malaria it is well to recall that at the onset of the fever, just prior to the chill and during the course of the chill, the mature schizonts predominate in the peripheral blood in the tertian and quartan types, but are present only in severe infections of the malignant tertian type, in which segmentation takes place almost entirely in the internal organs. At the height of the fever the merozoites predominate in the blood. During the sweating stage most of the parasites have entered the blood cells to complete their development in the subsequent afebrile period.

Diagnosis The presence of malarial parasites in the peripheral blood is diagnostic. If the patient has been under treatment, finding the parasite may not be possible. Repeated examinations of thick films, however, will usually reveal the organisms, especially the resistant gametocytes

The important diagnostic symptom in active infections is an intermittent fever which has been characterized by relapses, in a patient who has had the opportunity to acquire the disease; a fever that does not respond to the administration of quinine or atabrine is not of malarial origin. In latent infections there is a history of relapses following provocative stimulants such as digestive upsets, getting wet and chilled, hot baths, strenuous exercise, purging, alcohol, injections of nonspecific foreign protein, and epinephrine.

Group-specific reactions (precipitins and complement-fixing antibodies) yield vari [illegible]
stan [illegible]

patients are not of diagnostic value for a high percentage of positive reactions are obtained in syphilis, tuberculosis, leptospiroses, leukemia, eclampsia, hepatic diseases, carcinoma, and diseases causing disturbed equilibrium of the serum proteins.

Malaria is a self-limiting disease unless repeated infections occur. *Plasmodium falciparum* infections usually disappear in 1 to 2 years, and *Plasmodium vivax* infections in 4 to 5 years, *Plasmodium malariae* infections persist up to 5 years. Prognosis is favorable in acute *Plasmodium vivax* and *Plasmodium malariae* infections, even without treatment It is grave in *Plasmodium falciparum* infections in which a pernicious type often develops unless adequate early treatment is instituted Chronic malaria in patients who are poorly nourished or weakened by other diseases may terminate fatally.

Complications of Malaria The cerebral type of malaria is serious when caused by any type of infection. Cerebral malaria is manifested by apathy and coma Often there are meningitic or encephalitic delirium, psychic disturbances, paralysis and convulsive seizures Generalized infection may produce hyperpyrexia (temperature of more than 105 F or 40 5 C), headache, delirium, symptoms simulating sunstroke, and hemorrhages in the internal organs. When both the circulatory and nervous systems are involved, the disease may assume the algid form of malaria. In the algid form there is a rapid loss of strength, with cardiac weakness, chilly sensations, perhaps low temperature (97 F, 36 C), and finally collapse and death Dysenteric or choleric symptoms may result from necrosis of the intestinal mucosa but this is usually a terminal event

Blackwater fever occurs most frequently in men and is commonest in tropical countries where malignant tertian malaria is prevalent. Its cause is unknown, but it may be due to an inherent or induced hemolytic tendency associated with hypersensitiveness to, or with inadequate amounts of, quinine. In many instances of blackwater fever the treatment has been inadequate.

Blackwater fever is a frequent complication in malignant tertian malaria During the course of this complication cardiac dilatation, gastroenteritis, hepatitis with

frequent. The tertian fever lasts for 8 to 12 or even 16 hours, the quartan for 10 hours, and the malignant tertian, which has a slower rise and is more prolor for 16 to 18 or even 36 hours. At its climax the febrile curve of *Plasmodium fa arum* infection shows a plateau with minor oscillations that are often mist for an irregular quotidian (daily) infection, and the decline may be interru by one or more sharp peaks. In some cases an irregular fever may persist for we

A latent period of about 3 weeks follows the initial series of intermittent fe attacks and in turn is followed by characteristic relapses, which may recur ov period of years The tendency to relapse is most marked in *Plasmodium mala* infections and least marked in *Plasmodium falciparum*. As the disease progresses latent periods become longer and the relapses fewer.

Relapses are influenced by seasonal changes and climatic variations. Provoca factors that lower resistance, such as exhaustion, diet, alcohol, muscular exert sexual excesses, injuries, exposure to cold, and intercurrent diseases, favor recur attacks Clinically a relapse resembles a primary attack and is difficult to different from reinfection It may be that remissions and relapses are due to the contin presence of small numbers of parasites, the curtailment of asexual development, production of resistant forms, and the retention of the parasites in the tissue c

Plasmodium falciparum frequently causes a pernicious and often fatal form malaria. Malaria of such severity is rarely observed in tertian and quartan infectio

In the natural course of tertian malaria the acute symptoms gradually subs latency develops, and eventually most patients become entirely free of the infecti Infections with *Plasmodium falciparum* either increase in severity or gradually prove, whereas with *Plasmodium vivax* and *Plasmodium malariae* spontaneous missions occur only after frequent relapses.

Chronic tertian malaria, as has been stated, is usually benign, but because reinfections or relapses may become a serious and debilitating disease All degr of clinical manifestations may occur. Persons who do not have clinical sympto may harbor the gametocytes in their blood and so constitute important sources infection Children, who are more susceptible than adults, may show severe sym toms, including fever with or without chills; lethargy and convulsions in the ac stage, and anemia, apathy, debility and splenic enlargement in the chronic stage

In *Plasmodium falciparum* infections, gastrointestinal symptoms consisting nausea, bilious vomiting, diarrhea, abdominal pains and perhaps jaundice may present The abdominal pain may be severe enough to simulate that of an ac biliary obstruction by a gallstone or acute appendicitis or salpingitis When a h fever and bloody dysentery are present the condition may simulate that of an ilei amebic dysentery, bacillary dysentery or acute exacerbation of a chronic ulcerat colitis. Typhoid fever and various rickettsial infections may be simulated by t high fever, headache and delirium.

EXAMINATION. The significant finding on examination of a patient suspected having malaria is the presence of an enlarged spleen The definitely ill malar patient has intermittent fever In the presence of cerebral malaria, signs of encep alitis are present such as apathy, stupor and coma. In some the neck is stiff Vario degrees of heart affections are evidence of cardiac involvement A hemorrha nephritis may be encountered if the kidneys are heavily laden with parasites. In blac water fever the first sign of diagnostic value may be the passage of blood or da urine.

The erythrocytes are reduced in number. They are abnormally resistant to hyp tonic sodium chloride solutions and in severe infections tend to auto-agglomera

jaundice, albuminuria and nephritis, and rupture of the spleen may occur. The onset of symptoms is sudden, with the passage of dark urine The symptoms may advance rapidly with severe hemoglobinuria, jaundice and rapidly developing anemia. In severe forms of the disease impaired renal function may produce uremia.

Those who have been infected with *Plasmodium vivax* may exhibit clinical signs and symptoms of active malaria within several weeks or months after administration of quinine has been stopped. The *temperature, which is elevated slightly at the* onset, rises gradually or abruptly within a few days to 103 or 104 F (39.4 or 40 C) or it may be completely irregular or of a septic remittent type. Severe shaking chills, which are so characteristic of relapses, may be absent during the first few days of the delayed primary attack despite high fever. Often confusing is the fact that one or two routine smears made early may be negative for malarial parasites. When parasites do appear they may be present in relatively small numbers, in contrast to a relapse

The leukocyte count is usually low, and if the spleen is palpable, one may think of typhoid fever or some other bacterial infection of the blood stream.

In some instances, after suppressive medication has been discontinued, attacks of vivax *malaria may ensue which are manifested by gastrointestinal symptoms.* Nausea, vomiting and abdominal pain and tenderness are common, usually follow the paroxysm, and are rarely of such intensity as to confuse the diagnosis of malaria.

In a small number of cases, however, the abdominal symptoms and signs may precede the paroxysm by a day or two and be of such severity as to suggest a primary acute abdominal condition, particularly acute appendicitis, intestinal obstruction or acute cholecystitis.

Occasionally protracted low-grade malarial activity in some persons who have good immunity may be manifested by slight to moderate anemia, slight icterus, and enlargement of the liver or the spleen or of both Inadequate treatment of frequently occurring mild attacks may also produce the same findings Either there is no fever or, if present, it is low grade Parasites are almost always present in the circulating blood, but their density may be very low

Physicians who have had experience with malarial infections in the tropics have referred to "malaria sensitization and malaria asthma." Urticaria of varying severity may precede or accompany an acute attack of vivax malaria.

It is presumed that these patients have been sensitized by the plasmodia or their products and that, when the former are present in sufficient number to exceed the amount of antibody present, urticaria or some other allergic manifestation follows Urticaria may precede attacks of vivax malaria, and if blood smears are examined, the diagnosis can be made early and time-consuming studies of allergy dispensed with.

Respiratory symptoms in the upper part of the tract, especially during winter months, are common in chronic vivax malaria. Likewise, thoracic pain and rales are not uncommon during an attack These findings in a patient who has a chill and a high fever may suggest pneumonia. Roentgenograms of the thorax do not reveal anything abnormal, and smears will contain parasites, establishing the diagnosis of vivax malaria. In malaria the elevation of temperature is not sustained beyond a few hours after the chill, and the accompanying symptoms, negative roentgenogram, and blood smear positive for parasites should simplify diagnosis if both malaria and pneumonia are considered.

Rupture of the spleen is a most serious and fortunately a rare complication of malaria. The symptoms and signs are so dramatic and the abdominal findings such that the diagnosis is usually made.

Often it has been observed that trauma, general anesthesia or surgical operation may induce a relapse of vivax malaria. Such relapse may occur years after all

infections. The parasite is one cause for the endemic blindness in the Anglo-Egyptian Sudan.

Examination. In the African disease the nodules may appear on the trunk, thighs and arms, and in the Central American disease, on the scalp and head. The number of nodules varies from 1 to 6, however, many may be found.

The disease may involve the skin without the formation of nodules. The tumors are late manifestations of the disease. In the French Sudan the chronic cutaneous manifestations take the form of xeroderma, lichenification, achromia, atrophy and a pseudo-ichthyosis with thick, wrinkled skin. In the American disease there is sometimes a myxedematous-like thickening of the skin over the cheeks and forehead with a bluish pigmentation known as erisipela de la costa.

Ocular involvement frequently is observed when nodules are present on the head. Iridocyclitis with perikeratic injections and a contracted, sometimes irregular, pupil develops. The iris is thickened, altered in color and is sometimes covered with an exudate. It finally becomes adherent by a ring of synechiae to the anterior surface of the lens capsule and undergoes radiate atrophy. A variable punctate keratitis, corneal infiltration with small nests of leukocytes and monocytes, and superficial and deep vascularization of the cornea are present. The microfilariae invade the lymph spaces of the conjunctiva, cornea and iris Involvement of the choroid may spread to the choroidoretinal apparatus, the retinal pigment accumulating in thick plaques. Finally, there are atrophy of the eyeball and entrance of the microfilariae into the sheath of the optic nerve The microfilariae penetrate deep into the choroid and retina from which they have no exit. The eye sets up reactions to the dead microfilariae Individuals hypersensitive to the microfilariae have the severest reactions.

There is often an eosinophilia

Diagnosis Diagnosis is established by finding the adult worms in the nodules and the microfilariae in the skin and nodules In endemic areas the presence of nodules, eosinophilia and ocular lesions is suggestive of onchocerciasis. It is impossible to differentiate the subcutaneous tumors, except by microscopic examination, from dermoid cysts, lipomas, fibromas and juxta-articular nodules

Except in serious ocular involvement prognosis is favorable

Eye Worm (Loasis) (Fugitive or Calabar Swellings). The disease is due to *Loa loa*, also known as *Strongylus loa*, *Filaria oculi humani*, *Filaria lacrymalis*, *Dracunculus loa*, and *Filaria subconjunctivalis*. The worm is indigenous to tropical West Africa

Man is the only definitive host The intermediate hosts are the flies *Chrysops silacea* and *Chrysops dimidiata*, more rarely *Chrysops longicornis* and *Chrysops distincti*, and possibly *Chrysops centurionis* Man is infected by the escape of the infective larvae from the proboscis to the skin when bitten by *Chrysops* The larvae apparently require several years to attain maturity in man

The symptoms do not ordinarily appear until 3 to 4 years after the initial infection The adult worms migrate through the subcutaneous tissues They are particularly troublesome when passing in front of the eyeball or across the bridge of the nose

The [illegible]

tions

tive

nonpitting, subcutaneous swellings are observed on the hands, forearms and in the vicinity of the orbit. They appear spontaneously and disappear in about 3 days There may be present urticarial dermatitis, and soreness from induration of the fascia and connective tissue in the vicinity of the tendon sheaths

Diagnosis is established by recovering the adult worms and more frequently by finding the characteristic microfilariae in the blood during the day The successful surgical removal of the worms effects a cure.

infections in endemic areas when compared with the number who have clinically manifested disease indicates that only a small percentage of infected persons have symptoms.

The symptoms commence with recurring attacks of lymphangitis and fever. There are anorexia, chills, fever, severe headache, malaise and vomiting. The acute attack lasts about 1 week, at the end of which the fever subsides and there is profuse sweating. The attacks often recur periodically, in some persons every few weeks and in others at longer intervals.

EXAMINATION The examination in the early stages of the disease reveals the affected part to be red, painful and swollen, with an erysipeloid that has a sharply defined line of demarcation The lymph nodes are enlarged and tender. After an acute attack the skin and subcutaneous tissues tend to remain swollen

The chronic stage of the disease is characterized by enlarged inguinal lymph nodes, lymphoceles, obstructive lymphatic involvement of the genitalia, and elephantiasis of various parts of the body Elephantiasis commonly affects the lower portion of the legs and the genitalia and may result in extensive deformity. Chyluria is always a suggestive finding though not diagnostic.

On examination in the chronic stage of the disease the elephantiasis is the significant finding The erythrocytes and hemoglobin show no noticeable changes and the leukocyte count may be normal or slightly subnormal. The leukocytes rarely number more than 10,000 per cubic millimeter even during acute attacks of lymphangitis

DIAGNOSIS. Diagnosis in asymptomatic patients is made by finding the microfilariae in the peripheral blood or chylous exudates. Because of nocturnal periodicity the blood in most localities should be taken from 10 P.M to 2 A.M., except where the nonperiodic type prevails.

Clinical diagnosis is based on lymphangitis, lymphatic enlargement, hydrocele, chyluria and elephantiasis Calcified worms may be demonstrated by roentgenologic examination, which is of assistance in locating associated living worms for surgical removal

In asymptomatic infections the prognosis is good, although symptoms may develop later in some patients When severe lymphangitis and elephantiasis are present, the chances of recovery are poor, although afflicted persons may live for years.

Onchocerciasis. The causative organism, *Onchocerca volvulus*, is called also *Filaria volvulus, Microfilaria nuda*, and *Onchocerca caecutiens*.

African onchocerciasis occurs from Sierra Leone to the Congo Basin, and extends eastward across the Congo and the French and British Sudan to Uganda, Nyasaland, and possibly Kenya American onchocerciasis, caused by the same parasite, occurs on the Pacific slope of the volcanic region of Guatemala, centering at Yepocapa In Mexico it is present in the states of Oaxaca, Chiapas and Guerrero. The American form of the disease is largely confined to the mountainous villages of the large coffee plantations.

Man is the only definitive host The intermediate hosts are flies, *Simulium damnosum* and *Simulium neavei* in Africa, and *Simulium ochraceum, Simulium callidum* and *Simulium metallicum in Guatemala and Mexico The microfilariae are* ingested by the fly when it bites the skin Infection of man takes place through contamination of the bite of an infected fly

PATHOLOGY. Onchocerciasis, a chronic infection of the skin and subcutaneous tissues, is characterized by the formation of nodules from 0 5 to 2 5 cm in diameter but occasionally 5 0 cm.

SYMPTOMS. As a rule the patient suffers little discomfort. The nodules may be extremely painful and the affected skin becomes painfully itching

The ocular symptoms, photophobia, iritis and keratitis, occur *some years* after ... hyperemia.

Cutaneous Leishmaniasis. The disease has received various names, according to the locality of its occurrence, among them oriental sore; Delhi ulcer; Aleppo or Natal boil; Bagdad, Lahore or Penjdeh sore; and Biskra button. The causative organism, *Leishmania tropica*, also is known variously as *Helcosoma tropicum*, *Herpetomonas tropica*, *Herpetomonas furunculosa*, *Leishmania furunculosa*, and *Leishmania nilotica*. The life cycle is probably the same as that of *Leishmania donovani*.

Cutaneous leishmaniasis is endemic in the Mediterranean countries of southern Europe and northern Africa, in western and southern Asia, and in central and northeast Africa, and is found in the same countries as kala-azar, but not in the same localities Considered a disease of the Eastern Hemisphere, it has been reported, however, in northern South America and in Central America, although the infecting organism in these regions may have been *Leishmania braziliensis*

The disease is limited to the cutaneous tissues and the mucous membranes. There are atrophy of the epidermis and hypertrophy of the corium Ulceration results from coagulation necrosis and secondary bacterial infection. One attack confers a solid immunity.

The incubation period varies from 1 week to 2 months A small papule appears, continues to enlarge, and acquires a purple color and a glazed surface which give it the appearance of a pustule The lesion becomes covered with brownish scales and by the third or fourth month it has turned to an indurated crusted ulcer, which discharges a thin, offensive pus. Single or multiple sores may develop on the exposed parts of the body. At times the coalescence of ulcers and secondary bacterial infection may result in extensive ulceration and general infection New lesions may be accompanied by chills and fever Uncomplicated sores heal slowly but leave ugly scars.

The presence of the leishmanian parasites establishes the diagnosis. The parasites are found in the exudative material obtained by puncture biopsy from the indurated margin of the ulcer Oriental sore must be distinguished from ulcers due to syphilis, blastomycosis and other infections. The prognosis is favorable.

American Leishmaniasis. This form of leishmaniasis, known as nasopharyngeal or mucocutaneous leishmaniasis, and by many local names, including espundia, uta, forest yaws, bouba braziliana, and pian bois, is caused by *Leishmania braziliensis* (*Leishmania tropica, Leishmania peruviana*).

American leishmaniasis occurs in South and Central America except Chile between latitude 21 degrees N and 25 degrees S , the greatest prevalence being between latitude 5 degrees and 25 degrees S

American leishmaniasis is characterized by ulcerative granulomatous lesions of the mucocutaneous surfaces, particularly the mucous membranes of the nose, mouth and pharynx The lesions are similar to those of cutaneous leishmaniasis The lesions of the mucous membranes of the mouth and nasopharynx take the form of fungating, eroding, indurated ulcers, which may develop into extensive necrotic lesions destroying the

or before, secondary mucomembranous lesions of the mouth, nasopharynx and larynx appear The secondary lesions appear as a thickening of the mucosa which proceeds to formation of nodules and ulceration These lesions are painful and are accompanied by fever, anemia, malaise and, if the larynx is affected, by loss of voice They frequently cause great deformity. The disease may heal spontaneously or result in death from secondary infection and general debility

Examination by physical means is important to assess the general condition of the patient.

The diagnosis of American leishmaniasis is determined by the presence of *Leishmania braziliensis* in stained smears from the indurated edges of the primary or

Trypanosomatidae. The family Trypanosomatidae, of the class Mastigophora and order Protomonadida, includes the hemoflagellates that live in the tissue of their hosts. In the genera *Leishmania* and *Trypanosoma* are species which are pathogenic to man.

Leishmaniasis. Leishmania are of the family Trypanosomatidae of the order Protomonadida of the class Mastigophora

Three species of leishmanian parasites, similar in morphology but differing in geographic distribution, in clinical manifestations and serologic reactions, affect man· (1) *Leishmania donovani* or *Leishmania infantum*, which produces visceral leishmaniasis or kala-azar, (2) *Leishmania tropica*, the cause of cutaneous leishmaniasis or oriental sore, and (3) *Leishmania braziliensis*, the cause of mucocutaneous leishmaniasis or espundia These parasites are flagellate protozoans which occur as small oval or round intracellular organisms chiefly in the reticuloendothelial cells of the skin or the viscera

Leishmanian parasites may be transmitted from one vertebrate to another by contact They pass through a developmental cycle in the arthropod hosts that feed on infected vertebrates Transmission from sandflies, *Phlebotomus papatasii* and *Phlebotomus sergenti*, to a vertebrate host may be by the bite of the insect

***Leishmania donovani* and Kala-Azar or Visceral Leishmaniasis.** This disease, visceral leishmaniasis, also known as Dumdum fever, and febrile tropical splenomegaly, is caused by *Leishmania donovani* or by *Leishmania infantum*. It is endemic in the Mediterranean countries, in Asia Minor, Mesopotamia, southern Russia, India, Turkestan, northern China, the Sudan and Abyssinia. Visceral leishmaniasis occurs in Brazil and Argentina.

The life cycle and transmission of *Leishmania* are not well known Infection has been transferred from dog to dog through infected sandflies. When the infective flagellate gains access to man, it loses its flagellum and assumes the leishmanian form. It multiplies rapidly within endothelial cells, rupturing them, and the freed parasites invade other cells or are phagocytosed

PATHOLOGY At necropsy the liver and spleen are large and congested The bone marrow is soft and red. The lymph nodes are enlarged and there are ulcerations of the colon

SYMPTOMS The symptoms differ in adults from those present in children Both show visceral and sometimes cutaneous manifestations The incubation period in the adult patient is indefinite, and identifiable manifestations do not develop in all infections. The first symptom is often an irregular fever which persists for 2 to 6 weeks, temporarily subsides, and then recurs. Intestinal ulceration may cause diarrhea. Bleeding from the nose and mouth is common.

In infantile kala-azar there are fever, splenomegaly, gastrointestinal disturbances, mental apathy, anemia, emaciation, abdominal distention, cancrum oris, bleeding from nose and gums, and cutaneous hemorrhages

A dermal form of kala-azar characterized by depigmented nodular, granulomatous, nonulcerating lesions of the skin, from which the organisms may be recovered, often appears if there has been insufficient treatment with antimony. The dermal form of the disease without visceral involvement may be an expression of resistance

EXAMINATION. The spleen is enlarged and by the sixth month the liver is increased in size. The lymph nodes are enlarged Anemia, cachexia, leukopenia, edema of the skin and emaciation may be present There is a marked leukopenia. These patients are prone to contract serious septic infections and pneumonia.

DIAGNOSIS The diagnosis depends on finding the parasite in smears or cultures of infected tissues. The infection must be differentiated clinically from enteric fever, malaria and Malta fever

Kala-azar should be suspected in a patient from an endemic area who has chronic irregular fever, leukopenia and splenomegaly.

With proper treatment with antimony the prognosis is good Among untreated patients the prognosis is 90 to 95 per cent fatal

examination of the blood and lymph nodes in the early stages and of the spinal fluid in the late stages.

The prognosis is favorable only if treatment is instituted before involvement of the nervous system occurs. If the patient is untreated, the disease generally proves fatal, although spontaneous recovery may occur in the early stages.

East African Sleeping Sickness. This form of trypanosomiasis is due to *Trypanosoma rhodesiense*, and occurs in Northeastern Rhodesia, South Rhodesia, Nyasaland, Portuguese East Africa and Tanganyika Territory

Irregular, febrile paroxysms, more frequent and severe than in gambian trypanosomiasis, begin after an incubational period of 1 to 2 weeks. There is only slight enlargement of lymph nodes There are edema, weakness, emaciation and myocarditis. Mental disturbances may develop The sleeping sickness syndrome is usually absent and neurologic symptoms are not pronounced

The blood or, better, a lymph node of any person from an endemic area who has symptoms should be examined for trypanosomes. The diagnosis is established by finding the organisms.

American Trypanosomiasis (*Chagas' Disease*) The American form of trypanosomiasis, Chagas' disease, is caused by *Trypanosoma cruzi* (*Schizotrypanum cruzi*, *Trypanosoma escomeli*, and *Trypanosoma triatomae*).

The disease occurs in South America, including Brazil, Venezuela, Chile, Peru and Argentina, and Central America in Guatemala and Panama Cases of the disease in man have not been reported in the United States of America and Mexico, but the trypanosome has been found by several investigators in various species of *Triatoma* in Mexico, California and Arizona

The vertebrate hosts are man, armadillos, bats (Mexico), dogs, cats, monkeys, opossums and wood rats
(a genus of the Reduviid
since the bug frequently
at the junction of cutaneous and mucous surfaces, the injured skin is readily contaminated.

I
mus
and
crithidial and trypanosomal forms The flagellated forms appear in the blood as thin trypanosomes about 20 microns long, or as short, stumpy forms about 15 microns long with pointed posterior ends, and, invading new tissues, continue the reproductive cycle It is possible that the leishmanian forms also invade new cells.

The acute symptoms commence after an incubation period of 1 to 2 weeks. At first there is a high irregular or continuous fever In about 2 weeks there begins to be tumefaction of the face and body due to deposition of mucoid material. Conjunctivitis with edema of the eyelids has been considered to be an early manifestation. The lymph nodes, thyroid, spleen and liver are enlarged on examination

The symptoms of the chronic infection depend on the location of the lesions. Likewise the findings on general examination depend on the lesions present.

The diagnosis is established on finding the parasite. Clinically the disease is differentiated from leishmanian infections, goiter, hypothyroidism, cretinism, chronic malaria and hookworm infection. The examination of blood is usually negative except during fever Laboratory animals may be inoculated with blood or tissues from the patient The complement fixation test with an antigen made from cultured *Trypanosoma cruzi* has proved useful in the diagnosis of chronic infections.

Although spontaneous recovery may occur, prognosis in the acute disease is unfavorable

secondary ulcers. American leishmaniasis must be differentiated clinically from yaws and syphilis. The prognosis is uncertain for untreated patients

Trypanosomiasis. The species of the genus *Trypanosoma* infect both vertebrate and invertebrate hosts.

Three species of trypanosomes are pathogenic to man. *Trypanosoma gambiense* and the closely allied if not identical *Trypanosoma rhodesiense* produce African sleeping sickness, and *Trypanosoma cruzi* produces South American trypanosomiasis or Chagas' disease

The method of transmission is by infective material from open lesions being transferred mechanically by contact or by insects through direct or indirect transmission Direct transmission is accomplished by bites of insects and involves no cyclic development of the trypanosome

Mid-African Sleeping Sickness. This sickness is caused by *Trypanosoma gambiense* (*Trypanosoma ugandense, Trypanosoma hominis, Trypanosoma nigeriense, Castellanella gambiense,* and *Trypanosoma castellani*).

The disease is restricted to the range of its vector, *Glossina palpalis*, in tropical West and Central Africa, limited by Lake Victoria and Lake Tanganyika On the west coast of Africa it is found between Senegal and Angola

PATHOLOGY The most important pathologic changes occur in the lymphatic and nervous systems In the early stages of the disease the postcervical, submaxillary, inguinal and femoral lymph nodes are swollen The spleen and at times the liver are enlarged In the late stages of the disease a chronic leptomeningitis develops The spinal fluid increases in volume. There is a meningo-encephalitis with perivascular cellular infiltration.

SYMPTOMS. The incubational period is usually about 2 weeks, but may be several weeks longer in resistant natives The first symptom of the disease is a fever of a wide diurnal range which lasts for about a week This is followed by a series of febrile attacks followed by afebrile periods. During the afebrile periods the patient feels comparatively well Glandular enlargement, edematous swellings about the eyes and joints, and erythematous skin eruptions are often present The lymph nodes of the postcervical triangle (Winterbottom's sign) are swollen and tender. There may be headache, cramps and a delayed sensation to pain with deep hyperesthesia

After about 12 months the chronic stage begins which is characterized by severe febrile paroxysms and headaches Between the paroxysms there is physical and mental weakness manifested by a morose, indifferent attitude.

EXAMINATION From about 18 months on, a rather profound mental lethargy begins which is the origin of the term sleeping sickness The mental lethargy is progressive. The patient becomes apathetic, dull and drowsy. Speech is not disturbed; conversation is intelligently, but slowly, conducted There is a lack of interest and the voice is weak. At times there may be periods of exaltation followed by deep melancholia. Tremors of the tongue and limbs and even choreiform movements may occur. The gait is slow and shuffling, the patellar reflexes are exaggerated, and there may be a positive Romberg sign, intention tremor and occasionally nystagmus. If the fever is not pronounced or if the patient is examined when afebrile, a disseminated sclerosis may be suspected.

The somnolence increases until finally the patient may fall asleep in the midst of activity. In the terminal stages there is almost continuous sleep. The pulse is rapid, the blood pressure low. The knee jerks are absent and emaciation is extreme. There may be convulsions. Death usually results from a terminal pneumonia

DIAGNOSIS. Trypanosomiasis is suspected when a patient from an endemic area shows an irregular fever, palpable lymph nodes, particularly in the postcervical triangle, erythematous eruptions of the skin, and delayed response to pain with deep-seated hyperesthesia.

Final diagnosis depends on the identification of the trypanosome by laboratory

TOXOPLASMOSIS

The protozoan parasite *Toxoplasma* (a genus of Sporozoa) is pathogenic for a wide variety of mammals and has an extensive geographic distribution.

The life cycle of *Toxoplasma* is incompletely known. Its exact classification is uncertain and the natural mode of transmission is obscure. However, the uneven distribution of latent toxoplasmosis indicates an extrahuman reservoir of infection. Evidence points to insect transmission as a mode of spread from a large potential reservoir of hosts such as dogs, rabbits, squirrels and voles

In experimental toxoplasmosis there is multiplication of the parasites at the site of entry followed by dissemination through the blood stream to every tissue, and invasion of the vessel walls and ultimately of the tissues themselves. The involvement of different tissues depends mainly on their susceptibility, regardless of the portal of entry. The nervous system seems to be especially susceptible

Sabin has made a serologic test which demonstrates the presence of specific serum antibodies By means of this test he has demonstrated that the mothers of some of the affected infants also had or have had toxoplasmosis. In some instances other members of the family also have had the disease. Toxoplasmosis therefore exists in a subclinical or unrecognized form

Among the inmates of institutions for the mentally deficient in the United States a number of previously unrecognized cases of toxoplasmosis have been found. The disease constitutes a known cause of mental retardation and of chorioretinitis.

Performance of the toxoplasmin skin test in Stockholm showed a high percentage of positive reactions The incidence increased from the age of 5 years to the age of 20 years, after which it remained about constant Preliminary investigations of similar kind in northern Sweden showed a far lower percentage of positive results in adults

Necropsy in serologically verified cases of congenital toxoplasmosis reveals an inflammatory process in the organs of the body, but without exception the most pronounced tissue changes are in the central nervous system The infection spreads by the hematogenous route, and the tissue of the central nervous system is especially susceptible The grave character and wide extent of the changes in stillborn infants or infants who died at birth point to fetal transmission of the infection. In all cases the mother's blood gives positive serum reactions with high-titer values Biopsy specimens from the lymph nodes in acquired toxoplasmosis with acute fever and pronounced serologic reactions to *Toxoplasma* show pronounced inflammation, characterized by swelling of the reticular cells and agglomeration of eosinophilic leukocytes and plasma cells in the tissue

Toxoplasmosis occurs in infants, children and adults

It seems that in infants the dissemination of the parasites occurs prior to birth so that in some at birth the original lesions caused by the parasite have largely healed. By the time of birth only the more slowly healing lesions in the central nervous system are left

The general manifestations of toxoplasmosis in children may be first observed when feeding difficulties arise. On examination it may be found that the child has fever, jaundice and enlarged liver and spleen Vomiting and diarrhea are common during the early course of the infection.

There is a predilection for the central nervous system and the eye There is an encephalomyelitis This encephalomyelitis is manifested by first convulsions, muscular twitchings, opisthotonos and hyperactive tendon reflexes Muscular paralysis and weakness of the respiratory muscles and cyanosis may ensue The spinal fluid examination reveals a pleocytosis, xanthochromia and increased concentration of protein

Ocular manifestations are common and result from direct involvement of the intrinsic structures of the eye and secondarily from involvement of the cranial portion of the central nervous system. The intrinsic manifestations consist of iridocyclitis with synechiae, cataract secondary to uveitis, vitreous opacities and fibrosis

Histoplasma capsulatum and *Blastomyces dermatitidis* In the doses commonly used for skin tests, individuals who have positive reactions to coccidioidin will give cross reactions with histoplasmin or blastomycin There seems to be a larger amount of this hypothetic common antigen in *Blastomyces dermatitidis* and *Histoplasma capsulatum* than in *Coccidioides immitis* Therefore histoplasmin, blastomycin and coccidioidin should be used simultaneously to determine which gives the greatest reaction.

In subclinical coccidioidomycosis and in many instances of blastomycosis, the infection does not stimulate the production of complement-fixing antibodies in detectable amounts However, in the progressive form of these three mycoses, complement-fixing antibodies are present regularly and persist even when the patient becomes anergic and the skin test is negative

Cross complement fixation does not occur between coccidioidomycosis and histoplasmosis. Those who fix complement in a high titer with histoplasmin also fix complement, but to a lower titer, with blastomycin This necessitates simultaneous tests with blastomycin and histoplasmin Some patients with histoplasmosis have a higher complement-fixing titer for blastomycin than other patients who have a true blastomycotic infection

The Actinomycetales. The Actinomycetales are an order under the class Schizomycetes. There are three families, Mycobacteriaceae, Actinomycetaceae and Streptomycetaceae in the order Actinomycetales The Actinomycetaceae contain two genera pathogenic to man, *Actinomyces* and *Nocardia*

The Actinomycetes and Actinomycosis. The actinomycetes, growing in the form of a branched mycelium, have characteristics intermediate between those of bacteria and molds Actinomycetes isolated from animals and man show wide variations in structure The parasitic actinomycetes may therefore be grouped provisionally in a single species, *Actinomyces bovis*, which causes actinomycosis

Actinomycosis is a subacute or chronic, progressive disease characterized by the development of indurated, granulating, connective tissue swellings, limited suppuration and pus which often resemble tuberculous manifestations

The pathologic changes in actinomycosis are necrosis, granulation tissue and the formation of dense fibrous tissue Sulfur granules are characteristic

Material obtained at necropsy after death due to infection with Actinomycetaceae reveals varying degrees of pathologic processes, some caused by the mycotic organisms, and others by secondary bacterial invaders For example, Weed and Baggenstoss recorded the bacteriologic findings in 35 cases in which diagnosis of actinomycosis was established by postmortem observations.

The organism *Actinomyces bovis* could be demonstrated in histologic sections with reasonable certainty in only 21 instances, with considerable doubt in 3 and not at all in 11 In 2 of the 11 instances there were different gross and microscopic features, and the observations were suggestive of nocardiosis *Nocardia* was isolated in pure culture from 1 of these In 13 of the 21 in which *Actinomyces bovis* was present, it was possible to demonstrate microscopic evidence of mixed infection The probable clinical significance of the organisms associated with *Actinomyces bovis* was reflected in the presence of renal involvement in 12 of 16 (pyelonephritis and formation of abscess) and nonactinomycotic brain abscesses in 5 Evidence from the study of fixed tissues indicated considerable variation in the detailed structure of colonies presumed to be *Actinomyces bovis* The variations included presence or absence of clubs, apparent fusion of clubs, staining reaction of clubs by the Brown-Gram technic, number of filaments, length of filaments, some of them being very short and closely resembling diphtheroids, and compactness of the colonies, some of which showed almost diffuse growth The sections also showed considerable variations in the amount of fibrosis. The presence of sulfur granules and the microscopic observations, usually considered characteristic of actinomycosis, may be produced by organisms other than *Actinomyces bovis*. In many instances cultures are necessary to establish the differentiation.

It may be possible to differentiate between the pathologic process produced by the

tuberculosis, which more commonly involve the same structures as do the mycoses, making the diagnosis of generalized mycotic diseases at times difficult and often entirely unsuspected until the offending organism is found by smear or culture.

The mycoses may be of either endogenous or exogenous origin.

The mycoses of endogenous origin are distributed uniformly. Men of all races are infected more frequently than women, and adults are infected more frequently than children.

In contrast with the mycoses of endogenous origin, those of exogenous origin are more numerous The exogenous mycoses, such as sporotrichosis, nocardiosis, aspergillosis, penicilliosis and mucormycosis, are uniformly distributed, whereas coccidioidomycosis is found in California, Arizona, New Mexico, southern Utah and the southwestern part of Texas *Histoplasma capsulatum* is widely distributed, but it seems to prefer to live in the Mississippi valley, the Ohio River valley and the Appalachian area Blastomycosis is a disease which is more frequent in the Mississippi valley and in the southeastern states than elsewhere Chromoblastomycosis, mycetoma and rhinosporidiosis occasionally are observed in the southern part of the United States

The exogenous types of fungous infection are commoner and more severe in Negroes, Mexicans and Filipinos than in light-skinned peoples. In these dark-skinned peoples coccidioidal granuloma is a highly fatal disease

Generally a mycotic infection is suspected in every patient who has chronic draining sinuses, whose sputum is negative for tubercle bacilli, and from whom has been obtained a negative biopsy study for neoplasia and a Papanicolaou smear negative for malignant cells The presence of *Cryptococcus neoformans* (*Cryptococcus histolyticus, Torula histolytica*), *Coccidioides immitis, Histoplasma capsulatum, Blastomyces dermatitidis, Sporotrichum schenckii, Actinomyces bovis, Nocardia asteroides, Rhinosporidium seeberi* or the various organisms which cause chromoblastomycosis or maduromycosis in the sputum or other discharges establishes a diagnosis. The presence of *Candida albicans* (*Monilia albicans*) or one of the various species of *Geotrichum, Aspergillus, Penicillium* or *Mucor* does not necessarily imply that these organisms are producing disease These fungi are often proved to be accidental or secondary invaders rather than the primary etiologic agents The presence of *Actinomyces bovis* in the gums or about carious teeth, in saliva, or in sputum which contains a considerable admixture of saliva, without a definite demonstrable focus in the mouth, also is considered an accidental finding even though pulmonary disease is present

The experienced mycologist can make a good many correct diagnoses by a direct study of the sputum or of the pus from discharging sinuses He examines the material unstained, with or without the addition of a few drops of 10 per cent solution of sodium hydroxide, and with or without staining suspected granules by Gram's method. In some instances the use of the methods usually employed for the demonstration of tubercle bacilli, provided the decolorization with acid alcohol is not excessive, is diagnostically helpful

Skin tests are of definite but limited value in the diagnosis of mycotic infections. Clinical and subclinical infections with *Coccidioides immitis* and *Histoplasma capsulatum* regularly induce a tuberculin-like sensitivity to coccidioidin and histoplasmin, respectively. Hence a negative result of a skin test eliminates the possibility of these mycoses unless the patient has an anergy as the result of a progressive terminal infection. Infections with *Blastomyces dermatitidis* may or may not induce sensitivity; therefore a negative result of a skin test to blastomycin cannot be used to eliminate the possibility of this disease Hypersensitivity to autogenous vaccines has been observed in most of the other mycoses, but there are insufficient data to enable evaluation of their frequency and significance.

It seems there is a small amount of an antigen common to *Coccidioides immitis*,

the skin, projection of the lesion beyond the surrounding integument, multiple nodules, with the formation of ridges and furrows in the creases of the skin of the neck and the presence of multiple scars are strongly suggestive of *Actinomyces bovis.*

Actinomycosis must be differentiated from tuberculous lesions. A tuberculoma opens as a single sinus and is painless, without the boardlike hardness of actinomycosis Tuberculous adenitis is a condition seen in early life, while actinomycosis may occur at any age. The biopsy may reveal epithelioid cells and giant cells, typical of the tuberculoid structure, but no granules will be found Periosteal sarcoma, Hodgkin's disease, lymphosarcoma and branchial cyst are distinguished by surgical removal and histologic study.

Metastasis from a cutaneous epithelioma appearing in the submaxillary region may simulate actinomycosis.

Thoracic Actinomycosis. The thoracic viscera may be affected by spread of a cervicofacial infection through the fascial planes of the neck. Actinomycotic lesions tend to spread widely by contiguity, sometimes pointing toward the skin and forming fistulas that tend to heal and re-form elsewhere. The organism may be disseminated through the blood, or, in the lungs, through the bronchi Bone is seldom affected interstitially except in the jaws.

If there is not present an actinomycotic infection of the head and neck, the manifestations of thoracic infection are not materially different from those of tuberculosis. The diagnosis has to be made by identification of the offending organism. (See Diseases of Respiration, Chapter 9)

Abdominal Actinomycosis. Actinomyces bovis exists as a saprophyte in the mouth, respiratory tract and gastrointestinal tract of man and animals. It becomes pathogenic only if it penetrates a break in the mucous membrane produced by trauma or disease. This uncommon disease occurs most frequently in men in the second to fifth decades. It has a wide geographic distribution and affects persons in all occupations Many cases of abdominal actinomycosis follow acute perforative or ulcerative disease of the gastrointestinal tract, very often rupture of the appendix The organism spreads by direct extension through adjacent tissue and tends to form fistulous tracts through the abdominal wall.

In still rarer instances of abdominal infections the first evidence of the disease is an abdominal mass, and the true nature of the process is discovered by histologic and bacteriologic study of materials removed surgically or later from fistulous formation postoperatively

Apparently primary infection of the stomach with *Actinomyces bovis* has been recorded

The diagnosis of abdominal actinomycosis cannot be made without demonstration of the organism by direct examination or culturally. Sulfur granules may be present in some instances. In other instances the organisms may be like *Actinomyces bovis* but no clubs accompany the granules. Sulfur granules, if present, are of diagnostic value If they are not present, the diagnosis rests on demonstration and identification of the organism by other means

The Nocardias (Saprophytic Actinomycetes) and Nocardiosis. Pathogenic aerobic acid-fast and nonacid-fast actinomycetes are free-living plant organisms which cause disease by air-borne contamination or by introduction into tissues through trauma Species of *Nocardia* are found in lesions of man and animals, and, unlike *Actinomyces,* are free living in nature as contaminants on the skin and as inhabitants of soil and in plant disease

The genus *Nocardia* includes several different species: (1) *Nocardia asteroides,* (2) *Nocardia brasiliensis,* (3) *Nocardia madurae,* (4) *Nocardia pelletieri* and (5) *Nocardia paraguayensis* (Names of species are those preferred by Conant, page 582, *Bacterial and Mycotic Infections,* edited by Dubos)

aerobic *Nocardia* and the anaerobic *Actinomyces bovis.* When it is possible, such differentiation is made, and is helpful diagnostically and therapeutically.

In reports from the pathologists it is well to know that not all species of pathogenic actinomycetes produce club-bearing granules, and clinically granules are not in evidence in all cases of actinomycosis Other infections produce granules as well. Granules with clubs are formed under certain conditions by such organisms as *Coccidioides immitis* and strains of *Aspergillus, Sporotrichum* and *Monilia.*

There is no evidence that actinomycosis is communicable. *Actinomyces bovis* is a true parasite of mucous membranes, never found in nature apart from a parasitic or pathogenic habitat, it occurs on mucous membranes, possibly in the absence of any disturbance, certainly in the presence of low-grade nonspecific inflammatory processes, for example, of the gums. It produces disease as an endogenous infection

The lesions of actinomycosis are subacute or chronic and they tend to appear on the skin (in primary cutaneous actinomycosis) or in one of three sections of the body: (1) head and neck, (2) thorax and (3) abdomen. However, the disease is often widely disseminated through the blood and then many organs may be involved including bones other than the jaw.

Primary Cutaneous Actinomycosis The term primary cutaneous actinomycosis designates the form of the disease in which the infection does not spread from a neighboring mucous membrane or arise from a systemic infection. All species of actinomycetes have been suggested as etiologic agents in primary actinomycosis

Actinomycosis of the Head and Neck. The commonest site of actinomycosis in both man and animals is the mouth and neighboring passages.

Cervicofacial actinomycosis apparently originates from the mouth, but affects the soft tissues and skin of face and neck, the tongue and, secondarily, the maxillary bones. The salivary glands, larynx, thyroid and lacrimal glands, the orbit and even the brain may be involved The lesions most commonly appear on the cheek or submaxillary skin, and are characterized by indurated or edematous swellings, bluish or reddish, with a tendency to form a series of irregular folds separated by furrows, the healing lesions forming scars as new lesions develop.

The jaw, when affected, becomes swollen. The tissues are at first hard and indurated, simulating a malignant tumor Later, necrosis takes place inside the tumor and draining sinuses form.

On the tongue the infection is manifested by indolent ulcers and formation of sinuses.

The onset of the disease is insidious The usual history is of chronic periodontitis surrounding a carious tooth or teeth, often going back for several years. In most cases the acute stage of actinomycosis is preceded by the removal of infected teeth. Twenty-four to 48 hours after extraction of such a tooth, there is a slight rise of temperature, with edema and swelling of the soft tissues about the mandible There are alternate regression of the active process and recurrence with exacerbation Each recurrence is accompanied by fever (temperature up to 101 to 102 F or 38 3 to 38.8 C) and reduces the resistance of the tissues to the parasite. There may be hoarseness and dysphagia

On examination the lesion consists of firm, subcutaneous, purplish tumors which may have gradually softened, ulcerated and broken down, leaving fistulous tracts In the acute form of the disease all the soft tissues as far down as the clavicle may show solid dense edema, with bluish red erythema. There is usually central necrosis in the region in which the infection originated, with little pus but with suppuration of a clear, straw-colored fluid As sinuses form, secondary bacterial invasion, particularly that of staphylococci and streptococci, is present.

The diagnosis of actinomycosis of the face and neck depends on the presence of both macroscopic and microscopic granules of actinomycetes in the pus and the demonstration of the organisms by cultural means. The dark red discoloration of

The cutaneous involvement may be primary or appear as a manifestation of an already established systemic infection. The lesions appear as acneform pustules, punched-out granulomatous ulcers, subcutaneous tumors or deep-seated abscesses. A cutaneous infection may progress to generalized infection with involvement of the brain, meninges, lungs, liver, spleen, pancreas, thyroid and aorta The primary pulmonary infections resemble neoplasm or tuberculosis. The primary brain infection may resemble an encephalitis, acute or chronic meningitis such as a tuberculous meningitis, or may resemble brain tumor, brain abscess, or degeneration or syphilis of the central nervous system

Sputum, pus, gelatinous exudates or sediment of centrifuged spinal fluid contains the fungus. In pulmonary infections the organism may be revealed in the sputum or exudates The pathogenicity of the fungus is revealed by its effect on mice.

Blastomyces dermatitidis and North American Blastomycosis (*Gilchrist's Disease*). *Blastomyces dermatitidis* is a spherical, thick-walled, budding, yeastlike fungus It produces a granulomatous infection of the skin and internal organs very similar clinically and histologically to tuberculosis

The cutaneous infection commences as a papulopustule which spreads peripherally, showing a granulating base covered with a bloody exudate and a raised papilliform or verrucous border with miliary abscesses. Spontaneous healing of the centers of such lesions produces characteristic thin scars surrounded by a raised and spreading border. The papulopustules are situated on the face and neck, on the dorsa of hands, wrists and forearms, ankles and legs, and in the perineal regions. By direct extension or hematogenous spread the lesions appear anywhere on the body as multiple, subcutaneous, gumma-like processes which rupture spontaneously, freeing bloody pus

In systemic blastomycosis the lungs are most frequently infected and show the most extensive lesions In the presence of septicemia, however, subcutaneous tissues and bones, the vertebrae and ribs, are commonly affected The central nervous system and the liver, spleen and kidneys may be involved.

The diagnosis is based on demonstration of the *Blastomyces dermatitidis* in the pus from miliary abscesses at the border of cutaneous lesions or from subcutaneous lesions of sputum Spinal fluid and urine should be centrifuged and the sediment examined In all of these materials *Blastomyces dermatitidis* should be identified by culture before a diagnosis is made

Blastomyces brasiliensis. This fungus is large, thick-walled, single budding or multiple budding, and yeastlike. It produces a granulomatous infection of the mucous membranes of the mouth, lymph nodes and internal organs which is known as South American blastomycosis, paracoccidioidal granuloma, Lutz-Splendore-Almeida disease, and Almeida's disease

Pus and scrapings from the buccal mucosa and the skin lesions, pus from fluctuant nodes, and smears of biopsied nodes should be examined as fresh preparations and cultured for diagnosis

Rhinosporidium seeberi. The infection rhinosporidiosis is attributed to *Rhinosporidium seeberi* (called also *Rhinosporidium kinealyi*). Natural infections have been observed in horses, mules and cows The disease occurs most frequently in children and in young adults but it may appear at any age. Persons who frequently swim and dive in stagnant fresh water are especially liable to this infection.

Itching in the nose and a mucoid discharge are the first symptoms. Subsequently a granuloma develops on the nasal mucosa and this may eventually become a pedunculated polyp which is pink or purplish Occasionally the granuloma develops in the larynx, on the conjunctiva, in the ear, on the penis, in the vagina or in the rectum Papillomatous lesions may develop on the skin of the face.

The presence of a nasal polyp suggests the diagnosis. It is easily confirmed by direct examination and demonstration of the large sporangia

Nocardia asteroides is the only species which shows pathogenic tendencies and even this species varies greatly in its ability to produce infection. *Nocardia asteroides* infections are not common. They do not occur spontaneously in any animal except man. In the large majority of cases the diagnosis is made at the time of necropsy. In those instances in which the diagnosis is made during life, the organism is demonstrated late in the course of the disease.

Nocardiosis Nocardiosis is a chronic suppurative infection of the superficial tissues and the bones or a generalized infection usually originating in the lungs

Nocardiosis involving the subcutaneous tissues and bones (mycetoma or maduromycosis) is characterized by multiple tumefactions and draining sinuses from which "granules" (yellowish white, red or black) are expressed in the pus or found in the tissues

In a nocardemia the organisms may be filamentous, bacillary or coccoid. They are acid-fast, and may be present in the sputum, spinal fluid, or pus from subcutaneous abscesses

Maduromycosis of the lower extremity is termed Madura foot. The characteristic lesion with pain, swelling, and formation of sinuses, and eventual clubbing and marked deformity of the infected member, develops only after months or years. Infection spreads by extension through adjacent tissues, with destruction of bone, multiple abscesses with rupture, and with no systemic reaction unless secondary bacterial invasion is established The walls of sinuses and abscesses may show only a chronic inflammatory reaction. Further development of the acute purulent abscess results in a surrounding layer of granulation tissue

Pulmon[illegible]
with sputum [illegible]
may reveal [illegible]
in the body may be affected as the result of a nocardemia

The generalized form of the disease is caused by *Nocardia asteroides*. When there is a nocardemia, the brain commonly is involved. When the infection once is established in the brain, there are symptoms of either brain tumor or brain abscess. In some the symptoms may be those of a meningitis resembling that of tuberculous origin with minimal or no findings in the lungs

Generalized nocardiosis may be manifested very much as is tuberculous infection of the lungs and pleura with hematogenous spread throughout the body, especially to the brain and meninges

The diagnosis of nocardiosis is established by the demonstration, by culture, of the nature of the offending organism Pus from the draining sinuses, scrapings from the walls of sinuses and biopsy sections should be examined for actinomycotic granules.

The Fungi Imperfecti. The Fungi imperfecti contain practically all of the fungi pathogenic to man other than *Actinomyces* and nocardias

The Fungi imperfecti are identified by the mycologist by their structure: *macro-* [illegible]

[illegible]a,
namely, *Microsporum*, *Trichophyton* and *Epidermophyton*. These were considered in Chapter 8.

Cryptococcus neoformans (Torula). *Cryptococcus neoformans* is a yeastlike, nonsporulating, nonmycelial, budding fungus characterized by the development of a wide capsule. It may involve the skin but it has a marked predilection for the central nervous system and produces a subacute or chronic infection of the meninges (Torula meningitis) or lesions simulating brain tumor or brain abscess The infection is known generally as cryptococcosis, torulosis, European blastomycosis, and Busse-Buschke disease.

Thirty-eight per cent of Ohio children who reacted neither to histoplasmin nor to tuberculin showed pulmonary calcifications Perhaps the recent development of a complement fixation test for histoplasmosis will aid in more accurate diagnosis of that infection. If specific, such a test might be of great value in the differential diagnosis of early precalcific pulmonary infiltrates

The symptoms of histoplasmosis are varied Since the disease is reticuloendothelial cytomycosis the symptoms are dispersed in the order of the reticuloendothelial system. Generally the symptoms are those of a systemic febrile illness often with the pulmonary symptoms being more manifest than other symptoms.

On examination during the acute phase of the infection often there is present a systemic febrile disease with enlargement of the liver and the spleen In other instances lymph-node enlargement may predominate, and the findings resemble those present in Hodgkin's disease, leukemia, lymphosarcoma or aplastic anemia In still another group pulmonary changes may predominate, and infection may be complicated by, or superimposed on, pulmonary or general tuberculosis

The parasites appear in the cells of the reticuloendothelial system They may be found in thin smears of peripheral blood or in sections of the lymph nodes, spleen, or material obtained by sternal aspiration. Anemia and leukopenia are present.

In the quiescent stage or the healed stage of histoplasmosis diffusely scattered pulmonary lesions are characteristic. Postulating that these pulmonary calcifications might represent a primary, benign form of histoplasmosis, workers have attempted to discover early pulmonary infiltrates in the endemic areas which could be attributed to histoplasma infection Studies in school children of Kansas City disclosed patients who when originally seen gave roentgenograms of the chest which were interpreted as normal and negative histoplasmin reactions and in whom there subsequently developed pulmonary infiltrates or hilar adenopathy or both, along with a positive reaction to histoplasmin These infiltrations could not be distinguished roentgenographically from active pulmonary tuberculosis The *Histoplasma capsulatum* was isolated from one of the children who had precalcific lesions.

The development of calcification in some of these precalcific lesions has been observed, so that the pathogenetic process has been followed from the negative roentgenogram of the chest and negative histoplasmin reaction through the appearance of the parenchymal infiltrate (with concurrent change in cutaneous sensitivity) to the final calcified focus in the lung associated with a positive reaction to the histoplasmin test

Negative reactions to tuberculin tests in the presence of pulmonary calcifications were formerly interpreted as being due to a loss of tuberculin allergy. However, it has been shown that there is an exceptionally high incidence of pulmonary calcifications among residents in the Ohio and Mississippi valleys and that the incidence of tuberculin negativity in these people is too high to be explained on grounds of anergy

As with coccidioidin, the histoplasmin skin test is performed by intradermal injection of 0 1 cc of diluted histoplasmin on the arm A dilution of 1:1,000 is usually employed, although stronger dilutions (1 100) are also used. The chief value of the histoplasmin test lies in its use in the differential diagnosis of unexplained pulmonary infiltrates or calcifications, especially in tuberculin-negative reactors. In the patient who has acute, disseminated histoplasmosis, analogous to the anergy of those with disseminated tuberculosis or coccidioidomycosis, reaction to the skin test is often negative.

Coccidioides immitis and Coccidioidomycosis. *Coccidioides immitis*, the cause of coccidioidomycosis, is a pathogenic fungus of the family Endomycetales. It is a spherical, thick-walled, endospore-filled organism that seems to be highly infectious to different animals and to man The fungus has been isolated from rodents, dogs, sheep and, in some districts, from cattle.

In the United States *Coccidioides immitis* seems to thrive in certain endemic

The disease runs a chronic course but it is not of itself fatal unless it causes obstruction of the larynx or the esophagus.

Candida albicans. *Candida* (formerly called *Monilia*) is a genus of yeastlike fungi which may produce mycelia but not ascospores. These organisms, particularly *Candida albicans*, are equivocal disease producers. The commonest form of moniliasis is thrush, a disease characterized by the formation of gray-white patches on the buccal mucous membranes, tongue and pharynx of feeble patients. In babies the disease may have been acquired during birth from a mother who had a vaginal infection.

Candida albicans, the causative organism of moniliasis, is an oval, budding, yeastlike fungus producing both blastospores and pseudomycelium in tissue and exudates. It is frequently found in the normal mouth and intestinal tract or as a secondary contaminant in recognized diseases. Its exact etiologic significance in any disease process is difficult to establish

Candida albicans, in addition to the production of infections of the mucous membranes of the mouth (thrush) may cause vaginitis or vulvovaginitis; irritations of the intertriginous areas and interdigital webs of the hands and feet, infections of the nails (onychia and paronychia); and systemic infections such as bronchopulmonary, or generalized infection of lungs, lymph nodes, liver, spleen and meninges

Vulvovaginitis, caused by infection of the vaginal mucosa and vulva, is a thrush-like infection characterized by irritation, pruritus and a thin discharge

Lesions on the hands follow maceration of tissue by continued immersion in water and therefore afflict housewives, waiters, chefs and bartenders.

Infection of the nails (onychia and paronychia) is characterized by swelling at the nail bed which may be painful and resemble a pyogenic infection, and by thickened, transversely grooved nails.

In the lungs *Candida albicans* may cause a mild bronchopulmonary moniliasis with persistent cough, or a more extensive pulmonary moniliasis resembling miliary tuberculosis with cough, fever, dyspnea, thoracic pain, hemoptysis and night sweats accompanied by signs of pleural thickening and consolidation.

Moniliids (candidids) occasionally accompany localized infections. Such lesions are sterile and appear on the body as a result of sensitivity to the yeastlike fungi found in lesions elsewhere in the body

Histoplasma capsulatum. Histoplasmosis is caused by *Histoplasma capsulatum*, a species of Fungi imperfecti.

The site of entry is uncertain; the skin has been suggested with possible bites or infestations by parasites as the mode of entry, but the portal most commonly accepted is the lungs They appear to be the site of the oldest and densest involvement.

Histoplasmosis occurs in temperate and subtropical climates and particularly in the Ohio and Mississippi valleys in the United States of America.

Pathologic alterations consist of an enlarged spleen and gray or white nodules in the lungs, liver, spleen, the intestine and the pulmonary and peritoneal surfaces Pathologically the disease is a reticuloendothelial cytomycosis Henderson, Pinkerton and Moore reported a case of histoplasmosis in which the chief lesion was an ulcerative enteritis. Examination of stools in such cases may reveal the histoplasmas The almost constant involvement of the mesenteric lymph nodes points, according to Henderson, to the gastrointestinal tract as the portal of entry

Residual lesions, nodular foci as well as cavities in the lungs, have been described in histoplasmosis. A characteristic feature is the occurrence of disseminated infiltrates resulting in "snowstorm" calcifications. If *Histoplasma* is the causative agent of snowstorm calcification, this presupposes the presence of the fungus in soil, an assumption which has been verified by Emmons. He also has pointed out the cross sensitivity between histoplasmin and blastomycin. The endemic areas of blastomycosis and histoplasmosis overlap. Tissue forms of blastomyces may resemble histoplasma forms.

the body, for example, in the lungs, larnyx, lymph nodes, bones, joints and central nervous system.

DIAGNOSIS OF COCCIDIOIDOMYCOSIS. The diagnosis of coccidioidomycosis in all forms is determined by the presence of *Coccidioides immitis* in pus, sputum, gastric contents, pleural fluid and spinal fluid

Complement-fixing antibodies and precipitins can be demonstrated in the serum of patients infected with *Coccidioides immitis.* The complement-fixing antibodies have the same significance as in blastomycosis; that is, they indicate spreading infection and poor prognosis. Hypersensitivity to the fungus can be demonstrated by the coccidioidin skin test. Positive results of the test usually develop in 3 to 21 days after infection, and a delayed tuberculin-like reaction occurs in 24 to 48 hours.

In the presence of a positive reaction to both the tuberculin and the coccidioidin skin test the diagnosis is difficult unless tubercle bacilli can be demonstrated. In the absence of tubercle bacilli a presumptive diagnosis of coccidioidomycosis can be made if there is a history of possible exposure in an endemic area; if there is roentgenologic evidence of a pulmonary lesion, usually a solitary cavity or nodular density, which reveals no change after months or years of observation, and if there is positive reaction to the coccidioidin skin test The diagnosis of coccidioidomycosis in the presence of active pulmonary tuberculosis as revealed by sputum containing tubercle bacilli cannot be made

An important feature in pulmonary coccidioidomycosis is the well-being of the patients, often without symptoms, unless there are pulmonary hemorrhages from a cavity. The presence of a coccidioidal cavity in a lung in the absence of tubercle bacilli may lead to an erroneous diagnosis of malignant disease

Commercially prepared coccidioidin is available. It is prepared by dilution to the desired strength with sterile isotonic sodium chloride solution For sensitive patients, for instance those who are suspected of having coccidioidal erythema nodosum, a 1·10,000 dilution of the coccidioidin is advisable. However, 1.100 dilution may be used which may evoke a severe local reaction and even some systemic reaction, but there seems to be no great danger of causing dissemination of an active infection or flaring up of a quiescent one if a reaction ensues In suspected ancient infections in the presence of pulmonary cavities presumably coccidioidal, a final test with 1.10 dilution is made. Caution is necessary in interpretation because the cross reactions associated with histoplasmin sensitivity are increased with these stronger concentrations. As in the Mantoux test, 0 1 ml of the antigen is injected intradermally Readings are at 24 and 48 hours, and induration of more than 0 5 cm in diameter at either time is considered positive If only one reading is possible, that at 48 hours is preferable. The reaction is interpreted as in the tuberculin test

A negative result of a coccidioidin test, like a negative result of a tuberculin test, apparently rules out infection except in the patients with coccidioidal granuloma, who are frequently anergic.

areas, for instance in the San Joaquin valley in California, parts of Arizona and New Mexico, and central west Texas. The morbidity rate in man follows closely a seasonal variation, most instances occurring in the dry months of summer and autumn when dust is most prevalent.

The usual portal of entry of *Coccidioides immitis* is the respiratory tract, but it can and does enter through abrasions in the skin. It is accepted that man becomes infected with coccidioidomycosis as a result of the inhalation of desert dust contaminated with chlamydospores of *Coccidioides immitis*. A parasitic stage in the life cycle of the fungus then occurs. It is believed that the saprophytic stage in the soil must then occur again before the fungus can be infectious to man because the disease is not transmitted from one human being to another.

Smith has reported, from evidences adduced from clinical observations, laboratory examinations and coccidioidin skin tests, that thousands of migratory workers in California have acquired coccidioides infection From the present evidence newcomers appear to be more susceptible to the benign infection than do natives or residents, who may have acquired a degree of immunity to the disease An investigation was made of 432 patients with "San Joaquin fever" in Kern and Tulare counties during the 17 months beginning December, 1937, which indicates the usual course, all recovered without sequelae.

The disease coccidioidomycosis occurs in two forms. (1) as an acute primary infection (valley fever) and (2) as a more chronic severe illness (coccidioidomycotic granulomatosis). Both sexes of all ages are susceptible

Valley Fever. After an incubation period of from 1 to 2 weeks the disease often begins with fever, generalized aches and pains. Soon there are skin manifestations resembling erythema nodosum, or occasionally erythema multiforme The cutaneous lesions are often associated with arthritis, sore throat and conjunctivitis As the disease progresses it may simulate the manifestations of bronchial pneumonia, tuberculosis, pleurisy, smallpox, measles, tularemia, syphilis and typhoid and occasionally poliomyelitis

The initial clinical manifestation may be an acute pneumonia indistinguishable from other types of pneumonia The physical findings and the roentgenographic evidence of pulmonary involvement may disappear promptly and completely as in an ordinary pneumonia However, in a considerable number of patients resolution of the pulmonic consolidation is slow The residual infiltrations consist of nodular densities, cavities, fibrosis and pleural effusion Characteristically these residual pulmonary lesions remain unchanged for months or even years The resemblance of the residual pulmonary lesions to tuberculosis is great.

Involvement of the joints in both benign and chronic types of coccidioidomycosis may occur The involvement may assume a mild form which usually subsides. In the serious phase of the disease the affected joints seem to be foci for dissemination of a generalized fatal infection

The joint manifestations are those of an acute or subacute bacterial infection.

Coccidioidal Granuloma. Coccidioidal granuloma in man is a chronic, progressive, highly fatal fungous disease affecting the lungs, skin, lymph nodes, bones, meninges, thoracic viscera and other body tissues. However, as in valley fever, it is probable that the initial lesion of coccidioidal granuloma is in the lung In contrast to the wide distribution of the lesions observed in man, the infection in cattle seems to be confined to the thoracic lymph nodes and the lungs.

Coccidioidal granuloma occurs more commonly among those who have dark skins than among those who have light skins.

Endogenous reinfection or dissemination at the time of the primary infection originates symptoms and physical findings of the more severe and usually fatal disease. This more fatal disease resembles disseminated tuberculosis. Lesions which are clinically indistinguishable from those of tuberculosis may appear anywhere in

the body, for example, in the lungs, larnyx, lymph nodes, bones, joints and central nervous system.

DIAGNOSIS OF COCCIDIOIDOMYCOSIS. The diagnosis of coccidioidomycosis in all forms is determined by the presence of *Coccidioides immitis* in pus, sputum, gastric contents, pleural fluid and spinal fluid.

Complement-fixing antibodies and precipitins can be demonstrated in the serum of patients infected with *Coccidioides immitis* The complement-fixing antibodies have the same significance as in blastomycosis, that is, they indicate spreading infection and poor prognosis. Hypersensitivity to the fungus can be demonstrated by the coccidioidin skin test. Positive results of the test usually develop in 3 to 21 days after infection, and a delayed tuberculin-like reaction occurs in 24 to 48 hours.

In the presence of a positive reaction to both the tuberculin and the coccidioidin skin test the diagnosis is difficult unless tubercle bacilli can be demonstrated In the absence of tubercle bacilli a presumptive diagnosis of coccidioidomycosis can be made if there is a history of possible exposure in an endemic area; if there is roentgenologic evidence of a pulmonary lesion, usually a solitary cavity or nodular density, which reveals no change after months or years of observation, and if there is positive reaction to the coccidioidin skin test The diagnosis of coccidioidomycosis in the presence of active pulmonary tuberculosis as revealed by sputum containing tubercle bacilli cannot be made.

An important feature in pulmonary coccidioidomycosis is the well-being of the patients, often without symptoms, unless there are pulmonary hemorrhages from a cavity. The presence of a coccidioidal cavity in a lung in the absence of tubercle bacilli may lead to an erroneous diagnosis of malignant disease

Commercially prepared coccidioidin is available It is prepared by dilution to the desired strength with sterile isotonic sodium chloride solution For sensitive patients, for instance those who are suspected of having coccidioidal erythema nodosum, a 1:10,000 dilution of the coccidioidin is advisable However, 1 100 dilution may be used which may evoke a severe local reaction and even some systemic reaction, but there seems to be no great danger of causing dissemination of an active infection or flaring up of a quiescent one if a reaction ensues In suspected ancient infections in the presence of pulmonary cavities presumably coccidioidal, a final test with 1 10 dilution is made. THE ALLERGIC STATE

A definition of the term *allergy* as adapted from von Pirquet and Rolleston describes all forms of altered reactivity of the organism, whether, according to time, early, accelerated or delayed, according to quantity, exaggerated, [illegible] or abolished, or according to quality, color of [illegible] includes all forms of [illegible] allergy is the term [illegible] ity or extreme inse[illegible] to express the hypersensitiveness produ[illegible] to a foreign protein, and depends on an antigen-antibody reaction

The *allergic state* indicates a condition of a human being, in relation to his peculiar internal, constitutional reactions to certain specific external materials These materials excite specific characteristic symptoms when they are applied to the body or come in contact with the body of one who has this state of altered reaction The same external materials, when applied to the body or when contacted in the same amounts by normal persons, are innocuous to them These materials are known as allergens

Hypersensitiveness is the ability of a person to react with characteristic symptoms to the application of or contact with certain substances (allergens) in amounts innocuous to normal persons

THE ALLERGENS

An allergen is any substance which is capable of inducing allergy or specific susceptibility Allergens at times are designated by the terms sensitinogen and sensibilisinogen An allergen may be a protein or a nonprotein It may be a purified protein or a protein of some food, bacterium or pollen

In practice it is observed that allergens or allergic excitants comprise large and heterogenic groups of materials They cannot be classified, they may be grouped These various substances or groups of substances have been referred to in many categories to which allergens may belong (1) foreign proteins and their degradation products as by digestion or chemical change, (2) water-soluble and fat-soluble plant extracts and pollen oils, (3) chemicals of low molecular weights including some metals (atomic) such as nickel, (4) bacteria, viruses, molds, fungi and yeast and (5) physical agents, such as heat, cold and certain wavelengths of light Any one or even a combination of these heterogenic groups of substances in a predisposed and previously exposed individual may excite an allergic reaction

Some of the allergenic substances producing allergic states are antigens; others, such as pollen extracts, can be shown to exhibit some degree of antigenicity, and many obviously are not antigens It is for this reason that the term allergen or allergic excitant is used to designate them all. Many of the nonantigens combine with proteins or other substances of the host's tissues and assume thereby the nature of an artificial antigen

It has become important from the standpoint of diagnosis to remember that

either living or dead microorganisms or their products which may be used in diagnosis such as bacteria, viruses, molds, fungi, yeasts, or their soluble constituents or the egg mediums on which they are grown, and possibly certain of their metabolites, may be allergens. During an infection there may be a progressive invasion of the host and multiplication of the invading material and this material is an allergenic excitant. In some persons certain wavelengths of light and chilling (classed as physical allergens) cause reactions.

The materials which may give rise to the allergic states, and thereafter produce allergic reactions, as has been stated, are numerous. Common among these materials are foods, drink, particularly beer, foreign proteins and digestion products of these. Substances which may be found to be allergens are the water-soluble materials contained in pollens; pollen oils and other fat-soluble plant extracts, including urushiol from poison ivy, fat-soluble materials such as those which may be found in chocolate; chemicals and drugs of low molecular weight, such as formaldehyde, 2,4-dinitrochlorobenzene, paraphenylenediamine, mustard gas, quinine, aminopyrine, and sulfadiazine; and metals such as nickel

Sensitization is the ability of a person to react to an allergen with each contact. In certain allergies such as hay fever the *genotype* of the individual seems to exert control over the capacity for sensitization.

Sensitization may be the result of repeated exposures, and the necessary number of these varies among individuals and is indicative of differences in the host factors determining susceptibility to sensitization

The manifestations of allergy are multiple, varied, and distinct. These different reactions are manifestations of basic mechanisms with which the body is endowed These basic mechanisms respond by the production of specific substances to counteract the offense of specific offending matter. The recognition of the specific offending matter previously met with is accomplished by means of antisubstances The production of antisubstances (antibodies) in response to the specific offending matter (antigenic stimuli) is the antigen-antibody reaction.

In human allergies related to circulating antibodies, it seems that antibodies can be distributed unequally. An expression of this supposition is the term shock organ, which is used to distinguish the sites of predilection for allergic reactions, for instance, the bronchial mucous membrane (asthma), the mucous membranes of the eyes and the upper part of the respiratory tract (hay fever, allergic coryza or rhinitis), epidermal cells (eczematous reactions), the gastrointestinal mucosa (gastrointestinal allergy), or endothelium of the superficial vessels in the skin (urticaria, wheal-reacting allergies)

No human antibodies have been found accompanying certain of the human allergic manifestations, as, for example, allergy of the tuberculin type, contact dermatitis, and allergy to certain drugs It must be recognized, however, that this in no way invalidates the idea of fixed cellular antibodies in these instances. At the same time, it is observed that the agents responsible for these human allergic manifestations will not induce anaphylaxis in animals

Heredity is peculiarly important in the predisposition to development of allergy. However, heredity appears to be of no importance in the development of anaphylaxis. It is known that allergic diseases are not inherited as such. The allergic person inherits a predisposition or capacity to become sensitized and in consequence there develop unusual and specific reactions to certain allergens if sufficient contact with the latter occurs. The term *atopy* (meaning strangeness) is widely used to designate those conditions in which this hereditary tendency is recognized and which are mediated through the mechanism of atopic reagin Atopic disorders in this sense include hay fever, asthma, atopic dermatitis (eczema), angioneurotic edema and natural serum sensitiveness *Urticaria is not always* atopic. Allergic diseases which appear not to be influenced by the m

heredity and in which the reaginic mechanism is not demonstrable include contact dermatitis, bacterial allergy (tuberculin type), induced serum sensitiveness (serum sickness) and drug allergies.

TYPES OF ALLERGIC RESPONSE

Allergic reactions are of two types: the immediate type (for example, urticaria) and the delayed type (for example, tuberculin reaction)

Immediate Type. The reactions of immediate type become well developed soon after application or after adequate absorption of the corresponding allergenic substance, for instance as in asthma, hay fever and hives. In many instances of sensitivity of this sort circulating antibodies are demonstrable, and there is some accompanying cutaneous reactivity which assists in recognition of the allergen by means of a wheal-and-erythema response in the skin where the allergen is applied.

Local reactions to foreign proteins are transient in man. These local reactions are analogous to, and differ only in degree from, the Arthus reaction in the rabbit. Depending on the degree of sensitiveness and the availability of antigen, the patient will react within 15 to 90 minutes at the site of intracutaneous injection, with development of erythema and edema of variable degree.

The local inflammatory reactions which occur in anaphylactically sensitive persons are fundamentally similar to the foredescribed local reactions, and likewise the ability to react can be generally transferred by means of serum if the transfer is made to a person who has by heredity received a constitution which will permit the occurrence of allergic sensitization

Prausnitz and Kustner discovered that certain local skin reactions are transferable. In their work Prausnitz received in his skin a small amount of serum taken from Kustner, who was sensitive to fish or to foods containing fish Twenty-four hours later an extract of fish was injected into the site so prepared A local reaction developed in the course of some minutes and rapidly faded This technic was then extended and found to be applicable in many clinical allergies Whealing occurs at a sensitized site not only when the allergen is introduced locally but also when it is injected into remote tiss [illegible]

or [illegible]

spontaneous allergic states such as seasonal coryza and asthma, and with some kinds of eczema in those who are hereditarily disposed

The possession of reagins coexists with the presence of a corresponding clinical disorder The location of the principal reactive sites, shock tissue, determines the particular disease In some instances, however, reagins may be present in the circulation without manifest disease

The reagins or skin-sensitizing antibodies belong in the gamma globulin fraction of serum, are unduly heat labile, and possess as a distinguishing characteristic the property of sensitizing and remaining fixed in normal human skin for 6 weeks. During this period at any time a reaction may be had on the administration of an allergen The reaction occurs at the site of discharge, for instance, on the skin The reagins present in natural instances of hypersensitivity are not likely to precipitate the allergen unless the antibody is sufficiently concentrated. In instances of induced hypersensitivity reagins may appear in admixture with other, precipitating antibodies These naturally occurring reagins do not pass the placental barrier.

The clinical improvement from treatment of allergic patients by repeated injection of their own allergens is not produced by a diminution in the amount of their circulating reagins, but the injection gives rise to another, thermostable antibody, that is, to one that fails to sensitize the skin and withstands temperatures deleterious to reagins Normal persons under the same treatment give rise to the same antibody, but they do not produce reagin. This thermostable antibody com-

bines readily and specifically with the allergenic material, thereby neutralizing the latter so that a mixture of the two will not produce a positive cutaneous reaction on a sensitive person. The thermostable antibody is therefore termed the blocking or inhibiting or neutralizing antibody

The development of this [illegible] [illegible] body has been considered responsible for the clinical improvement, the [illegible] ment This assumption, however, has not been proved

Delayed Type. Reactions [illegible] ed type, on the contrary, require at least several hours after introduction [illegible] llergen before an effect is manifest. Such reactions may be illustrated by [illegible] the reactions caused by poison oak or poison ivy, most drug sensitivities and reactions to products of microorganisms for example tuberculin and histoplasm[illegible] These delayed reactions show progressive changes for 2 to 3 days or longer after contact or cutaneous administration.

Systemic Anaphylaxis. Anaphylaxis is an acute systemic reaction that i[illegible] exhibited by those in the hypersensitive state on subsequent injection of the same materials. This reaction comes on soon after the injection of the material and i[illegible] therefore of the immediate type. It has been observed in different species of animals and it is essentially the same regardless of the species or the antigen-antibod[illegible] system involved.

The mechanism by which anaphylactic shock is brought about is not full[illegible] understood According to current concepts, the important element is injury to th[illegible] tissues, particularly the vascular endothelium, either by antigen-antibody interac[illegible] tion or by *nonspecific materials such as peptone or serotoxins; subsequent* event[illegible] are determined largely by materials leaving the injured tissues Those who give a[illegible] immediate type of skin-testing reaction are the [illegible] system[illegible] accidents However, there are the early allergic [illegible] tion and the anaphylactic shock. There are ma[illegible] cause anaphylactic shock but cause variable degrees of symptoms. Such sympton[illegible] are termed *anaphylactoid reactions*

In the early or allergic inflammation type of response the dose of the allerge[illegible] is small. When relatively small amounts of antigen or allergen are introduced in[illegible] the tissues of a sensitive person, contact is localized, and the rate of absorption c[illegible] dissemination is retarded by tissue barriers and by existing antibody mechanism[illegible] The primary response of the tissues concerned is a local inflammation, initiated an[illegible] for a time kept stimulated by the allergic mechanism

In these hypersensitive persons small doses of the allergen may cause anaphy[illegible] laxis; in others larger doses of the allergen may be required to produce anaphylact[illegible] shock Anaphylactic shock is characterized by collapse, fall of blood pressure tachycardia, dyspnea of the asthmatic type, suffusion of the face, urticaria witl[illegible] giant wheals, and sometimes marked edema of the entire body In fatal instance[illegible] death may occur within a few minutes or as late as 24 hours after administratio[illegible] of the allergen

Systemic anaphylaxis may be observed under many circumstances. It may occu[illegible] immediately if the patient has had prior contact with the injected materials In other instances anaphylaxis may come on only after repeated injections of tetanus *toxoid and of a prophylactic preparation of alum-precipitated diphtheria* toxoid and pertussis antigen

Among persons who have become sensitized to foreign serum because of prior administration, those who have become so hypersensitive that on skin testing they give the immediate type of reaction are most prone to systemic anaphylaxis. In these cases the *histologic findings* are far more violent than in those of mild, transient inflammations. In other patients who have become very sensitive the specific reaction which ensues after the allergen is introduced into the tissue may be either an early or a delayed tuberculin type of reaction

The occurrence of the early type of local reaction coincides with the presence in the serum of antibodies that are capable of transferring corresponding sensitivities to normal persons.

When antigen is deposited in the skin or the subcutaneous tissues of anaphylactically sensitized animals, local allergic inflammatory responses start almost at once, with hyperemia and edema These reactions may be either frankly evanescent or more persistent If the reaction is more persistent and the skin becomes necrotic and sloughs, the state is termed the *Arthus phenomenon* (rabbit).

HISTORY

Elaboration of the principal complaint of a patient who has an allergy usually reveals other symptoms of allergic manifestation aside from the one from which relief is sought. These multiple manifestations emphasize that shock tissue in man is widely distributed throughout the body and that these different manifestations are the result of a single basic mechanism This concept, if kept clearly in mind during the interrogations necessary for history taking, permits an understanding of the different symptoms which may result from a single antigenic substance

It is well to know that in order for the foreign substances to reach the sensitized cell, either direct contact with cells on the surface of the body or with the lining of the respiratory and the alimentary tracts, or the passage of the substance through the blood or the lymph is necessary Direct contact of the foreign substance, however, may permit it to reach the blood stream by being absorbed from the skin, mucous membranes, or intestinal canal or from parenteral injection made as a preventive or therapeutic measure Once the allergic excitant reaches the blood, it will reach the shock tissues wherever they be situated The same symptoms therefore are produced whether the excitant is absorbed from the skin, the intestinal tract or the lungs. For instance, atopic dermatitis, urticaria, angioneurotic edema and other manifestations may result from absorption of naturally occurring protein or other allergic substance from the intestinal canal or the skin

The history may make clear the manifestations of allergy and, by so doing, renders other allergic symptoms, often bizarre and heretofore undescribed, recognizable and explainable with demonstration of an allergic mechanism in the production of the presenting symptoms

In eliciting the family history it is remembered that specific hypersensitivity is not inherited The development of a specific hypersensitiveness depends on a sensitizing exposure to the particular substance or substances to which the patient may be demonstrably sensitive The factors and circumstances which attend the development of natural specific hypersensitiveness (atopic) are obscure. An acquired sensitivity does not endure so long as a natural sensitivity Those who have sensitivity acquired as a result of a serum injection may be desensitized, while those having sensitivity of the natural or spontaneously acquired type cannot be.

The existence of a hereditary predisposition in both hay fever and asthma has been postulated and recorded by numerous observers Doerr-Basel has expressed the belief that the variation in the clinical manifestations of constitutional sensitiveness in allergy suggests that the capacity to become sensitive is present in all human beings but in different degrees For these reasons an inherited tendency is carefully sought for in the family history, for it is to be regarded as the most important factor determining the probable development of an allergic state in any individual.

Allergens are similar to infectious agents in that both have unknown but definite causes for their methods of entrance. Thus, in patients who have nasal manifestations of allergy due to pollen, the nasal absorption of the allergen plays probably the most important part in sensitization.

Age at Onset. The incidence of the manifestations of allergy is highest in the first 10 years of life From the age of 10 years to that of 50 years the rate of onset is about evenly distributed. About one half of those who have an allergy are made aware of it before the age of 50 years The distribution between the sexes is equal.

CLINICAL MANIFESTATIONS

At one time or another diverse disease states which are in reality manifestations resulting from the mechanism of allergy have been described as disease entities of obscure etiology

In allergies related to circulating antibodies the antibodies can be distributed unequally among the various tissues Any tissue having more than its share of antibodies is termed a shock organ. The term shock organ is used therefore to distinguish the sites of predilection for allergic reactions. Basically the mechanisms for the election of the sites of predilection for allergic reactions are not explainable.

The allergic response may or may not correspond to the portal of entry of the allergen Some allergens are inhaled, some are swallowed, others are injected, while still others are obtained by contact. A number of allergens such as those associated with the infections are formed in the body and are detected by the injection of the proper excitant The method or means of obtaining an allergen cannot always be determined, for indeed the offending substance may enter through all routes

The common clinical manifestations which often may be proved to be an allergic response are manifested in the skin as a dermatosis (including conjunctivitis and rhinitis), respiratory manifestations such as hay fever and asthma, and certain digestive disorders

Skin (Dermatosis). The cutaneous manifestation of hypersensitiveness of the skin, or dermatosis, may be of the immediate type (wheal-and-flare reaction) or it may be a delayed response

In practice it very frequently is difficult to know whether a particular cutaneous reaction is immediate or delayed in type Likewise it is often difficult to determine whether a particular dermatosis has been caused by contact with an allergen or whether the allergen has been inhaled or ingested.

Hypersensitive Cutaneous Reactions. For purposes of clinical description hypersensitive cutaneous reactions may be associated on the bases of the degree of reaction (1) the mild reaction consisting of erythema, (2) urticaria and (3) vesicles and bullae

Erythema Erythema is the mildest reaction and may occur as a punctate red eruption, as in scarlet fever, or as irregular reddened areas over various parts of the body There is no elevation of the temperature of the skin as there is in hyperemia The color may vary from light red to smoky purple. The colors are changeable, and may vary from time to time during the reaction With or without immediate changes of the coloration of the skin, urticaria may appear.

Erythema multiforme is a disease of young adults. It has a seasonal incidence in spring and fall Maculopapules, varying in size, pink, not scaly, and generally itchy, occurring on forearms, hands and face, are the main features of the disease Sometimes the eruption assumes a bullous form, and at other times there is an urticarial element.

Psoriasis, seborrhea, dermatitis and ringworm are differentiated mainly on the basis of the recent history, the distribution of lesions, and the absence of scaling. The differentiation from syphilis rests mainly on persistently negative serologic reactions

Flexural Prurigo. The lesions of flexural prurigo occur at the bends of the

elbows and the knees, and on the neck. They consist of papules and vesicles on areas of thickened, lichenified skin.

Dermatosis from Wearing Apparel. Dermatosis may arise from fabrics such as silk, wool, synthetic fabrics, leather, and artificial leather; from furs, rubber, and rubber-containing articles such as rubber gloves, dress shields and girdles, socks, pajamas, and brassières, and from metal alloys and plastics used in jewelry and in eyeglass frames, wrist watches and straps

Hypersensitivity to Naturally Occurring Fabrics. Schwartz and Peck have expressed the belief that an occasional dermatosis may occur because of hypersensitiveness to naturally occurring, unprocessed fabrics such as silk, wool, fur, or leather. Hypersensitiveness does not occur from linen and cotton fabrics However, a dermatosis may develop in those who pick flax, and from the oils of flax and cotton. (The oil of cotton is oleum gossypii seminis.)

Dermatosis may result from friction of a woolen garment when worn directly in contact with an actively moving part of the body This is not an allergic response.

Dermatosis from feathers in wearing apparel is very rare

Dermatosis among the wearers of furs may occur from the mechanical friction of the coarse hairs against the skin or from a sensitivity to the unprocessed fur However, although the chemicals used for tanning and dressing fur rarely cause dermatosis, in the majority of cases in which it occurs the dermatosis is due to dyes and tanning agents In order to cause sensitivity the furs must be so poorly dyed that the dyes are leached out by moisture Once sensitivity has developed, even a well-dyed fur may cause dermatitis The reduction of the incidence of dermatosis among the users of furs is in the hands of the dyers In recent years the dyers have been aware of this fact and have processed the furs with greater care than formerly so that now reports of such cases of dermatosis rarely appear The preventive measures used by the dyers include the use of weak solutions of the dyes, applied frequently or applied for longer periods, the careful oxidation of the dyes and the thorough removal of excess or unoxidized dyes by washing and drumming

Dermatosis among leather workers is due to the many primary irritants and sensitizers used in processing the hides to convert them into leather Dermatosis from hatbands, gloves, wrist-watch straps, pocketbooks and other leather articles has been reported. However, the incidence of dermatosis due to wearing and handling leather goods is small In the majority of instances due to contact with leather the dermatosis is of the allergic type The sensitizing chemicals may have been dissolved out of the leather by water or perspiration

Dermatosis may occur from artificial leather from the dyes, the resins, the formaldehyde, sulfur, the antioxygen and other chemicals used in the manufacture. The inner lining of shoes as well as the backing contains chemicals which may cause dermatosis The backing of shoes contains adhesives, antimildews and fungicides. In a number of instances artificial leather is used on the inside of the shoes

Hypersensitivity to Synthetic and Processed Fabrics. Most instances of dermatosis among the wearers of fabrics, according to the experience of Schwartz and Peck, is caused by the finishes rather than by the dyes Processed fabrics are made of cellulose (rayon) and of a number of plastics and other materials

The synthetic resin finishes have caused a number of cases of dermatosis. The completely cured resins do not as a rule cause dermatosis When complete polymerization and stabilization do not occur, there may be enough uncured resins remaining on the fabric to cause dermatosis in sensitive persons

Fabrics treated with tar or resins and rubberized in order to make them waterproof cause dermatosis only among the processors of the fabrics Canvas and leather gloves, sleeves and aprons used as a protection by welders cause dermatosis among the workers who process the fabrics but not among the users of these fabrics

Silicofluorides, chloronaphthalenes (naphtha balls), chlorobenzene, chlorophenols, and synthetic camphor used in mothproofing do not cause dermatosis.

The best known of the purely synthetic resin fabrics is nylon In all instances dermatosis from nylon is caused by a certain finish and not by the nylon itself.

Cases of dermatosis due to glass fabrics have been reported The dermatosis is due

to the resins or the mechanical irritation of the rather sharp fibers and not to allergy.

Glass wool for insulating purposes causes a mechanical irritation from the sharp ends of the broken glass threads and occasionally from sensitivity to the resin binder (phenolformaldehyde).

Rubber hydrochloride, vinyl resins, acrylic acid resins and cellulose acetate are laminated onto cotton or other natural fabrics in order to make them impervious. Dermatosis in all instances of exposure is due either to plasticizers or to stabilizers used in the films.

Rubber gloves, girdles, dress shields, gas masks, and condoms have all been reported to cause dermatosis In these cases the accelerator and antioxygen or compounds formed on the surface of the rubber by "vapor cure" (sulfur monochloride) were the actual irritants, not the rubber itself Dermatosis from "vapor-cured" rubber is caused by continuous changes taking place on the surface of the rubber, and these changes result in the formation of sensitizing chemicals Those who have dermatosis from wearing vapor-cured gloves (for example, surgeons) may prevent it by soaking the gloves in a 5 per cent solution of sodium carbonate for 15 minutes and then rinsing them in water, sterilizing by dry heat, powdering them well on the inside, and wearing them dry. The same procedure may be adopted by those sensitive to rubber gloves made from latex, because in such gloves the accelerators and antioxygen are easily leached out by perspiration

Several types of synthetic rubber used in wearing apparel may cause dermatosis Most of the dermatoses from synthetic rubbers probably are due to the same compounds that cause dermatosis from natural rubber, although synthetic rubber does contain sensitizing substances not present in natural rubbers

Dermatosis due to fabric dyes is relatively infrequent When dermatosis is caused by the dyes, it is usually due to an idiosyncrasy to the dye itself or to a faulty process of dyeing, so that there is retained in the fabric some chemical which should not have been present

When dyes themselves cause dermatosis, they "bleed" or come out of the fabric easily. Dye intermediates are more likely to cause dermatosis than the finished dyes themselves Under conditions such as the heat of ironing, some dyes will break down into their intermediates Wool is often dyed by the aid of a mordant Of the mordants it is the dichromates which cause dermatosis and not the dye.

Special acetate dyes are used for dyeing of rayon and these may cause dermatosis.

Dermatosis produced by jewelry in most instances is due to metallic jewelry containing nickel. Dermatosis can occur from some of the modern jewelry made from various synthetic resins, glass and casein The finished products and not the unprocessed material may give dermatosis.

The essential indication that dermatosis originates from wearing apparel is that the eruption begins at the place of contact with the offending material, usually 5 or more days after the garment has been worn The eruption may commence immediately if the person is already sensitive to the chemical in the wearing apparel which causes the dermatosis It is exceptionally rare for a generalized eruption to appear, but such may be the case, and sometimes systemic symptoms such as elevation of temperature may accompany the dermatosis These illnesses resemble serum disease or serum sickness

Bacterial Toxins. There are a few dermatoses which result from infections by bacteria which are known to produce toxins which irritate the skin during the course of the infection or which give a delayed type of cutaneous reaction Some of the special types of delayed reactions are used in diagnosis.

Streptococcids. Streptococcids are grouped miliary papular *eruptions occurring* during the course of streptococcal infections

Tuberculids and Tuberculous Dermatosis. Tuberculids or the lesions of tuberculous dermatosis do not contain tubercle bacilli, but although an active primary focus may not be evident, there is a positive reaction to the Mantoux test

The *papulonecrotic tuberculid* affects the follicles of the skin, producing a deep-seated nodular and occasionally necrosing lesion Lesions of this type may occur without evidence of active tuberculosis. Whether or not there is active tuberculosis

does not minimize the importance of distinguishing these lesions from those caused by syphilis.

Lichen scrofulosus is a round or flattened, small reddish yellow papule in an inflammatory patch occurring in a patient who has glandular tuberculosis.

Erythema induratum (Bazin's disease, tuberculosis indurativa) begins as hard, deep-seated nodules on the skin of the lateral and posterior aspects of the distal regions of the leg At first the lesions are light brown, which changes to light red The color may become darker, and the lesions soften and finally break down, forming ulcers which have abrupt edges. The disease is chronic, and when the ulcers or nodules heal, their former sites are marked by deeply pigmented spots. Definite evidence of tuberculosis elsewhere may or may not be present. Reaction to the Mantoux test is positive.

Erythema induratum is differentiated from erythema nodosum by the fact that in the latter the lesion does not ulcerate, does not show pigmentation, and the disease yields to salicylate therapy Varicose ulcer is accompanied by an evident varicosity of the veins. A satisfactory differentiation from syphilis is not possible.

Trichophytids, generalized papular eruptions, may occur in those who have ringworm If a positive reaction to trichophytin is present, it may be diagnostically helpful.

Erythema nodosum is associated with rheumatic fever and tuberculosis. Erythema nodosum occurs in two young women for each young man so affected.

The etiology of erythema nodosum seems to be uncertain, for some consider it a disease caused by a specific virus, while others consider it an accidental phenomenon of allergic nature in different diseases The occurrence of erythema nodosum in association with various drugs and the significance of sulfathiazole in children, mainly with reference to primary tuberculosis, seem certain Erythema nodosum can develop in association with treatment with other sulfonamides, but frequency is low compared with that associated with sulfathiazole therapy There is no difference between the lesions of spontaneous erythema nodosum and those of erythema nodosum following the administration of drugs, although in the latter the lesions clear up rapidly when administration of the drug is discontinued without passing through the color phases of the spontaneous type.

The concept that erythema nodosum is associated with tuberculosis is prevalent Holmdahl concluded that the primary infections seem to be combined with erythema nodosum to about the same extent during the various periods of childhood, with the exception of the first years of life Holmdahl followed 657 patients who had primary tuberculosis with erythema nodosum from birth to the age of 16 years The observed prognosis was least favorable in those who had primary tuberculosis with erythema nodosum in whom primary tuberculous changes were demonstrable and in whom the course of the primary changes or the rise in sedimentation rate was protracted.

The lesions are of various sizes, some of them from 1⅕ to 2⅖ inches (about 3 cm to 6 cm) in diameter They are raised above the surface, are of a bright reddish color, and appear to be inflammatory, they are smooth, glistening, and are exquisitely painful on palpation At first the nodules seem to be firm and deep-seated. Later they may fluctuate, but they do not contain pus Erythema nodosum always comes on suddenly, and very frequently the lesions are accompanied by constitutional symptoms consisting of fever and generalized aches and pains. The lesions slowly clear up but tend to recur until the general health has been restored.

Urticaria. Urticaria is a more intense reaction than erythema. The hyperemia, if present, goes immediately to actual exudation of serum into the intercellular spaces and there are raised patches of skin with central white raised zones These urticarial wheals may have areas of redness around them. The urticarial lesion is of

short duration, perhaps a few minutes. Successive lesions may follow, and the disease may last, continuously or intermittently, for weeks, and *in some chronic cases, for* year[illegible] If pigmentation occurs with the lesions, the condition is urticaria pigmentosa, a st[illegible] [illegible]tion

[illegible] llergic state However, the association of urticaria with stress[illegible] [illegible]en observed by many.

Graham and Wolf found that in every pa[illegible] who could be adequately studied there was one leading factor in precipitating hives. This was a *feeling of intense* resentment generated in situations in which the person believed that he was unjustly "taking a beating" but could neither fight nor run Thus in every case in the series reported, exacerbations and remissions of the disease showed a good correlation with a particular attitude toward situations of living but little or no correlation with anything else.

It is important, according to Graham and Wolf, to distinguish between resentment, the feeling so characteristic of these patients, and hostility. Resentment is "a feeling of indignant displeasure because of something regarded as a wrong or insult," while hostility is "a feeling of antagonism or enmity, employing a wish to take aggressive action " Resentment, of course, may lead to hostility, but it is significant that in persons who have urticaria it usually does not

Prurigo. When an urticarial wheal subsides, an itchy papule may persist, *urticaria papulosa.* Prurigo may be a continuation of urticaria papulosa. The term prurigo designates secondary changes which take place in the skin following and accompanying the urticaria papulosa The thickened skin in the affected region loses its elasticity and manifests disturbances of pigmentation Many places may show depigmentation, and others show increased pigmentation Interspersed between these regions there are the hard, subsiding papules, generally 2 or 3 mm in size The regional lymph nodes become enlarged

Urticaria Pigmentosa In urticaria pigmentosa wheals can be produced by trauma (rubbing the skin with the hand) The additional characteristic of the disease is the *appearance of pigmented macules and nodules The disease begins in early infancy* and usually ceases after puberty, however, it may continue into adult life

Vesicles and Bullae. Severe reactions to toxins are characterized by vesicles *and bullae Dermatitis and pemphigus are examples of such reactions*

Dermatitis Herpetiformis. This is a chronic intermittent disease, mainly of young adults, though it occasionally occurs in older persons The patient's general *health remains good The intensely itching cutaneous lesions consist of symmetric* herpetiform groups of vesicles on an erythematous base The itch in dermatitis herpetiformis is as intense as this sensation can be, and still this itch is relieved by scratching The patient may remove the lesion with the fingernails, preferring the pain thus produced to the intense itch When the vesicles are thus destroyed by scratching before the patient is seen by a physician, the diagnosis may be difficult because the typical vesicles cannot be observed Reliance is placed on the history of the vesicles and the occurrence of erythematous patches with excoriated spots situated symmetrically over the thorax and limbs Tearing of the skin by scratching leaves scars Untouched lesions heal without scars Healing of these lesions is often followed by a brown *pigmentation which will finally fade away*

The prognosis is good as regards life, but the recurrent character of the disease and its indefinite duration are not pleasant to contemplate

Pemphigus. The varieties of pemphigus, namely, pemphigus acutus, pemphigus vulgaris, pemphigus foliaceus and pemphigus vegetans, are all included in this group of toxic dermatoses (dermatitis herpetiformis and pemphigus). All are characterized by serous effusion into the epidermis, giving rise to bullous eruptions. General symptoms do not always occur In some cases severe toxemias develop; when these occur, the patients often die.

The lesion of pemphigus is a blister, tense and clear, rising from apparently normal skin but becoming turbid, with a red inflammatory areola at its base as it becomes infected. When ruptured, a red, oozing region is left, composed of the superficial layers of prickle cells. This rapidly dries up and the horny layer re-forms, leaving no trace of the lesion. All forms of pemphigus are accompanied by evidence of general toxemia, but in contradistinction to dermatitis herpetiformis, there is no itch

Pemphigus Acutus. Acute pemphigus is a dangerous and fortunately a rare disease It is a form of pemphigus known as butcher's pemphigus because of the relative frequency with which it formerly occurred in butchers In these cases there is a history of a cut followed by general symptoms and only 1 or 2 bullae. These lesions gradually increase in number, often become hemorrhagic, and toxemia sets in.

Pemphigus Vulgaris This is chronic pemphigus It begins as an acute pemphigus with a few bullae, usually not grouped There is slight itch or pain The bullae heal as others form elsewhere, and thus the disease continues for months. The process may clear, not to return, or it may recur after a period The mucous membranes of the mouth may be affected. If the disease recurs, the patient's general health suffers and death may result ultimately The lesions of the mucous membrane in the mouth, nose and pharynx prevent eating because of the intense pain

In young, healthy persons the disease often runs a mild course and clears up permanently In a person of 40 years of age or more there is a tendency to relapse, and each relapse is more serious than the original attack.

Pemphigus Foliaceus The term pemphigus foliaceus derives from the loose epidermis remaining after the bullae have been ruptured. Two varieties of pemphigus foliaceus occur, a primary form, and the other secondary to pemphigus vulgaris.

When firm slanting pressure is made with the finger on an area of apparently sound skin, the top layers of the epidermis will separate and slide along on the lower layers, leaving an exposed raw surface This skidding phenomenon of the epidermis is pathognomonic of pemphigus foliaceus. The mucous membranes are affected. As the disease becomes generalized, the hair and nails are lost The raw surfaces become widespread, especially over the flexures. Shortly prior to death this is truly a terrible disease.

The prognosis is poor In many cases, after a variable period of time, death ensues from pneumonia or septicemia

Pemphigus Vegetans. This disease affects the lips, mouth, axillae and pubes. The bullae rupture and on their bases arise vegetations, hypertrophic, painful lesions which refuse to heal. Like pemphigus foliaceus, the disease often is fatal

Mixed Dermatoses. There are unknown toxins which may cause an erythematous, an urticarial, or a vesicular or bullous eruption When the skin reacts in a nondescript way, the condition is termed a dermatitis or an eczema One, two or more of these responses may occur simultaneously and the response is then termed a mixed response

Eczema. The etiologic agent or agents responsible for eczema are unknown There are factors, such as irritation, which determine the onset of eczema A lesion is present on the skin, for instance, an area of contact dermatitis, which becomes infected by scratching, after which eczema appears Scratching is a factor in keeping eczema active

Eczema comprises many types of cutaneous lesions, depending on the reaction to a toxin These lesions are (1) erythematous, (2) urticarial, (3) papular, (4) pustular and, when regressive, (5) scaly

Eczema is characterized by commencing in the epidermis The reaction of the skin in eczema is not so great as in dermatitis A patient who has eczema may have a personal or a family history of allergy There may be a history that the progression of the disease is by acute exacerbations of the chronic process. Easy exhaustibility may occur just before appearance of the eruption Eczema often reaches its peak

of severity by repeated acute exacerbations separated by more quiescent periods, and may remain for a long time fluctuating at the peak. In time the disease slowly subsides, but during the period of regression there are still relapses. Some persons never get well. Fever is not a feature of eczema unless the skin becomes infected by pyogenic organisms.

Patchy Eczema. A chronic eczema consists of slightly raised, dull red patches, studded with crusts of millimeter dimensions over a circumscribed area of skin The chronicity of these patches is the characteristic of eczema. These lesions often are associated with anxiety, tension and worry, failure to relax, and resultant fatigue. A lessening of the anxiety coincides with disappearance of the eruption.

Generalized Eczema. A generalized eczema frequently starts from an irritation of a patch of chronic eczema. There is an acute exacerbation of the patch, say on one limb, manifested by becoming larger and spreading, and often having the appearance of urticaria as it spreads Then areas of eczema occur on various parts of the thorax, across the shoulders and the sacro-iliac region General symptoms may accompany these acute exacerbations

Respiratory Passages. As has been stated, the portal of entry does not necessarily determine the site of the shock organ. However, in respiratory allergic disorders the allergen usually is inhaled

Pollens cause many of the respiratory allergies They may be the cause of the recognized states of seasonal hay fever and asthma, or any other allergic ailment which is restricted to the seasons during which these occur, or they may become manifested in the presence or the handling of certain blooming house plants Likewise seasonal dermatitis and some urticarias caused by pollens have been definitely proved A patient sensitive to the pollen of tall ragweed, for example, is sensitive to all other ragweeds of the same genus as well as to closely related genera The same antigenic relationship appears to exist in regard to all members of other taxonomic groups

Dander from any hair-bearing or fur-bearing animal is potentially a source of allergen for predisposed persons. The relative importance of the respective members of this group appears directly proportional to the extent that conditions of contact are favorable to it

The *feathers* of geese, ducks, chickens, parrots, canaries, pigeons, sparrows, pheasants, and grouse have been known to cause asthma and vasomotor rhinitis. Feathers may also be the cause of cutaneous manifestations.

Although *dust* is omnipresent, not all types are allergenic. Occupational dusts of various types are important *House dust* is the commonest allergen of this type because of its universal distribution All types of dust, from road and field dust to those originated by occupations or industry, are present wherever man lives Not all of these are the means of production of allergic diseases. Some of these dusts produce disease by the presence of particulate matter

The *seeds* of cotton, kapok, and flax may be allergens. *Cottonseed oil* is a common food oil and fat Occasionally it is an allergen Kapok is used in the manufacture of mattresses, pillows, and furniture The oils of kapok, and occasionally of flaxseed, have uses similar to those of cottonseed oil.

Orris root is present in face powders, face packs, tooth powders and pastes, bath powders, scented soap, and perfumes and hair tonics Confectioners and bakers mix orris root with candies and pastries to impart the odor of violets Its use as a dry shampoo is common Tincture of orris is sold as a cheap violet perfume. Orris root is a very important source of allergens

Allergic disease of respiration is suspected in those who have symptoms of hay fever or asthma with or without an accompanying eczema, urticaria, or angioneurotic edema Respiratory allergic diseases often occur and are related to a known environment where there exist dusts of domiciliary or of occupational origin which are inhaled, or where there is contact with certain plants or chemicals and other suspected materials

An uncommon frequency of "colds," bronchitis or pneumonia in childhood suggests the existence of an early allergic stage.

The history of asthma, hay fever, or eczema among the relatives bespeaks a strong probability of allergic constitution of the patient This probability is proportional to the genealogic incidence and the proximity to the patient of allergic individuals in the family

Hay Fever. The symptoms of hay fever begin suddenly and often there is a punctuality in the date of annual recurrences There are the symptoms of severe coryza with moderate to profuse watery discharge The eyes are reddened and watery, with itching lids. The senses of taste, smell, and hearing are dulled and in some instances greatly impaired In some patients a cough may be mild, in others it is severe The cough is excited by a tickling sensation in the throat When symptoms are severe, there are chilliness, insomnia and poor appetite, which are soon followed by weakness. The symptoms vary from day to day and there may be attacks of bronchial asthma. The symptoms last just as long as the patient is exposed to the offending allergen

Allergic Bronchitis. Allergic bronchitis is a perennial or seasonal allergic reaction to sensitizing substances in a susceptible individual It is characterized by a chronic recurring or paroxysmal cough, which usually occurs in the absence of infection of the upper part of the respiratory tract or of intrathoracic disorder.

The primary symptom of chronic dry cough may be accompanied by blood-streaked sputum, expectoration of mucoid or mucopurulent sputum, wheezing, dyspnea, frequent colds, fever, fatigue, loss of weight, anorexia, thoracic pain, sweating, hoarseness, and aggravation of cough with exertion

Diagnosis is primarily the exclusion of all other possibilities A family history of allergy and other personal manifestations of allergy may indicate the diagnosis, but lack of them does not exclude it Most of the causative allergens are inhalants or caused from foods The high incidence of sensitivity to fungi and mold is probably indicative of strong antigens and also of a high incidence of epidermophytosis

The roentgenologic examination of the lungs is the most useful procedure in excluding organic disease of the lungs and pleurae Cardiovascular disease is considered and excluded. Most helpful is a history of similar attacks or other allergic manifestations

Asthma. Allergic asthma is a paroxysmal respiratory reaction manifested by an expiratory dyspnea of a noisy wheezy type

A working classification of allergic asthma has been made by Rackemann based on the assumption that asthma occurs in only those who have inherited the "asthmatic state" and that asthma due to extrinsic causes begins before the age of 30 years Asthma occurring after the age of 30 to 40 years is due to intrinsic causes.

The disease commencing before the age of 30 years is caused by something present in the environment, it is extrinsic In such case the symptoms come and go and are precipitated by, for instance, pollens, dusts, cosmetics, textiles, chemicals and animal products

Asthma which begins after the age of 30 years, particularly after the age of 40 years, is intrinsic asthma The cause is in the patient An occasional older patient will have idiopathic emphysema, cardiac asthma, or bronchial tumors, but many of them will have none of these things

These older patients will have nothing more definite than evidence of psychic or somatic stress or tension. To assign a psychic or emotional etiology for this group of patients is probably correct, but rarely is this the only cause for poor health Emotional disturbances which may be thought to be the cause of the asthma may be the result of the exhaustion from the repeated asthmatic attacks Abscessed teeth, nasal polyps, sinusitis, bronchitis, heart disease, diseases of digestion, urogenital disorders and malnutrition may precipitate asthma in a person who has inherited the allergic state. Once a person has had an asthmatic attack, the fear of more attacks is deeply seated and it may be difficult to give genuine assurance that death will not result from an attack of asthma, for indeed it may do so in rare instances

The disease has no sex preferences but affects the sexes differently during certain

of severity by repeated acute exacerbations separated by more quiescent periods, and may remain for a long time fluctuating at the peak. In time the disease slowly subsides, but during the period of regression there are still relapses Some persons never get well Fever is not a feature of eczema unless the skin becomes infected by pyogenic organisms.

Patchy Eczema. A chronic eczema consists of slightly raised, dull red patches, studded with crusts of millimeter dimensions over a circumscribed area of skin The chronicity of these patches is the characteristic of eczema. These lesions often are associated with anxiety, tension and worry, failure to relax, and resultant fatigue A lessening of the anxiety coincides with disappearance of the eruption.

Allergic disease of respiration is suspected in those who have symptoms of hay fever or asthma with or without an accompanying eczema, urticaria, or angioneurotic edema *Respiratory allergic* diseases often occur and are related to a known environment where there exist dusts of domiciliary or of occupational origin which are inhaled, or where there is contact with certain plants or chemicals and other suspected materials

An uncommon frequency of "colds," bronchitis or pneumonia in childhood suggests the existence of an early allergic stage

there being a fully developed attack of asthma. A cough beginning in the early hours before day which clears as the day passes may be attributed to asthma A cough which does not clear up as the day passes is due to chronic bronchitis on a nonallergic basis

The asthmatic attack develops by a slow increase in the cough and the wheezing in the thorax, and then the *paroxysmal stage* may be gradual or abrupt. In those who have hay fever, coryza, sneezing and lacrimation often precede the paroxysm. However, not all who have hay fever have asthma Attacks of asthma often may come with an acute infection of the upper part of the respiratory tract.

The cough in the earlier part of the attacks is short and unproductive, but increases and becomes more productive. In the severe attacks the dyspnea increases to orthopnea and the patient seeks to support himself in a semireclining position on the elbows and hands in order to utilize all the accessory muscles of respiration to the greatest advantage as an aid to getting more air out of the lungs

The prolonged attack or status asthmaticus frequently occurs as the result of conditions imposed on the patient. These patients are nervously overwrought and have been overmedicated and lack sufficient sleep, fluids and foods The patient has extreme, constant dyspnea of a wheezy nature as a manifestation of the continuing attack There are an unproductive cough, cold clammy skin, and cyanosis. There may be fever The pulse rate is rapid and may be irregular. The demand to breathe requires total effort Unconsciousness or disorientation may develop. The elevation of temperature in the presence of pulmonary signs may appear to be that indicative of pneumonia Such signs as consolidation and leukocytosis are characteristic of bronchial obstruction These patients, however, usually will develop a loose cough, and on expectoration of large amounts of mucus dyspnea will subside and the attack ends The duration of the attack varies from a few days to a week and occasionally longer. In status asthmaticus there is prolongation of the attacks or they are often repeated The paroxysm may be present for days and consequently no food, drink or sleep is obtained In these patients, in contrast to acute asthma of short duration, death may ensue.

The acute paroxysms of asthma which occur only after intervals of months do not cause deterioration of health As the disease progresses, the paroxysms become more frequent and are of longer duration, emphysema and a deterioration of health are inevitable results The excessive bronchial secretion is continuously present, occupying space in the bronchial system which should be filled by air. Cough, breathlessness and weakness are now chronically present.

Physical Examination. During the attack respirations are increased and difficult There are audible wheezing and prolonged expirations There are whistling, or sonorous rales heard throughout the lungs, *particularly in the expiratory phase.* The pulse is accelerated and in severe asthma is enfeebled. In the absence of complications cyanosis is not remarkable, but may be intense when moderately severe emphysema is present In the absence of secondary infection the sputum is clear and tenacious Eosinophil cells in the sputum are pathognomonic of asthma

Diagnosis The diagnosis is established by observation of the patient during the attack, for the paroxysm of asthma once seen is unforgettable The specific diagnosis in extrinsic asthma is established by finding the allergen or allergens which excite the disturbance The presence of eosinophil cells in the sputum is helpful diagnostically In the chronic stage of either extrinsic or intrinsic asthma the diagnosis is attended with more difficulty, since emphysema may cause severe dyspnea and it is often present Asthmatic attacks which occur only at night in the aging patient arouse the suspicion of an early left-sided heart failure.

The discovery of the causative allergens is the first essential to effective specific treatment. Since the inhalant allergens are more frequent causes and since hyposensi-

age periods. Before puberty boys are most commonly affected. From puberty to menopause women are most commonly affected. After the age of 50 years men have a greater morbidity rate than women. The incidence decreases with the racial darkening of the skin, and consequently it is said to be less common in the black race. The most important factor in the susceptibility to asthma is the exposure to organic dusts There is a definite increase in morbidity rates in all of those who are exposed to organic dust in their occupational duties.

In a survey conducted by the United States Public Health Service in recent years, asthma ranked fifth among all causes of disability.

There is no paucity of theories which have been offered to explain the paroxysmal seizure of labored breathing characteristic of asthma. Some of these theories are enumerated as follows. (1) the theory of spasm of respiratory passages, (2) the theory of anaphylaxis (allergic asthma), (3) the theory of edema, (4) secretory factor and (5) nonallergic asthma. There are various others. Not all of these theories are discussed here

The theory of spasm postulates an exaggeration of the normal expiratory contraction of the bronchiolar musculature. Inspiratory relaxation allows air to enter through the open bronchi and bronchioles into the alveoli where it is entrapped during expiration The proof of such a spasm is lacking, and if it were present, the cause for it is unknown. However, it has been thought that such a spasm of the bronchiolar musculature might be due to disturbances of innervation or of psychic control.

The demonstration of bronchial constriction in the anaphylactic reaction in the guinea pig suggests that a similar reaction might account for the asthmatic seizure in man Asthmatic seizures in man have been observed to follow the ingestion of certain foods, for instance, eggs It has been observed too that an application of an extract of buckwheat to the skin will cause asthma in certain hypersensitive persons.

The edema theory of the asthmatic attack attributes the symptoms of the attack to a swelling of the bronchial mucosa comparable to that of the nasal mucous membrane or the skin in angioneurotic edema

The presence of tenacious mucoid secretion adhering to the walls of the passages of the bronchi and perhaps occluding some of the smaller passages might account for the asthmatic paroxysm

This secretory mechanism has no more than a secondary role in the production of the acute paroxysm which can come on within a few seconds and end in a few minutes without any evidence of increased or decreased secretion.

There are considerable numbers of patients who have attacks of asthma which cannot be proved to be the result of an allergy

SYMPTOMS The asthma attack often develops insidiously and progressively In some instances, however, paroxysmal dyspnea seizes the patient with terrifying suddenness.

The time and the frequency of the asthmatic attacks due to a single allergen occur when contact is made with that allergen For instance, in asthma due to atmospheric pollen the attacks characteristically occur during the season of a particular pollen The asthmatic attacks due to less well defined or to unknown allergens have a tendency to be manifested at night, often after midnight. The nocturnal exposure to bedding containing feathers, cotton, wool and the dander of pets may be responsible in some instances but not in all. The nocturnal periodicity of the asthmatic attack due to pollen is difficult to understand because less pollen is inhaled during the night than during the day. Apprehension and fatigue are important predisposing factors for nocturnal asthma, for in some patients the sequence of events is a strenuous day, a few hours of rest and sleep and then being awakened by asthma

Some patients can predict when they are about to have an attack of asthma

filling of the lungs with air and creates a desire to breathe

times will recede without an ensuing attack A cough may occur nocturnally without

fever, migraine, vasomotor rhinitis and urticaria either before or at the time of the illness Some persons have suspected that the eosinophilia is of parasitic origin

Meyenburg, in 4 patients with Loffler's syndrome who had accidental death, found that the infiltrations were of pneumonic type with exudation into the alveoli and with eosinophilic infiltration of the pleura, alveoli and the interstitial tissue Meyenburg failed to demonstrate tubercle bacilli or *Ascaris* larvae in the pulmonary tissue.

Symptoms when present consist of fatigue, irritating cough, associated sometimes with pain in the chest and with scanty sputum. The presence of fever is not constant.

Exaggerated vesicular breathing and sibilant rales over the region of infiltration are the only physical signs. The eosinophilia ranges from normal limits to 50 per cent.

Repeated roentgenologic examinations reveal the distinguishing feature of the syndrome as emphasized by Löffler which is the fleeting, migratory character of the infiltrations. They may be extensive and irregular in shape, or small and round. They may be soft or dense, unilateral or bilateral, and they may involve the entire lung or be limited to one lobe. Breton stresses the fleeting, migratory and in some cases recurring character of the roentgenologic shadows. The attacks of asthma, which may accompany the syndrome, are not considered to be an essential feature of the syndrome. Loffler's syndrome is observed more frequently in allergic asthma than in other conditions. It is therefore much like chronic allergic pneumonia

Diagnosis is established by the characteristic changes in the lungs on roentgenologic examinations. Loffler's syndrome is attended by eosinophilia in the absence of pulmonary tuberculosis or mycotic disease.

Eosinophilic Granulomas of the Skin. Eosinophilic granulomas of the skin are the cutaneous manifestations in Loffler's syndrome in the form of persistent erythema multiforme In view of the frequent plaquelike involvement of the face, the disorder must be taken into account in the differential diagnosis of sarcoid

Gastrointestinal Allergy. The intestinal membrane is impermeable to certain colloids and does not generally permit unaltered proteins to pass There is some evidence, however, to suggest that small amounts of food protein can pass unchanged through the normal intestinal mucous membrane and enter the blood stream A protein thus entering the blood stream may create a hypersensitivity in the same manner as one reaching the blood stream through other mucous membranes or the skin

Cardiospasm, dysphagia, and discomfort and a feeling of constriction in the esophagus may be due to an allergic reaction. In patients in whom edema of the esophagus occurs as an allergic reaction, the edema often appears in minutes after the ingestion of the allergen

Pain, nausea, vomiting, distention, belching, pylorospasm, and hematemesis may occur in association with an allergic reaction Hematemesis which is caused by allergic edema is a diapedesis of blood which is controlled by epinephrine Edema of the gastric mucosa has been observed endoscopically in those who have an allergic state

Allergic reactions involving the colon are said to be manifested by pain, abdominal distention, constipation, diarrhea and bleeding. Eusterman observed pain simulating that of acute appendicitis which he attributed to food allergy reactions

Gastrointestinal allergy may be suspected as a cause of all acute dramatic episodes of abdominal pain, vomiting or diarrhea if the usual concomitants of organic disease and neurosis can be eliminated The suspicion of allergy is enhanced by the history of previous similar episodes if appropriate studies made at the time did not disclose organic disease. A dietary history may reveal the partaking of certain items of food just prior to the attacks. Attacks of gastrointestinal allergy may follow acute

tization with these may be successful, this method of treatment not only may be advisable but may be necessary in case of inability to separate the patient from the allergen

Many patients who suffer from severe asthmatic attacks, and some who have mild attacks, are fearful and apprehensive of succeeding attacks. The fear and apprehension may be of such degree that much assurance that death will not occur as the result of an attack of asthma is necessary to allay their apprehensions Mild asthma in a psychoneurotic person often is a total disability.

Allergic Pneumonia. Acute allergic pneumonia and chronic allergic pneumonia are described

Acute allergic bronchopneumonia is, according to Miller, Piness, Feingold and Friedman, a pneumonic or bronchial process in an allergic individual characterized by signs and symptoms indicative of bronchial obstruction and pulmonary infiltration with or without fever

SYMPTOMS The symptoms may appear during the course of a prolonged attack of bronchial asthma or may appear suddenly during a bad cold An unproductive, distressing cough may be the only symptom. In the seriously ill, tachypnea, noisy expiration and orthopnea are present

EXAMINATION. The skin is cold. There is no cyanosis The tonsils are enlarged but not inflamed. Lymphoid tissue, in excessive amounts, may be present On respiration there are retractions of the intercostal spaces Abnormalities of percussion resonance and of breath sounds if present are characterized by areas of hyperresonance, impaired resonance, changeable rales, and suppressed or accentuated breath sounds

DIAGNOSIS In a patient known to have an allergic state, who has the foregoing history and findings attended by evidence of a bronchial pneumonia on roentgenologic examination, an allergic pneumonia is suspected The diagnosis is not made unless no other cause for the pneumonia is found.

Chronic allergic pneumonia is characterized by infiltrative pulmonary reactions and by eosinophilic leukocytosis In many instances no symptoms of the disease are present and the condition is found during a routine physical examination and confirmed by roentgenologic examination. These pneumonias are generally the result of unknown and indeterminate allergens

When symptoms are present, they may be from the original disease, one which is prone to give allergic manifestations, or from a low-grade fever for which chemotherapy has been employed Weakness, cutaneous eruptions, anorexia, headaches and vomiting are due to chemotherapy and not due to the pneumonia

On general examination there is evidence of pulmonary consolidation There is often leukocytosis with marked eosinophilia

A continued fever associated with pulmonary infiltration in the absence of prostration in cases in which no likely etiologic bacterial or viral agent can be demonstrated, combined with leukocytosis and eosinophilia, is almost diagnostic of chronic allergic pneumonia There may be a relative increase in eosinophils in the sputum Clearing of the cutaneous and pulmonary findings following the discontinuance of drug therapy substantiates the diagnosis of allergic pneumonia

Löffler's Syndrome. Loffler described a syndrome characterized by transitory pulmonary infiltrations, eosinophilia, and a mild clinical course which was in contrast to the extensive pulmonary lesions as seen in the roentgenograms in his cases Some instances of the syndrome were discovered in supposedly normal persons in the course of mass roentgenologic examinations The illness is attended by an eosinophilia which suggests the allergic nature of the disease

Loffler first suspected that the disorder was a mild atypical form of pulmonary tuberculosis Maier reviewed 100 such cases and found only 2 patients who had active tuberculosis. Fifty-two of the 100 patients in Maier's series had eczema, hay

the family of the affected person are likewise susceptible. Therefore there are often both an individual and an inherited susceptibility. It is those who have this predisposition to enteritis who are affected most commonly by the ingestion of food and drink which act as irritants either by physical or by chemical means. A non-susceptible person eating and drinking the same food and drink will not be affected

Sudden changes in weather causing chilling or overheating of the body surface predispose the susceptible patient to "a bowel upset" In susceptible patients the drinking of cold drinks when the body is overheated is often followed by vomiting, intestinal cramps, and perhaps loose bowel motions Ascent to a high altitude (hill diarrhea) is a conditioning influence in susceptible patients

Reactions to Serum and Bacterial Products. The use of horse serum and egg products in the preparation of antitoxins and antiserums produces dangerous allergies Failure to test the sensitivity of the patient before the use of these substances has resulted in numerous accidents and occasionally death.

Serum Sickness (*Serum Disease*) Subsequent to an initial injection of foreign serum there is a latent period of from 1 to 18 days, but usually 7 to 10 days, after the injection of a serum or an antitoxin containing serum A local reaction appears at the site of the injection. Immediately thereafter general symptoms develop consisting of edema, pruritus, urticaria, and erythema in topographic areas or generalized Accompanying these cutaneous reactions there are malaise, headache, vomiting, fever, adenitis, albuminuria, arthralgia, and occasionally a truly allergic arthritis These symptoms usually disappear in a few days The allergic arthritis of serum sickness is the only surely proved form of allergic joint disease.

Clinical manifestations closely resembling serum disease can occur as a consequence of drug therapy, for instance, with the sulfonamides, the arsphenamines, and various antibiotics such as penicillin

The Nervous System in Allergic Reactions. Reaction of the nervous system to allergies is poorly understood. However, it is known that neurologic manifestations, usually lesions of the spinal nerve roots or peripheral nerves, follow the injection of serums for therapeutic purposes or, less commonly, for the purpose of producing immunity Cerebral symptoms, meningeal reactions and perhaps spinal syndromes may follow these injections When the allergic state is present, neurologic conditions, usually cerebral symptoms, may occur without the injection of any foreign protein Occasionally either acute ascending spinal paralysis or polyneuritis may follow the injection of foreign protein, especially typhoid vaccine, without any of the usual signs of allergy

There is little or no information available about the anatomic basis of these conditions Cerebral edema and multiple meningeal hemorrhages have been described in meningeal reaction arising in the course of treatment for meningococcic meningitis. It seems that peripheral nerves may be injured by the reactions from injections of serum There is in such cases a perineural edema However, radicular lesions may be connected with the meningeal reaction. Kennedy has expressed the belief that the cerebral symptoms that he has described are due to edema of the cerebral cortex. Experimental work has revealed that congestion and even minute hemorrhage in the nerves and spinal cord may be produced by violent allergic reactions

During the course of serum sickness or toward its termination signs and symptoms referable to the nervous system appear and rapidly reach their maximal intensity There is often severe reaction at the site of injection, and the entire arm or leg, as the case may be, is greatly swollen. The distribution of the paralysis is independent of the site of the injection, at least to a large extent, for brachial plexus palsy may follow the injection of the serum into the thigh. Frequently serum has never been administered previously.

Often the first manifestations are neuralgic pains which follow the course of the

infections, or injection of serum or vaccine, or may occur in association with migraine.

Allergic manifestations in the abdomen are often said to be related to intestinal dysfunction giving symptoms like those present in the so-called irritable colon syndrome. There is mucous discharge in the feces, and episodes of pain occur along the course of the colon. In an allergy affecting the colon there should be attacks of disruption of colonic function in which the symptoms begin abruptly in the absence of the common precipitating factors for the irritable colon syndrome.

Gastrointestinal symptoms are common in those known to be allergic, and gastrointestinal allergic reactions are occasionally the first recognizable evidence of an allergic state In the patient who has acute symptoms, such as severe abdominal pain or fulminating vomiting or diarrhea, resort cannot be had to time-consuming investigative procedures In the event of pain simulating that of an acute abdominal emergency, if the possibility of an allergic reaction is considered, the correct diagnosis may at times be made and unnecessary operation avoided.

Unlike the finding of a high percentage of eosinophils in nasal secretion which is apparently diagnostic of an allergic reaction rather than of infection, cytologic examination of the gastric, intestinal and rectal secretions has given little assistance in determining the etiologic basis of suspected gastrointestinal allergy

If parasitic infections and leukemia can be excluded, an eosinophilia is usually of allergic origin In some instances eosinophilia has been noted as following the ingestion of food to which patients are sensitive

Despite the unpredictable reactions the skin may give to sensitivity tests, these tests are employed in selected cases For diagnostic purposes in patients who have gastrointestinal diseases it is not often desirable to make skin tests until complete diagnostic studies have been made.

Because of the uncertainties of the specificity of skin tests, trial or so-called elimination diets in the diagnosis of gastrointestinal allergy have been employed The use of elimination diets in the diagnosis and treatment of allergy is sound, but obviously no standard diet can be universally applied. If one of the standard elimination diets is used, it will need to be modified in accordance with information obtained from the history of diet, skin tests, and the individual response of the patient

Food diaries often supply more diagnostic information than any other procedure which is used in gastrointestinal allergy. In order to obtain a food diary, the patient is required to keep a diary of the daily intake of food, and an attempt is made to find some relationship between the ingestion of a certain food and the occurrence of symptoms

The diagnosis of gastrointestinal allergy can be made with a much greater degree of certainty if the general rules for the diagnosis of allergy in any part of the body are adhered to, namely, (1) previous history of other allergic manifestations or a strongly positive family history, (2) the presence of other allergic manifestations at the time of the attack such as urticaria, angioneurotic edema, nasal or bronchial symptoms, and migraine, (3) history of exposure to a known allergen, (4) minimal physical findings in the presence of constitutional signs of shock, in the absence of abdominal rigidity or muscle guarding and rebound tenderness in patients who are not infants or aged persons and (5) the presence of eosinophilia When these diagnostic demands are fulfilled, the patient will have a marked amelioration of symptoms after an injection of epinephrine (0 5 to 1 ml. of 1.1,000 solution).

Acute Enteritis Due to Increased Susceptibilities. An acute enteritis due to an increased susceptibility is worthy of separate mention in connection with gastro- [illegible] of etiologic

a cutaneous reaction of the specific type results from bringing together the allergen and the reagin in the skin. This association of allergen and reagin produces histamine or a histamine-like substance in the tissues and wheal and flare ensue. The wheal, with a surrounding flare, or an erythema results from the histamine formed in the skin Skin tests are made by (1) direct or (2) indirect methods.

Direct Skin Testing. The principle of the direct method of skin testing is to effect contact between the allergen and the reagin of the skin of the patient under investigation. Various technics have been used for this purpose under the following descriptive terms: (1) scratch, (2) multiple puncture, (3) intracutaneous and (4) contact (patch test).

Materials for testing for hypersensitiveness to many of the naturally occurring allergens are available in the market as (1) dry powders, (2) pastes and (3) liquids. All of these prepared allergens are adaptable to scratch, multiple puncture and patch test technics Only liquid preparations are reliable for use in intracutaneous technics It is well to exercise care in preparing the dilutions of the allergens, especially for large doses, to obviate danger to the patient In rare instances, if dilutions of the preparations have been improperly calculated, not only may constitutional reaction occur, but death may ensue.

Scratch tests are performed by effecting an abrasion about ⅛ inch long (3 mm) just through the epidermis, being careful not to draw blood, with a sharp pointed instrument such as a needle Additional scr [illegible]
of the allergen are made in the follow [illegible]
(1) If the allergen is liquid (or a [illegible]
powdered preparation, apply 1 drop of tenth normal sodium hydroxide to the scratch, add powder with a blunt instrument, and mix. Reactions usually are fully manifested in 10 to 20 minutes. This method is very reliable in testing for sensitivity of such substances as dry pollen

The multiple puncture technic is performed by placing a drop of liquid allergen on the skin and with a needle making a number of punctures of the skin through the liquid allergen Controls for the scratch and multiple puncture technics are effective by employing in performance of the test the vehicle or solvent used in preparation of the allergen.

The intracutaneous technic requires the use of a fine needle and syringe The material is introduced intradermally This test is often employed in the presence of dermographia and thus, like the scratch test, may result in many false positive reactions. Controls for these tests are usually separately injected comparable amounts of a 1 per cent solution of sodium chloride

Positive skin reactions are expressed by the presence of a zone of erythema surrounding the test site. The degree of positive reaction is based on the size of the zone of erythema in comparison with the control or with the test site. When there is formation of an urticarial wheal at the test site, it is recorded The following signs are employed and are generally understood (−) negative; (±) doubtful, (+) weak positive, (++) moderate positive, characterized by wheal formation up to 0 5 cm in diameter; (+++) marked positive, with wheal formation up to 2.5 cm, with pseudopodia and large zone of erythema, (++++) a marked positive differing from (+++) only in its larger size The skin of the forearm is the site usually selected for testing. If the patient is hypersensitive to an allergen, an erythema may extend proximalward from the site of injection, and constitutional or generalized reactions may occur. If an unusual local reaction occurs, it is well to inject epinephrine (1 1,000), 0.1 to 0 2 ml, into the central aspect of the wheal as a prophylaxis

The *patch test*, properly carried out and interpreted, is the most practical method for demonstrating the actual cause of a contact dermatitis It is employed by reputable manufacturers of wearing apparel to determine the possible skin-irritating or skin-sensitizing properties of the materials used (containing new chemicals) before placing the garments on sale.

Patch testing with strong concentrations of known primary irritants will result in reactions on any skin This does not mean that patch tests should not be performed with dilute solutions of chemicals which, in strong concentration, are known to be

spinal nerve roots. These pains are commonest in the arms and shoulders and may be unilateral or bilateral. Symptoms of meningeal irritation such as cervical rigidity, Kernig's sign and hyperesthesia are common. The nerve trunks are sensitive to pressure. Soon weakness or paralysis of the muscles appears and atrophy develops rapidly Often the muscles innervated by the fifth and sixth cervical segments are affected. The deltoid, spinati, rhomboids, biceps, brachialis anticus, brachioradialis and often the supinator and extensor muscles of the wrist may be partially or completely paralyzed. In rare instances, only the lower roots of the cervical plexus are affected. Paresthesia and hyperesthesia are present If the paralysis is extensive, small areas of hyperesthesia and analgesia may be detected

Lesions of the peripheral nerves are often but not always bilateral and symmetric The nerves most commonly involved are the radial, sciatic, peroneal, tibial, thoracalis longus and the axillary.

Occasionally there is a polyneuritis with emphasis on sensory phenomena.

A *meningeal reaction* occurs in those who have serum sickness Often these reactions are of an allergic type after intraspinous treatment with serums Deafness may be associated with serum sickness.

The essential features in diagnosis of allergic involvement of the nervous system are the history of injection of serum from 5 to 12 days before and the development of generalized signs of serum sickness just before the appearance of the neurologic manifestations

EXAMINATION

Both topographic and general examinations are performed The nose and throat abnormalities which so frequently accompany allergic conditions of the chest often require the services of the specialist, but not the specialist who calls all rhinitis "allergic rhinitis" The specialist describes the characteristic allergic nasal mucous membrane as being swollen, boggy and pale with a grayish or bluish color The gray color is due to generalized epithelial hyperplasia which is the essential feature of polyp formation Polyp formation is considered by many authorities as pathognomonic of allergy It is important to recognize also that allergy involves the sinuses as well as the nose

It is well to know that the roentgenologist cannot distinguish the true etiology of an edematous process from an infiltrative process, nor can he distinguish the etiology of one infiltrative process from that of another. Allergic pneumonia and allergic bronchial pneumonia, therefore, cannot be distinguished from other conditions producing similar shadows It has been shown that the edema due to allergy in the sinuses may at times be sufficiently great to produce shadows comparable with those of empyema

An endoscopic examination may be desirable, and if so the services of a bronchoscopist may be necessary for a complete diagnosis of the pulmonary condition, for even though asthma be demonstrated, an asthmatic patient may have some other pathologic condition which can be definitely determined only by this procedure

The presence of eosinophil cells in the blood in excess of 300 per cubic millimeter is considered abnormal. An eosinophilia is characteristic of allergy, but is not necessarily pathognomonic, for eosinophilia may result from blood dyscrasias which have been grouped under the term lymphogranulomatosis These blood diseases [illegible] as from the nose

[illegible] ic patients contain potential shock tissue. In order to detect the presence of this shock tissue, advantage is taken of the fact that these patients have shock tissue or potential shock tissue in the skin irrespective of the situation of the shock organ. It is postulated that

In cases of dermatitis suspected to be caused by elastic girdles and dress shields, patch tests should be performed with the rubber in the thread as well as with the fabric.

In testing with jewelry, first test with the suspected material itself. To test for nickel sensitivity, a 5 per cent solution of nickel sulfate is employed.

It requires considerable experience to interpret correctly reactions to patch tests The gradations of the reaction are the same as those for the scratch, the puncture or the intradermal methods and are recorded by the symbols 1+, 2+, 3+ and 4+. By this method an erythema on the area of skin to which the chemical was applied is indicated by 1+; erythema and edema by 2+, and an erythema, edema, papules and a few vesicles by 3+. Erythema, edema, many vesicles and in some cases ulceration are recorded as a 4+ reaction.

The degree of reaction will be greatest at the site of greatest concentration It is for this reason that weak concentrations of sensitizers must be left on longer than strong concentrations. They should be observed for at least 5 days after the patches are removed A reaction not present when the patch is removed but which becomes manifest less than 5 days after the patch is applied, is considered a delayed reaction. The delayed reaction indicates that a low degree of specific sensitivity is present or that a weak concentration of the sensitizer was used To report a patch test reaction properly, there should be given (1) concentration of the chemical tests, (2) amount of the chemical used, (3) area of skin contacted, (4) site of application, (5) number of days patch was left on and (6) periods after removal of the patch on which the readings were made. In this way a comprehensive appraisal of the reaction in terms of the degree of sensitivity can be made.

The true allergic reaction, as a rule, increases rather than decreases in intensity for 24 to 48 hours after the patch is removed Reactions of primary irritation with few exceptions tend to subside after the removal of the irritant

The evaluation of a weakly positive reaction (1+) depends a great deal on the observer's experience In dealing with a fabric or other substance containing a weak concentration of a sensitizer, a 1+ or 2+ reaction is significant.

The Intradermal Test. The intradermal test is most successfully employed for bacterial toxins, as in the Mantoux test, in which the reaction to varying doses of the toxin can be observed Other substances, such as pollens, are tested in this way by injecting them intradermally Certain substances are tested by placing the suspected agent into cross hatches or punctures made into the epidermis, as in smallpox vaccination A positive reaction is manifested by an urticaria shortly afterward, from one half hour to 1 hour usually, but in some instances, as in the Frei test (granuloma inguinale), 72 hours

Indirect Skin Testing. Indirect skin testing is an application of the Prausnitz-Kustner phenomenon, the passive transfer test (p 1323). The principle of this test is based on the transfer of atopic reagins in the patient's serum to local areas of the skin of a nonallergic person upon whom the test will then be made This passive transfer of sensitivity may be accomplished with either serum or plasma of the patient's blood A testing spot is usually selected on the back of the recipient; 0 1 ml of the patient's plasm or serum is introduced into a number of sites, depending on the number of materials to be tested After a period of 12 to 24 hours, and not until the traumatic reaction of the transfer injection has subsided, these areas are tested by the intradermal technic. Resulting reactions are similar and are recorded in the manner described for direct testing This procedure is not to be regarded as a routine, but it is most useful under certain circumstances Patients may present dermatitis so extensive as to preclude direct skin testing. The procedure may be desirable in the case of very young patients also.

The ophthalmic (eye) test is used most frequently in the determination of serum sensitivity when heterologous serum is to be used prophylactically or therapeutically. Reaction consists of hyperemia and itching of the conjunctiva accompanied by lacrimation A positive ophthalmic reaction indicates a higher degree of constitutional sensitivity than does a positive skin reaction A positive ophthalmic reaction contraindicates the injection of the serum or at least is an indication for the exercise of extreme caution.

Interpretations of Allergic Responses. A patient may exhibit a positive skin reaction to an allergen which provokes no symptoms when the allergen is other-

primary skin irritants These primary irritants can usually be removed from fabrics and therefore the chemicals which are not primary irritants are responsible for the great majority of cases of contact dermatitis caused by wearing apparel, cosmetics and ornaments. These nonprimary irritants induce a specific skin allergy and thus cause dermatitis. They are cutaneous sensitizers; that is, agents which do not necessarily cause demonstrable cutaneous changes on first contact but which may effect such specific changes in the skin that it will react after 5 to 7 days or more. Future contacts with the same materials will produce similar reactions or cause dermatitis on the same or other parts of the body

The patch test when used for diagnostic purposes consists in applying a small portion of the suspected substance to a site of normal skin of the patient. This is covered with innocuous impermeable material, which is then sealed to the skin by adhesive plaster There have been many modifications proposed in order to overcome certain objections.

The diagnostic patch test is performed by Schwartz and Peck in the following manner. If a liquid is to be tested, saturate a piece of four-ply gauze ¼ inch square and apply it to uninflamed skin on the arm or the back The liquid from the gauze should not be permitted to escape from the patch site. For insulation a 1 inch square of nonwaterproof cellophane is used This is sealed to the skin with adhesive plaster about 2 inches square. The reactions which may result from the adhesive plaster are separated from those resulting from the test substance by the uninflamed skin which is in contact with the cellophane only In performing a number of patch tests, care should be taken to avoid overlapping of adhesive plaster

If a powder is to be tested, the powder is placed on a moistened piece of gauze in order to keep the reaction localized

When solids insoluble in water are to be tested, they are dissolved in the solvent used in preparation for their use in the fabric A piece of gauze is then soaked in a saturated solution of the material In order to eliminate the action of the solvent the gauze is then allowed to dry before being placed on the skin.

When the insoluble solid is of a resinous nature, the solution may be painted directly on the skin, the solvent allowed to evaporate, and the cellophane and the adhesive plaster then applied If the resin adheres firmly to the skin, it is not necessary to cover it with cellophane and adhesive

It is usually sufficient to leave the patch on for 24 hours Sometimes, however, when testing with low concentrations or with weak sensitizers, it may be necessary to leave the patch on for several days, but not for more than 5 days, since the patient may by that time become sensitized to the patch itself The reactions are read on the removal of the patches every day for 5 days thereafter Reactions occurring at longer intervals after patching indicate a lesser degree of sensitivity than an early reaction.

A convenient way to test fabrics is accomplished by using a piece of the fabric about 1 inch square and applying it as a patch The reaction is observed each day up to 3 days, and after the removal of the patch at the end of 5 days. If the reaction is negative at the end of 5 days, the site should be inspected once more at the end of 1 week All patches are removed as soon as a positive reaction is obtained. Best results from a patch test are obtained while the dermatitis is still present

In patch testing with fur, the test should be carried out with the hairy side of the fur applied to the skin of the patient.

The first determination to be made when a patient is to be tested with leather, is whether the leather is real or artificial This can often be determined by tearing the [illegible]
fabric. If [illegible]
ance To [illegible]
perspiration [illegible]
to something in the leather

In investigating a shoe dermatitis, patch tests should be made with the backing In some instances the leather on the inside of the shoe, such as the tongue, the inner sole and the sock lining, may be the cause of the dermatitis, but rarely if ever the outside leather. The chemical which causes the dermatitis must get through the sock or stocking Therefore first patch test with the sock or stocking (before washing)

In patch testing with sponge rubber, test with both the spongy and smooth surfaces

In cases of dermatitis suspected to be caused by elastic girdles and dress shields, patch tests should be performed with the rubber in the thread as well as with the fabric.

In testing with jewelry, first test with the suspected material itself. To test for nickel sensitivity, a 5 per cent solution of nickel sulfate is employed

It requires considerable experience to interpret correctly reactions to patch tests The gradations of the reaction are the same as those for the scratch, the puncture or the intradermal methods and are recorded by the symbols 1+, 2+, 3+ and 4+. By this method an erythema on the area of skin to which the chemical was applied is indicated by 1+; erythema and edema by 2+, and an erythema, edema, papules and a few vesicles by 3+. Erythema, edema, many vesicles and in some cases ulceration are recorded as a 4+ reaction.

The degree of reaction will be greatest at the site of greatest concentration. It is for this reason that weak concentrations of sensitizers must be left on longer than strong concentrations They should be observed for at least 5 days after the patches are removed A reaction not present when the patch is removed but which becomes manifest less than 5 days after the patch is applied, is considered a delayed reaction. The delayed reaction indicates that a low degree of specific sensitivity is present or that a weak concentration of the sensitizer was used To report a patch test reaction properly, there should be given (1) concentration of the chemical tests, (2) amount of the chemical used, (3) area of skin contacted, (4) site of application, (5) number of days patch was left on and (6) periods after removal of the patch on which the readings were made. In this way a comprehensive appraisal of the reaction in terms of the degree of sensitivity can be made

The true allergic reaction, as a rule, increases rather than decreases in intensity for 24 to 48 hours after the patch is removed Reactions of primary irritation with few exceptions tend to subside after the removal of the irritant

The evaluation of a weakly positive reaction (1+) depends a great deal on the observer's experience In dealing with a fabric or other substance containing a weak concentration of a sensitizer, a 1+ or 2+ reaction is significant.

The Intradermal Test. The intradermal test is most successfully employed for bacterial toxins, as in the Mantoux test, in which the reaction to varying doses of the toxin can be observed Other substances, such as pollens, are tested in this way by injecting them intradermally Certain substances are tested by placing the suspected agent into cross hatches or punctures made into the epidermis, as in smallpox vaccination A positive reaction is manifested by an urticaria shortly afterward, from one half hour to 1 hour usually, but in some instances, as in the Frei test (granuloma inguinale), 72 hours

Indirect Skin Testing Indirect skin testing is an application of the Prausnitz-Kustner phenomenon, the passive transfer test (p 1323) The principle of this test is based on the transfer of atopic reagins in the patient's serum to local areas of the skin of a nonallergic person upon whom the test will then be made This passive transfer of sensitivity may be accomplished with either serum or plasma of the patient's blood. A testing spot is usually selected on the back of the recipient; 0.1 ml of the patient's plasm or serum is introduced into a number of sites, depending on the number of materials to be tested After a period of 12 to 24 hours, and not until the traumatic reaction of the transfer injection has subsided, these areas are tested by the intradermal technic. Resulting reactions are similar and are recorded in the manner described for direct testing This procedure is not to be regarded as a routine, but it is most useful under certain circumstances. Patients may present dermatitis so extensive as to preclude direct skin testing The procedure may be desirable in the case of very young patients also.

The ophthalmic (eye) test is used most frequently in the determination of serum sensitivity when heterologous serum is to be used prophylactically or therapeutically. Reaction consists of hyperemia and itching of the conjunctiva accompanied by lacrimation A positive ophthalmic reaction indicates a higher degree of constitutional sensitivity than does a positive skin reaction A positive ophthalmic reaction contraindicates the injection of the serum or at least is an indication for the exercise of extreme caution

Interpretations of Allergic Responses. A patient may exhibit a positive skin reaction to an allergen which provokes no symptoms when the allergen is other-

wise encountered. A skin sensitivity to a specific reagin may be present without clinical sensitivity to that substance. A patient may have definite sensitivity, in a shock organ, to an allergen without there being skin sensitivity to that substance *Negative cutaneous reactions in the* presence of specific reagins and allergens are less frequent than positive reactions which have no significance.

A positive skin reaction to dander of a dog or a cat in a patient who has asthma becomes significant when the removal of the house pet brings relief. A positive skin reaction due to the products of hens' eggs is significant when a dermatosis is relieved by an egg-free diet. When there are multiple positive cutaneous reactions, which is usually the case, an environment simultaneous free of all allergens for which positive cutaneous reactions have been obtained is attempted. If this procedure results in relief, contact may then be renewed with the suspected causes singly or in groups with deliberate intention of reproducing the symptoms. When it is feasible, such causes, if proved to be of clinical significance, are eliminated permanently. Those proved not important may then be restored

The history which suggests that an illness is referable to the allergic state is diagnostically important despite a failure of skin tests to confirm such an implication. A trial of eliminating the suspected allergens from the patient's environment is in order to effect a diagnosis

Some patients may be relieved by geographic change Such a change may involve many factors, such as disposal of pets and of articles of furniture, and other factors too numerous to mention or too obscure for recognition. In such instances, when change has effected a relief of symptoms, an inhalant allergen is indicated, especially when a return to the previous environment results in recurrence. Geographic change from a district where certain pollens are present to a district free of these offending pollens will give relief from symptoms such as hay fever and asthma.

The principle of elimination has been widely employed among patients who are suspected of being sensitive to foods but who give negative reactions to skin tests In applying the principle to foods, Rowe, whose plans of elimination are still used extensively, first popularized elimination diets. The elimination diet consists of lamb chops and rice Once the patient is established on the diet suspected articles of food are added and the results are observed

Certain specific allergic reactions require several hours to become manifest after the test material is deposited in or on the tissues These reactions exhibit no demonstrable relation to circulating antibodies, and the ability to react cannot be transferred by means of serum. When a substance which will cause this sort of reaction in the skin of a susceptible person is present, often only the epidermal cells react In other instances the deeper layers of tissue are involved The epidermal reactions of eczematous type present macules, papules, or vesicles, with hyperemia and itching. A sensitiveness manifested in the deeper layers of the skin results from invasion of the body by a variety of infective agents such as bacteria, viruses, fungi, and parasites, or from the use of drugs These allergies are designated simply by adding the term allergy to the name of the offending agent, for instance, *bacterial allergy*

The best known example of bacterial allergy or reaction of a delayed type is the tuberculin-tuberculosis relationship.

When diluted tuberculin is injected into the skin of the tuberculous patient, there is ... appears at the injected ... sity ... the ...

Skin testing for the detection of evidence of the presence of acqu...

sensitization to the living agents of disease during the course of acute, chronic and clinically unrecognized infections or infestations have been successfully employed for: (1) tuberculosis, brucellosis, tularemia, glanders and soft chancre, (2) lymphogranuloma venereum and mumps and (3) the dermatophytids, coccidioidomycosis, sporotrichosis, histoplasmosis, echinococcus, trichinosis, filariasis, schistosomiasis and leishmaniasis.

Equivocal skin testing occurs in the presence of acquired allergic sensitization due to many and diverse disease agents, for instance, in bacterial focal infections, dermatophytosis, moniliasis, filariasis, schistosomiasis, ascariasis, enterobiasis, uncinariasis, leishmaniasis and trypanosomiasis

All bacterial infections show some degree of delayed-type reactions when extracts of the corresponding bacteria are put into the skin; such extracts may at times give immediate-type reactions as well, particularly in relation to a content of specific polysaccharides Usually these reactions are less pronounced than in the tuberculin-tuberculosis relationship.

Thus, when large samples of the population are tested with culture filtrates of a group A streptococcus (Dick test), there is found to develop with age a gradually increasing incidence of sensitivity and, superimposed upon this whenever diseases intimately associated with streptococci occur, a sharp rise in the number of reactors

In p[illegible] [illegible]en observed: [illegible] onset of conv[illegible]e, the other due to species-specific nucleoprotein and being of the delayed type of reaction.

In infections by fungi useful diagnostic information can be obtained In coccidioidomycosis, on skin testing with coccidioidin (an extract of ground, heated culture growth), evidences of local or of general systemic reactions may be observed In histoplasmosis, local or general reactions are obtained with histoplasmin. In trichophytosis various preparations of trichophytin have been used with variously reported specificity of results of diagnostic importance.

Delayed-type reactions have been secured with certain viral materials. The skin reaction shown in smallpox-immune persons by killed vaccinal virus is an example The Frei test has been used diagnostically in cases of lymphogranuloma venereum.

The skin reactions of the host when tested with extracts of the body substance of the same or related parasites may give certain diagnostic indications in parasitic helminth infestations, such as in schistosomiasis, echinococcus disease, filariasis, trichinosis, and ascariasis These reactions are the immediate or the wheal-and-erythema type of reaction However, skin testing in this manner lacks sufficient specificity for routine employment for diagnosis of the same or related parasites Antibodies can usually be demonstrated in the serum by serologic methods in the positive reactors Asthma and rhinitis are sometimes elicited upon exposure to the specific agents While there is often an early reaction to hydatid fluid in echinococcus infestation, it appears that the delayed type of reaction should be given chief diagnostic interpretation.

In protozoan infestations only leishmaniasis seems to yield a tuberculin-like reaction which can be interpreted as being definitely useful diagnostically

As an aftermath of sensitization by insect bites and stings, delayed allergic reactions have been demonstrated independently of early reactions which occur at times; both varieties of reaction, however, may be seen in the same person

In general, when the method of skin testing is specific, in the presence of bacterial, viral and higher plant and animal infections such tests have a significance similar to that of tuberculin, a positive reaction denotes the occurrence of infection but gives no reliable indication of current activity It is most informative when

wise encountered. A skin sensitivity to a specific reagin may be present without clinical sensitivity to that substance. A patient may have definite sensitivity, in a shock organ, to an allergen without there *being skin sensitivity to that substance.* Negative cutaneous reactions in the presence of specific reagins and allergens are less frequent than positive reactions which have no significance.

A positive skin reaction to dander of a dog or a cat in a patient who has asthma becomes significant when the removal of the house pet brings relief. A positive skin reaction due to the products of hens' eggs is significant when a dermatosis is relieved by an egg-free diet. When there are multiple positive cutaneous reactions, which is usually the case, an environment simultaneous free of all allergens for which positive cutaneous reactions have been obtained is attempted. If this procedure results in relief, contact may then be renewed with the suspected causes singly or in groups with deliberate intention of reproducing the symptoms When it is feasible, such causes, *if proved to be of clinical significance, are eliminated permanently.* Those proved not important may then be restored.

The history which suggests that an illness is referable to the allergic state is diagnostically important despite a failure of skin tests to confirm such an implication. A trial of eliminating the suspected allergens from the patient's environment is in order to effect a diagnosis

Some patients may be relieved by geographic change Such a change may involve many factors, such as disposal of pets and of articles of furniture, and other factors too numerous to mention or too obscure for recognition. In such instances, when change has effected a relief of symptoms, an inhalant allergen is indicated, especially when a return to the previous environment results in recurrence *Geographic change from a district where certain pollens are present to a district free of these* offending pollens will give relief from symptoms such as hay fever and asthma

The principle of elimination has been widely employed among patients who are suspected of being sensitive to foods but who give negative reactions to skin tests. In applying the principle to foods, Rowe, whose plans of elimination are still used extensively, first popularized elimination diets. The elimination diet consists of lamb chops and rice Once the patient is established on the diet suspected articles of food are added and the results are observed

Certain specific allergic reactions require several hours to become *manifest after* the test material is deposited in or on the tissues. These reactions exhibit no demonstrable relation to circulating antibodies, and the ability to react cannot be transferred by means of serum When a substance which will cause this sort of reaction in the skin of a susceptible person is present, often only the epidermal cells react In other instances the deeper layers of tissue are involved. The epidermal reactions of eczematous type present macules, papules, or vesicles, with hyperemia and itching. A sensitiveness manifested in the deeper layers of the skin results from invasion of the body by a variety of infective agents such as bacteria, viruses, fungi, and parasites, or from the use of drugs. *These allergies are designated simply by adding the term* allergy to the name of the offending agent, for instance, bacterial allergy.

The best known example of bacterial allergy or reaction of *a delayed type* is the tuberculin-tuberculosis relationship.

When diluted tuberculin is injected into the skin of the tuberculous patient, *there is* [illegible] *at the injected* [illegible] nsity [illegible] the [illegible] patient allow of a *severer reaction,* there are central blanching and the [illegible] lopment of an innermost *livid* zone which may become necrotic The inflammation then slowly fades, but the *lesion* is palpable for some days and pigmentation may be observed for several weeks thereafter.

Skin testing *for the detection* of evidence of the presence of acquired allergic

nodosa, rheumatic fever, pneumonitis, disseminated lupus erythematosus, and rheumatoid arthritis. Whichever anaphylactic event occurs in a given animal is referable primarily to individual predispositon and the peculiarly elective sites in which either *the antigen becomes fixed or the antibody is produced.* Despite many analogies in the diseases so produced and those naturally occurring in man, the thesis is not proved that these diseases or even some instances of them are referable to sensitization, for the variety of reactions which tissues exhibit is very limited and the response of tissues to injuries of different origin may be similar

The studies of Rich and of other recent workers suggest that anaphylactic reactivity in man may at times be prominent in only a particular tissue.

At the present time it seems reasonable to assume that some sort of mechanism such as a chronic anaphylaxis is etiologically important in the origin of certain diseases.

Periarteritis Nodosa. Periarteritis nodosa is a rare disease, of unknown etiology, of the medium-sized and small arteries and arterioles.

Rich stated reasons to believe that the arterial lesions of periarteritis nodosa are dependent on increased sensitivity of tissue to foreign substances He reported a series of cases of serum sickness and reactions to sulfathiazole in which the lesions of periarteritis nodosa were found.

The condition belongs to the group of diseases now designated as collagenic diseases. Acute rheumatic fever, erythema nodosum and rheumatoid arthritis are examples of such diseases *The disease usually affects those between the ages of 20* years and 40 years.

The essential pathologic change is the localized necrosis of the medial coat of many of the arteries followed by exudation, necrosis, aneurysms and thrombosis In a few cases small aneurysms may rupture and cause hemorrhage or hemorrhagic extravasations In rare instances multiple aneurysms are present and give rise to beadlike lesions palpable along the course of the vessel.

Periarteritis nodosa is often like an infectious disease. There may be chills, fever, emaciation, marked and progressive weakness, insomnia and headaches, generalized muscular pains, peripheral neuritis, anorexia and various gastrointestinal disturbances. A rather characteristic feature of this disease is that during a period when there is no fever and the patient is generally comfortable and improvement should be had, the patient does not improve, but becomes weaker, more anemic and emaciated Subcutaneous hemorrhages, urticaria and purpura are common. Attacks of asthma may supervene. Instances of the disease simulating fibrositis may occur.

The disease may be difficult to separate from acute nephritis or hemorrhagic nephritis Fatal renal hemorrhage may occur Arterial hypertension and cardiac failure on the basis of coronary or hypertensive heart disease may appear to be the common variety developing a rapid course The central nervous system is involved in a few cases There may be symptoms of peripheral neuritis, even including the cranial nerves Abdominal pain accompanied by indefinite gastrointestinal symptoms may be the sole complaint.

There are no clinical findings solely indicative of periarteritis nodosa. The presence of this disease is suspected in all instances of pyrexia of unknown origin which is accompanied by leukocytosis and eosinophilia.

[illegible]

tions [illegible] a
regi[illegible] e
or a cutaneous lesion Thus the correct diagnosis of periarteritis nodosa has been made by histologic study of the appendix or the gallbladder removed at operation when the organ was suspected of being acutely inflamed.

The disease lasts from a few days to several years. It is often fatal.

Rheumatic Fever. Synonymous names for rheumatic fever are acute articular

the cutaneous reactivity is known to have been acquired recently. It is well to recall too that in advanced stages of all infections, including tuberculosis, the skin may fail to react· this condition is called *anergy* and has been considered a consequence of an exhaustion on the part of the tissue cells. Also in intercurrent infection such as measles and chickenpox, even the tuberculous host may temporarily cease to give skin reactions to tuberculin or other test substances. A positive reaction which is specific may not always be of *practical diagnostic value; the interpretation of* positive reactions may be of little or no diagnostic value when all members of a certain segment of the population have been exposed to the infecting agent or to closely allied genera or species which produce similar sensitivity to that of the suspected infecting agent.

The cutaneous and sometimes the patch test are of value in the detection of certain natural and acquired allergies to drugs and other chemical agents. For instance, a patient may be suspected of and found to be sensitive to diodrast. In instances of sensitivity, penicillin and streptomycin may be tested intracutaneously

Any means of testing may give falsely negative reactions in allergies to the sulfonamides

DIAGNOSIS

The diagnosis of allergic state and disease depends on the discovery of the causative agents. The complexities of the diagnostic task are enlarged because there often are many different etiologic agents responsible for the same group of symptoms. Even geographic change may not be of diagnostic importance if in the new environment there are new antigens to which the patient is just as hypersensitive as he was to the old ones The use of skin tests as a means for discovering specific sensitivity has become widespread; yet the etiologic diagnosis is seldom accomplished by the application of these procedures alone Disappointing indeed are the diagnostic implications portrayed by reactions to skin tests indicating a marked sensitivity to a particular allergen, when the patient is known never to have had contact with this substance That the diagnostician who diagnoses allergic disease should be well versed in the sources and contacts of specific substances, their usual as well as unusual occurrences in the environment of the patients, is mandatory

In the diagnosis of disease due to pollen, reference works in botany listing the geographic distribution of proved hay fever-causing plants are helpful. It is understood that when these references are used, approximate distributions and average seasonal dates for the appearance of certain pollens are given These reference works consist of lists of wind-pollinated plants, and the approximate periods of bloom, together with estimates of the amount of distribution.

Pollen counts furnish information concerning atmospheric pollen pollution both qualitative and quantitative The pollens which cause hay fever are so nearly the same that any differences in the antigenic properties of pollen of species of the same taxonomic group cannot be distinguished.

Despite all of the inherent diagnostic difficulties, if it is realized that these difficulties may be present, the history of the illness and the findings on physical examinations correlated with the appropriate selection of specific tests permit of a correct diagnosis in most instances of allergic disease

CHRONIC DISEASE AND ALLERGY

(Collagenous Diseases; Chemical Anaphylaxis)

Rich and others have stimulated anaphylactically sensitive animals repeatedly with large amounts of *antigen* with the intention of producing chronic tissue changes similar to those found in certain human diseases In recent years such changes in the tissues of animals have been produced which resemble those of periarteritis

The cardiac lesions of rheumatic fever are dispersed throughout the endocardium, myocardium, pericardium and conduction system The specific lesions are the Aschoff bodies, which are of microscopic dimensions They occur in association with small blood vessels in the subcutaneous tissues, but most importantly in the subendocardial regions of interstitial tissue of the left ventricle. The pericardium becomes thick and rough, numerous adhesions are formed between the pericardial layers and are adherent to neighboring extracardiac structures Calcification may occur. The lesions of the left atrium consist of raised series of ridges ranging from light gray to light yellow in color. The ridges are situated on the posterior wall immediately above the posterior cusp of the mitral valve When the disease is inactive, the lesions become translucent. In the active stage the valve cusp is thickened, with loss of transparency, and verrucae are present The verrucae appear as rows of fine, clear grayish or yellow vegetations on the closure line of the valve The predilection for the mitral valve is due to the peculiarity of its blood supply.

The atrioventricular chordae and cusps may become shortened With the shortening of the chordae and changes in the auricular endocardium a stenotic valve is formed. Infiltration with lime increases the rigidity and stenosis of such a valve The semilunar valves likewise become thickened and shortened

The occurrence in rheumatic fever of partial heart block may be due to lesions in the conduction system by the rheumatic process

Rheumatic pneumonia, serous pleurisy, and peritonitis are commonly present in acute stages of rheumatic fever

In chorea, cerebral lesions consisting of a meningo-encephalitis and cardiac lesions identical with those present in rheumatic fever may be present in the same person.

Symptoms Rheumatic fever is characterized by its chronicity, variety of forms, and tendency for remissions and relapses of symptoms For instance, the first attack may be one of chorea, the second, polyarthritis and the third, pancarditis The acute attacks generally last 1 to 3 months, but occasionally there are fulminating instances of the disease ending fatally in several days or weeks The acute attack is followed by a period of varying lengths of time in which there may be no symptoms.

The onset may be insidious or acute. Often there is a history of sore throat, tonsillitis or scarlet fever from which an apparent recovery took place Often full *recovery from the infection did not occur and there was a continuing loss of body* weight, epistaxis, and unaccountable weakness, fever and night sweats

Loss of body weight may be extreme Recordings of body weight at regular intervals may prove to be a valuable indicator of the progress of rheumatic fever An increasing body weight during the course of a rheumatic attack often signifies the beginning of convalescence.

Nosebleed is a common symptom of rheumatic fever in children, especially during rheumatic activity or before a recurrence.

In adults *arthritis* is the commonest local manifestation of the disease. In children rheumatic arthritis is not nearly so common as it is in adults In adults there is a symmetric, rapidly developing arthritis, usually limited to the large joints. The inflammatory symptoms subside as rapidly as they developed At times the inflammation seems to involve other joints as inflammation regresses in those previously affected A single joint only may be affected. In both adults and children the large joints are more frequently involved, however, almost any joint may be affected, including the small joints of the hands and feet, the vertebrae, the sternoclavicular, temporomandibular and cricoarytenoid joints and the symphysis pubis.

The respiratory symptoms consist of those referable to a pleurisy, in some instances a low-grade pneumonia

Gastrointestinal and abdominal symptoms consist of constipation, diarrhea and abdominal distention which in children often usher in the first attack or subsequent attacks of rheumatic fever

When abdominal pain arises in the course of a well-developed attack of rheu-

rheumatism, the rheumatic state, acute rheumatism, specific infectious rheumatism, acute rheumatic polyarthritis, rheumatic granulomatosis and Bouillaud's disease.

Rheumatic fever is a chronic inflammation-like disease which affects the joints primarily and the heart secondarily It is characterized by remission and relapses and often by a progression of the cardiac symptoms with each successive relapse The carditis of rheumatic fever places it in a position equal to that of arteriosclerosis as a cause of heart disease The cardiac injury sustained from rheumatic fever may be fully compensated for, and the patient lives comfortably until hyperthyroidism, pregnancy, septicemia, severe anemia or arteriosclerosis begins to affect the heart, it is then that the rheumatic lesions become manifest for the first time.

Often rheumatic fever has been considered to be of infectious nature. Belief in the infectious origin of rheumatic fever is based on the observation that the disease may occur in epidemics, or after infectious disease, has high familial association, and that its seasonal incidence is similar to that of the hemolytic streptococcus. Hemolytic streptococcal infections and rheumatic fever are similar in their geographic, climatic and seasonal incidence

In the practice of medicine it is often observed that sore throat, tonsillitis or scarlet fever (erythrogenic strain) due to the hemolytic streptococcus (Lancefield's type A) just prior to an attack of rheumatic fever is common. These acute streptococcal infections may occur in epidemics which are followed by epidemics of rheumatic fever 1 to 3 weeks later. Familial outbreaks of hemolytic streptococcal infections are followed in some members of the family by suppurative lesions such as otitis, in others by acute glomerulonephritis and in still others by rheumatic fever. Epidemics of pharyngitis and tonsillitis in crowded schools have similarly been followed by an outbreak of rheumatic fever Probably more important is the observation that in young patients a throat infection caused by hemolytic streptococci may be followed by rehumatic fever, or that such an infection may cause an exacerbation of an existing rheumatic state.

Rheumatic fever or rheumatic heart disease has never been proved to be produced by hemolytic streptococci. Results of blood cultures during the active uncomplicated stages of these diseases are negative for hemolytic streptococci.

The belief has been expressed that rheumatic fever is an allergic response to infection with hemolytic streptococci Others are of the opinion that rheumatic fever is an allergic response to any of the streptococci, hemolytic or nonhemolytic, or even to other microorganisms A few have concluded that rheumatic fever may result from sensitization to many types of foreign proteins, bacterial or nonbacterial

Rich produced lesions which he considered typical of rheumatic fever in the hearts of previously sensitized rabbits by the injection of horse serum Because of the evidence that periarteritis nodosa is an "allergic" disease and because Rich found that both periarteritis nodosa and rheumatic fever could be produced by the same technic of foreign protein sensitization, he concluded that rheumatic fever is also an allergic disease with lesions due to anaphylactic hypersensitivity in a sensitized person.

The greatest incidence of rheumatic fever is in January, February, March and April. The disease has a higher incidence in urban and suburban populations than in rural folks. Rheumatic fever can and does affect children who are well fed and clothed. In this respect it is like some of the viral infections.

Nine of every 10 have their first attacks of rheumatic fever before the age of 15 years. More attacks occur between the ages of 5 and 10 years than between 10 and 15 years Less frequently rheumatic fever begins between the ages of 15 and 20 years. Excluding the girls who have chorea, the incidence is essentially the same in both sexes. Likewise the disease has no racial preference.

Acute rheumatic fever affects tissues lined by endothelium, such as the blood vessels, endocardium, pericardium and synovia.

The cardiac lesions of rheumatic fever are dispersed throughout the endocardium, myocardium, pericardium and conduction system The specific lesions are the Aschoff bodies, which are of microscopic dimensions They occur in association with small blood vessels in the subcutaneous tissues, but most importantly in the subendocardial regions of interstitial tissue of the left ventricle The pericardium becomes thick and rough, numerous adhesions are formed between the pericardial layers and are adherent to neighboring extracardiac structures Calcification may occur. The lesions of the left atrium consist of raised series of ridges ranging from light gray to light yellow in color. The ridges are situated on the posterior wall immediately above the posterior cusp of the mitral valve. When the disease is inactive, the lesions become translucent. In the active stage the valve cusp is thickened, with loss of transparency, and verrucae are present. The verrucae appear as rows of fine, clear grayish or yellow vegetations on the closure line of the valve. The predilection for the mitral valve is due to the peculiarity of its blood supply.

The atrioventricular chordae and cusps may become shortened. With the shortening of the chordae and changes in the auricular endocardium a stenotic valve is formed. Infiltration with lime increases the rigidity and stenosis of such a valve. The semilunar valves likewise become thickened and shortened

The occurrence in rheumatic fever of partial heart block may be due to lesions in the conduction system by the rheumatic process

Rheumatic pneumonia, serous pleurisy, and peritonitis are commonly present in acute stages of rheumatic fever

In chorea, cerebral lesions consisting of a meningo-encephalitis and cardiac lesions identical with those present in rheumatic fever may be present in the same person

SYMPTOMS Rheumatic fever is characterized by its chronicity, variety of forms, and tendency for remissions and relapses of symptoms For instance, the first attack may be one of chorea, the second, polyarthritis and the third, pancarditis The acute attacks generally last 1 to 3 months, but occasionally there are fulminating instances of the disease ending fatally in several days or weeks The acute attack is followed by a period of varying lengths of time in which there may be no symptoms.

The onset may be insidious or acute Often there is a history of sore throat, tonsillitis or scarlet fever from which an apparent recovery took place Often full recovery from the infection did not occur and there was a continuing loss of body weight, epistaxis, and unaccountable weakness, fever and night sweats

Loss of body weight may be extreme Recordings of body weight at regular intervals may prove to be a valuable indicator of the progress of rheumatic fever An increasing body weight during the course of a rheumatic attack often signifies the beginning of convalescence.

Nosebleed is a common symptom of rheumatic fever in children, especially during rheumatic activity or before a recurrence

In adults *arthritis* is the commonest local manifestation of the disease. In children rheumatic arthritis is not nearly so common as it is in adults. In adults there is a symmetric, rapidly developing arthritis, usually limited to the large joints. The inflammatory symptoms subside as rapidly as they developed At times the inflammation seems to involve other joints as inflammation regresses in those previously affected A single joint only may be affected In both adults and children the large joints are more frequently involved, however, almost any joint may be affected, including the small joints of the hands and feet, the vertebrae, the sternoclavicular, temporomandibular and cricoarytenoid joints and the symphysis pubis.

The respiratory symptoms consist of those referable to a pleurisy, in some instances a low-grade pneumonia.

Gastrointestinal and abdominal symptoms consist of constipation, diarrhea and abdominal distention which in children often usher in the first attack or subsequent attacks of rheumatic fever

When abdominal pain arises in the course of a well-developed attack of rheu-

matic fever, it is not likely to be misinterpreted. However, it may precede any definite rheumatic symptoms There may be abdominal tenderness, nausea and vomiting. Abdominal pain most commonly is referred from the thorax when there is pericarditis or pleurisy. There may be polyserositis including perihepatitis as well as pleuropericarditis. In right heart failure, pain, abdominal tenderness and vomiting may be due to a congested liver.

Acute diffuse glomerulonephritis is uncommon. Chronic glomerulonephritis frequently is combined with rheumatic heart disease. The combination is no commoner, however, than is to be anticipated from the incidence of the two diseases, *both frequently* commencing with a throat infection by streptococci

The presence of almost constant fever is the commonest complaint. Often the temperature may rise only to between 100 and 101 F (37 8 and 38 3 C), and at certain times of the day it is normal. When the local symptoms of arthritis or cardiac disease develop, the fever increases and is irregular, but when the local symptoms disappear the low-grade fever returns.

A high fever is rare in rheumatic fever except in rheumatic hyperpyrexia which usually is a terminal event The terminal rise in temperature to 106 to 107 F (about 41 to 41 7 C) occasionally occurs. Rheumatic hyperpyrexia often occurs in the second or third week of the first attack, sometimes when the infection is subsiding and convalescence seems to have begun

Rheumatic hyperpyrexia is associated with symptoms of cerebral rheumatism Delirium at night (when not due to salicylates) and excessive micturition are premonitory symptoms Convulsions, squint, risus sardonicus, opisthotonos, deafness, irregular respiration, lividity and progressive coma may develop Rheumatic hyperpyrexia has been practically eliminated since the introduction of salicylates in the treatment of this disease

The fever is variable in duration. In abortive instances it may be absent except for a few days at a time In definite attacks the fever may last for a few weeks up to a few months. If all symptoms subside except the fever, the disease is still active Occasionally, however, the temperature is normal despite the presence of active infection. In chorea, which is generally accepted as a manifestation of active rheumatic fever, *the temperature may remain normal throughout the attack* In the prearthritic or precardiac stages of rheumatic fever there is often no fever although progressive anemia, fatigability and loss of weight indicate active disease. Similarly there may be no fever toward the end of a rheumatic attack when all symptoms have disappeared; yet there may be persistent rheumatic inflammation as indicated by tachycardia, leukocytosis and increased rate of sedimentation of erythrocytes. There may be little or no fever with subcutaneous nodules although these represent active rheumatic disease

Sweating may be limited to the night or may occur throughout the day and night, and may become severe enough to cause maceration of the skin

In *rheumatic myocarditis* precordial pain of variable severity is frequent. This pain occurs without exertion and may be due to an associated pericarditis or to disease of the coronary arteries It may simulate true angina pectoris Precordial pain is distinguished from precordial distress due to palpitation and tachycardia, which is common.

Examination The findings on examination depend on the stage, the degree of severity and the presenting manifestations of the attack or the attacks

Usually there are observed a loss of body weight, pallor and weakness The pulse is full, bounding, easily compressible and often dicrotic. A tachycardia of 100 to 140, which is out of proportion to the fever, is a common sign of rheumatic activity. In convalescence there may be bradycardia. When the temperature has subsided, a persistent tachycardia with or without fever usually indicates continued rheumatic activity, probably within the heart

The significant cutaneous lesion is variously termed erythema annulare, erythema marginatum, erythema circinatum, or erythema gyratum according to its configuration. These lesions occur on the thorax or on the extremities They begin as reddish macules or papules 1 to 5 mm. in diameter and develop rapidly. As the lesions enlarge their centers become a dull brown in color. The lesions have pale pink or dull red margins, sharply circumscribed and slightly elevated

The subcutaneous nodules are commonest in children but may develop in young adults. The nodules are rounded elevations varying in size from a few millimeters to about 2 cm (4/5 inch) in diameter. They are situated subcutaneously, unattached to skin so that the skin can be moved freely over the nodule They tend to assume a symmetric distribution They occur on the extensor surfaces of the hands or the feet, elbows, on the malleoli, patellae, skull, spines of scapula, vertebrae, clavicles, ribs, crests of the ilium, sternum and acromion, and rarely the flexor tendons of the hand may be involved There is no redness and usually neither pain nor tenderness. The nodules vary in number from a few to many. The characteristic rapid evolution and disappearance of nodules are followed by the appearance of other nodules in another location The successive appearances of these nodules may be observed for weeks or months.

There are disability and pain, redness, swelling and increased warmth of the skin overlying the joint. Synchronous with the onset of arthritis, a rise in fever and an intensification of all other general symptoms ensue. The pain may be so intense as to make the weight of the bedclothes or jarring of the bed intolerable. Swelling is chiefly of the periarticular tissues In the large joints there may be intra-articular effusion with fluctuation. Suppuration does not occur except in the presence of a septicemia of pyogenic organisms which in many instances originate from a focus in the throat Pain in the juxta-articular region may be due to inflammation of neighboring tendons and muscles. Tendon sheaths as well as tendons may become inflamed. In tenosynovitis of the hand considerable effusions may occur. Myalgias are common They are responsible for the "growing pains" in the legs of children.

The clinical signs of endocarditis result essentially from inflammation of the valve ring and cusp. The development of endocarditis is manifested by an alteration in the heart sounds, the occurrence of cardiac murmurs, or a change in the character of murmurs already present.

At the onset of rheumatic endocarditis it will be observed that there is a loss of the distinctive muscular quality of the first sound of the apex. Sometimes a splitting or reduplication of the second sound at the apex will be the only manifestation Early and frequently a blowing systolic murmur, situated at the apex, to the left of the sternum, at the level of the fourth rib, over the pulmonic or aortic area or over an extensive precordial area is heard It is impossible to distinguish the systolic murmur occurring early in active rheumatic fever from functional murmurs. Occasionally a middiastolic murmur appears in the early stages of rheumatic fever and disappears with the rheumatic attack

In the active stage of rheumatic fever an acute fibrinous pericarditis and pericarditis with effusion may occur The onset of a pericarditis is often synchronous with an increase in the fever.

The essential symptom of pericarditis is substernal, precordial or abdominal pain, and the essential sign is a pericardial friction rub. The precordial pain and pericardial rub of the acute fibrinous pericarditis may or may not disappear with the formation of a considerable effusion The patient may suffer from precordial oppression and a sense of anxiety Restlessness, insomnia, delirium and other mental symptoms may occur With large effusions the patient is exceedingly dyspneic and orthopneic so that he must sit upright in bed He may become cyanotic or flushed, but often he presents an intense pallor. Dysphagia, aphonia and an irritative cough may result from pressure on the esophagus or recurrent laryngeal nerve

The earliest signs of myocarditis are changes in the quality, intensity and pitch of the first sound. The first sound becomes enfeebled. The clinical evidence of pericarditis indicates a serious form of rheumatic heart disease. Pericarditis often is associated with pleurisy and pneumonia

Cardiac enlargement may appear rapidly with active rheumatic heart disease if there is severe myocardial infection with failure. It can be interpreted as a sign of rheumatic activity only if there are other evidences of active rheumatic fever. Disturbances of cardiac rhythm are frequent and valuable signs of rheumatic myocarditis. The arrhythmias are often clinically recognizable, discovery and confirmation of their exact nature require electrocardiograms

Evidences of right and left heart failure are commonly observed in children suffering from severe forms of rheumatic myocarditis. Cardiac failure is often seen in adult patients who have inactive rheumatic heart disease and who experience an acute recurrence

Inactive rheumatic heart disease is essentially valvular disease of the heart.

A polymorphonuclear leukocytosis is common in active rheumatic fever and is a *significant index of active infection* The leukocyte count is generally between 10,000 and 20,000 per cubic millimeter of blood. Occasionally it may exceed 20,000 or it may lie within normal limits. A leukocytosis may persist after the fever has gone. It then becomes an index of rheumatic activity Rheumatic activity may persist, however, even after the leukocyte count has fallen to normal There is a shift to the left in the number of nonfilamented polymorphs by the Schilling count The remaining white cells are normal, but in chorea there may be an eosinophilia

Anemia, the cause of the characteristic pallor, is commonly present in active rheumatic fever The hemoglobin may fall as low as 6 or 7 gm. per 100 ml of blood although it usually lies between 8 and 12 gm and gradually rises as active infection subsides The erythrocyte count ranges between 3,000,000 and 4,000,000 per cubic millimeter The anemia is of the microcytic type

Electrocardiographic abnormalities are almost always present at some time during the course of active rheumatic fever Three types of electrocardiographic abnormalities are described by cardiologists (1) impaired atrioventricular conduction, (2) abnormalities in the QRST complex and more rarely in the P wave and (3) changes in cardiac rate and rhythm

Diagnosis The diagnosis of rheumatic fever in the early stages may be only presumptive The disease is most easily diagnosed in retrospect when there is well-developed valvular heart disease

The diagnosis of rheumatic fever and rheumatic heart disease requires the recognition of an active rheumatic fever with or without cardiac involvement, and of rheumatic heart disease in patients who have passed the period of *rheumatic* activity. In the absence of involvement of the joints or the heart the diagnosis can be suspected but not made

Rapid cardiac rates after the temperature is normal often are present when *there is persistent rheumatic activity* Occasionally a rapid pulse rate appears during convalescence if the patient is gradually permitted to resume activity. This appearance may not indicate a persistent rheumatic activity It is the *result of resumption* of physical activity after a long illness However, a fast heart rate attended by a leukocytosis in a convalescent patient usually denotes the presence of *persistent rheumatic activity*.

Distinct prolongation of the PR interval and a prolonged QT interval in the electrocardiogram may help to identify rheumatic heart disease.

Rheumatic fever is to be differentiated from infections of the respiratory tract, rheumatoid *arthritis in adults* and Still's disease in children, subacute bacterial endocarditis, pulmonary tuberculosis, and acute appendicitis when abdominal symptoms are prominent.

Recovery is the rule in the first acute attack of rheumatic fever. If the initial attack is experienced before the age of 10 years, a recurrence is to be anticipated in most of these patients but not in all.

Rheumatic pericarditis is serious both because of relatively high immediate mortality and because of the probability of permanent cardiac damage. The presence of auricular fibrillation in children is serious. In adults auricular fibrillation may persist for years.

The *complications* of rheumatic heart disease are: cardiac failure, auricular fibrillation and other arrhythmias, subacute and acute bacterial endocarditis and embolization

Chorea Minor (Sydenham's Chorea, Saint Vitus' Dance). The essentially rheumatic nature of chorea minor (Sydenham) is no longer doubted, although chorea is not always associated with active rheumatic fever. Chorea is primarily a manifestation of rheumatic fever in childhood It may be the first symptom and is frequently complicated or followed by carditis.

At least one half of the instances of chorea in children are unaccompanied by other symptoms of rheumatic fever or by the development of cardiac disease. These nonrheumatic instances are characterized by absence of family history of rheumatic fever, by absence of preceding respiratory infection, and by normal leukocyte count and sedimentation rate during the attack of chorea

Pathologically chorea (Saint Vitus' dance) is a meningo-encephalitis involving particularly the basal ganglia, especially the caudate nucleus and putamen in the corpus striatum, and also the internal capsule and cortex In pregnancy it is occasionally observed in a severe form (chorea gravidarum); abortion or premature induction of labor may be required

The onset of chorea is usually insidious It may commence after an injury, fright or an emotional upset

[illegible]

ness

the

wetting As the disease advances, exaggerated un-co-ordinated and explosive movements occur spontaneously as well as with muscular effort and are beyond voluntary control Facial grimaces, rolling of the eyes, tossing of the head and wrinkling of the forehead combine to form an imbecilic appearance The children soon begin to slur their words and to phonate badly The gait is awkward, and too rapid A hand or half of the body may be affected, simulating hemiplegia The patients may become unable to swallow, and lose control of bladder and bowels. The nature of the disease can be verified by holding the patient's hands enclosed in those of the examiner, whereupon the exaggerated twitchings are observed In all, the movements are constant, un-co-ordinated and purposeless.

The attack of chorea may last 6 to 8 weeks or longer Recurrences, sometimes with additional cardiac damage, may be observed. Death rarely occurs except in pregnant women, of these, 1 or 2 of every 10 who have the disease will die.

Chorea minor is distinguished from choreiform movements of cerebral palsy; from general tic disease, from hysteria (the so-called chorea major or magna is hysterical, in most female patients more than 16 years old choreiform movements are hysterical), from Huntington's chorea (on the basis of age, etiology, heredity, chronicity, and dementia) and from double athetosis

Relapsing Febrile Nodular Nonsuppurative Panniculitis (Weber-Christian Disease). The etiology of relapsing, febrile, nodular, nonsuppurative panniculitis is unknown. This disease is regarded not as a disease entity but rather as an allergic systemic reaction to nonspecific stimuli, with focal manifestations in the subcutaneous or intraperitoneal fat, resulting in destruction of the supporting framework of

the fat cell and liberation of free fat. Nodular panniculitis is probably allied to th group of collagen diseases

The disease occurs more frequently in females than in males in every age group and occurs most commonly as a single entity, unassociated with another specific disease There have been no epidemics.

The nodule consists of fatty tissue which is thicker and denser than normal. Various stages of fatty atrophy in the same piece of tissue may be observed.

The interstices of the adipose tissue are infiltrated with leukocytes, with separation and partial to complete resorption of fat cells Serous atrophy and even necrosis of fat have been observed Eventually the fat cells are completely replaced by scar tissue, which generally contracts to dimple-like skin depressions The liver appears fatty and the spleen is enlarged There are fat emboli in the lungs. The cells of the adrenal cortex show hydropic degeneration

SYMPTOMS. Relapsing, febrile, nodular, nonsuppurative panniculitis is characterized by recurrent episodes of fever, the temperature ranging as high as 104 F (40 C), and by single to multiple recurrences of tender or painless, freely movable nodules ranging from about 0 5 to 3 cm in diameter in the panniculus adiposus. The nodules do not produce pus and may regress in a few days or weeks, either leaving a shallow dimple in the skin or showing no superficial evidence of their site. The overlying skin may be normal in color but usually is red

EXAMINATION The nodules are usually a few centimeters in diameter, are movable beneath the skin, may be tender and firm, and are most commonly found on the thighs, legs, abdomen, breasts and arms Some nodules may attain 20 cm. in diameter or may be even larger They may occur on other parts of the body, including the scalp, neck, hands, and back.

The nodules may remain from several days to months, finally regressing and leaving dimples in the skin or disappearing without any superficial trace Usually there is no suppuration or break in the skin The nodules tend to enlarge during the height of the fever.

The spleen may enlarge slightly. The liver does not increase in size. The regional lymph nodes are enlarged

Recurrences, with the same clinical findings, occur at intervals of a few days, weeks, months or years Patients who had frequent relapses have been followed for years Between relapses the only evidence or residuum of the disease may be the dimpled skin where lesions have regressed.

DIAGNOSIS A biopsy is important in establishing an accurate diagnosis. A diagnosis of relapsing, febrile, nodular, nonsuppurative panniculitis is made on the basis of clinical course, the typical subcutaneous nodules and the histopathologic findings of the nodules The disease is suspected from its clinical course and findings on physical examination.

Lupus Erythematosus. Lupus erythematosus appears in many varieties and forms. It may be acute or subacute but more commonly it is chronic. The subacute and chronic forms are characterized by cutaneous lesions These lesions are rather ill-defined patches which are mostly circular, varying in size, covered with oily appearing desquamating rough skin, laterally limited by fine scarring as the lesion spreads. When the scabs are removed, small projections may be revealed on their lower surfaces which have extended into the skin follicles. The lesions usually begin on the face, ears, and scalp, and over the upper part of the sternum, back and hands Affecting simultaneously the bridge of the nose and the cheeks, they produce a butterfly configuration.

... scaling irregular

skin

ay be involved.

The lesions may remain stationary in size for years. Some patients seem to recover from this form of lupus erythematosus.

Disseminated Lupus Erythematosus. Disseminated lupus erythematosus is a prolonged febrile disease usually accompanied by cutaneous manifestations, and may resemble rheumatic fever, rheumatoid arthritis, chronic nephritis, or Libman-Sacks disease. In some instances the cutaneous manifestations may be absent. The disseminated form of the disease is fatal, after a variable period which may be weeks, months or years

The etiology is unknown. The disease has many features resembling other conditions, which often are termed collagen diseases. Recent investigators have rejected the concept of tuberculous origin of the disease. Disseminated lupus erythematosus most commonly affects young women.

PATHOLOGY. There are widespread structural alterations of the connective tissue. These changes affect the heart, kidneys, serous membranes, blood vessels, lymph nodes, muscles, skin, and mediastinal and retroperitoneal tissues. There is a specific predilection for the heart, glomeruli, blood vessels, skin, spleen and retroperitoneal tissues In biopsies of 96 cutaneous lesions of disseminated lupus erythematosus, Montgomery and McCreight found alterations of collagen in less than one fourth of their cases of chronic, subacute and acute disseminated lupus erythematosus. In most instances in which fibrinoid degeneration could be demonstrated, it was minimal and no greater than that seen in many other chronic inflammatory infectious diseases of the skin.

Hargraves, Richmond and Morton observed in preparations of bone marrow in only certain cases of acute disseminated lupus erythematosus a cell termed by them the L E cell This cell is a mature neutrophilic, polymorphonuclear leukocyte which differs from other similar cells by the structure of the engulfed material In the L E cell the engulfed mass, characterized by lack of chromatin structure, is almost homogeneous and has a smoky appearance

Montgomery and McCreight were able to demonstrate the lupus erythematosus cells described by Hargraves in sternal aspirations in 5 of 7 cases of acute disseminated lupus erythematosus and in 3 of 18 cases of subacute disseminated lupus erythematosus These cells have not thus far been observed in any other condition, except in 1 case of myeloma They may provide an important diagnostic feature of the disease.

Montgomery and McCreight maintained O'Leary's classification of chronic, subacute and acute types of lupus erythematosus The chronic type has also been termed the generalized discoid type. Sensitivity to light in acute disseminated instances, lesions of the mucous membranes, fever, the presence of infected tonsils, leukopenia, false positive serologic reactions and renal disorders all occur Any organ may become involved, although the tendency has been to focus attention on cardiac, renal, hepatic, splenic or arthritic involvement. It is emphasized that there are also ocular and gastrointestinal symptoms

SYMPTOMS The symptoms of lupus erythematosus are varied They cannot be enumerated except as they occur in association with the organ or organs affected In the active stage there is constant fever and there may be arthralgias, weakness, loss of weight, fatigue, characteristic erythematous eruptions, ulcerative lesions of the mucous membrane of the mouth and local or generalized lymphadenopathy. There may be clinical evidence of pneumonia Often the manifestations are those of a glomerulonephritis with albumin and erythrocytes in the urine A retinopathy may be present. It is now known that *Libman-Sacks disease* characterized by atypical verrucous nonbacterial endocarditis is a manifestation of lupus erythematosus.

Tumulty and Harvey emphasized the importance of manifestations due to involvement of the nervous system In their series of 32 patients, 4 had convulsive episodes, 4 presented toxic psychosis, 3 patients had transient periods of coma, 3 had hemiplegia, 2 had transient episodes of bilateral ptosis and 1 had attacks of jacksonian epilepsy.

Baehr and Pollack stressed that the predominant occurrence of lupus in skin exposed to sunlight and wind is not the primary manifestation of lupus erythematosus, and that these lesions are not responsible for the alterations in the viscera. The cutaneous lesions may be absent throughout the entire course of the disease or may appear only during acute exacerbations or in the terminal stage.

EXAMINATION. The findings on physical examination are exceedingly varied and complex, depending on the organ or organs involved

The cutaneous lesions of the disseminated form of lupus erythematosus may develop at any time during the course of the disease. They consist of slightly raised erythematous butterfly eruptions across the bridge of the nose and extending to the cheeks Papular and erythematous lesions of a bluish red cast affect other parts of the face, the forehead, the ears, the manubrium sterni, the volar surface of the fingers, the thenar and hypothenar eminences and other parts of the upper and lower extremities Telangiectatic and petechial lesions occur over the extremities The skin of the face may become scaly and edematous, and the lesion may resemble that of seborrheic dermatitis or erysipelas Erythematous or ulcerative lesions may appear over the face, lips and on the hard palate or other parts of the oral mucosa Healing of these lesions may leave ugly scars.

The liver and the spleen may be palpable. The lymph nodes are often enlarged

Albuminuria and microscopic hematuria often are present The fundi may contain cotton-wool exudates and hemorrhages due to local vascular lesions Fleeting or persistent pleurisy with effusion which may be eosinophilic often is present. Evidence of serofibrinous pericarditis is commonly observed. Raynaud-like phenomena, scleroderma, cerebral manifestations, evidences of impaired renal functional activity, bronchopneumonia and bacterial endocarditis appear late if at all in this disease Leukopenia, anemia, occasional thrombocytopenia, a reduction in plasma albumin, hyperglobulinemia and an occasional false positive serologic reaction are sometimes present

The albumin-globulin ratio may become reversed as the disease progresses. Aspiration of sternal marrow will reveal lupus erythematosus cells, as described by Hargraves and associates in the disseminate type when the disease is active or is increasing, but these cells are not demonstrable when the condition is quiescent.

DIAGNOSIS The combination of fever, arthralgia, lupus erythematosus and leukopenia is usually diagnostically suggestive In the absence of characteristic cutaneous lesions the presence of lupus erythematosus may not be suspected, and then the diagnosis will be that of the dominant manifestation.

In the absence of characteristic cutaneous lesions, acute lupus erythematosus may be suspected in illnesses resembling rheumatic fever in which there is evidence of acute glomerulonephritis and hyperazotemia, but with a normal blood pressure. Similarly the association of thrombocytopenic purpura or of leukopenia or both in disease resembling rheumatic fever suggests lupus erythematosus. The combination of hyperazotemia, fever and normal blood pressure may also be due to this disease. Lupus erythematosus may resemble a subacute polyserositis with fever, with or without arthritis and glomerulonephritis This disease may resemble bacterial endocarditis However, blood cultures are persistently negative.

The presence of Hargraves' L E cells, if identification of the cells is made by an examiner of adequate experience, is of diagnostic value. These cells are obtained by sternal aspiration. Hargraves has more recently devised a clot test which is of diagnostic value.

Dermatomyositis. Dermatomyositis is characterized by a subacute or chronic inflammatory-like process involving the muscles, skin and subcutaneous tissues. It may occur at any age of life. The etiology is unknown. It is collagenous in origin.

The skin may be atrophied, and the subcutaneous fat is partially replaced by connective tissue. The blood vessels beneath the skin are thickened or partially occluded. The

muscles are pale, and may be soft and friable, or fibrous, depending on the age of the process. The superficial portions of the muscle which lie directly under the skin are most severely affected.

SYMPTOMS The symptoms commence with pain and swelling and tenderness over the proximal muscles of the extremities The process soon becomes symmetric and general Evidences of infection are almost always present in the early stages of the disease. The temperature may be only slightly elevated or may reach 99 to 100 F (37.2 to 37 8 C). Tachycardia is often present and seems to be independent of the fever. Sweating is profuse and characteristic. Delirium is rare

EXAMINATION. The cutaneous lesions may precede or follow the myositis. There is edema of the subcutaneous tissue or a dense infiltration either with or without redness. The skin of the forehead and the eyelids is involved and gives rise to the characteristic "marble brow" A thickening of the skin and fibrosis of the subcutaneous tissue may be of a degree which closely resembles scleroderma. The cutaneous lesions are likely to appear during the course of the disease and may desquamate. Cutaneous lesions may be entirely absent

The skeletal muscles are at first swollen and edematous. Later they are hypotonic and small In the active stages of the disease there is almost always tenderness on pressure over the involved muscles, and both active and passive movements cause pain Either paralysis or mild paresis may be present Tendon reflexes are normal, diminished or abolished Passive movements reveal loss of the normal elasticity of the muscles In some cases the process may involve the muscles of respiration, giving rise to dyspnea Involvement of the myocardium or myocarditis may cause decompensation which ends in death The jaw muscles may be affected, and the patient becomes unable to chew Tenosynovitis is almost always present to some degree, and in rare cases the joints are affected An extension of the inflammation to the nerve trunks initiates a neuromyositis A neuromyositis is but an extension of a dermatomyositis to the nerve trunks It is distinguished from dermatomyositis by observing that the nerve trunks are tender and sensory disturbances are present.

Severe residua may be found after the active stage of the disease. The muscles may be atrophic and partially replaced by connective tissue so that they feel dense and inelastic. Severe flexor contractures are common The skin is often deeply pigmented and indurated so as to resemble scleroderma Roentgenograms of the muscles sometimes reveal fine calcareous deposits lying in the superficial layers of the muscle, muscle sheath and subcutaneous tissues.

The spleen and lymph nodes may be enlarged There is rarely leukocytosis. A relative eosinophilia often is present.

DIAGNOSIS The diagnosis is established by biopsy The diagnostic features of importance are the tenderness of the muscles, the edema of the subcutaneous tissues, and the dermatitis

The prognosis is unfavorable but not absolutely bad In some cases in which the symptoms are mild the patient may make a complete recovery

Scleroderma (Acroscleroderma, Acrosclerosis, Diffuse Scleroderma). Scleroderma is a disease of the skin and subcutaneous tissues in which there is a hard, rigid, hidebound appearing skin in which often appear pigmented patches When scleroderma appears on small areas of the skin it is designated scleroderma circumscriptum The term acroscleroderma designates mature scleroderma which attends Raynaud's disease

The etiology of scleroderma is a mystery The disease commonly affects young women

PATHOLOGY. In acroscleroderma according to O'Leary and Waisman the cutaneous changes consist of increase and swelling of collagenous connective tissue with fragmentation and swelling of the elastic fibers and an accumulation of melanin in the basal cells The epidermis may be hyperkeratotic, and the rete, the hair follicles and sebaceous

glands are atrophic or absent. In some instances the skeletal muscles undergo changes.

Fibrous tissue changes may be present in the lungs, esophagus, heart and other organs

The esophageal changes in scleroderma consist of dilatation of the distal two thirds of the esophagus and chronic ulceration in the region of the phrenic ampulla In the later stages stricture is present.

SYMPTOMS. The symptoms of scleroderma depend on the situation and distribution of the process Scleroderma attending Raynaud's phenomenon, situated in the upper extremities and termed acroscleroderma, commences in about one half of these patients with aching, soreness, stiffness and swelling of the joints and of the fingers and toes *In about a fourth of patients the first symptoms are coldness,* increased sweating, and cyanosis made worse by being cold. In the rest of the patients articular and vascular symptoms are so intermingled that it is impossible to distinguish the one from the other.

In the syndrome of acroscleroderma the manifestations of Raynaud's phenomenon are far advanced and in these patients the scleroderma involves not only the extremities but extends to the skin of the face and upper thorax. However, the *syndrome of acroscleroderma may involve the skin of the extremities, face and* thorax with minimal manifestations of Raynaud's phenomenon. Finally there are patients who have stiffness of the skin attended by progressive sclerodermatous changes without any subjective or objective evidence of vascular disease including Raynaud's phenomenon.

Sclerodactylia is the term employed to designate the condition when the process and the symptoms are confined to the fingers. When the process is thus limited the *symptoms may closely resemble rheumatoid arthritis.*

The symptoms of scleroderma commence gradually and are manifested by tensing and stiffening of the skin This discomfort is experienced only during use of the fingers in performance of co-ordinated movements As Raynaud's phenomenon progresses, the symptoms are manifested in warmer environments In the early stages the vascular or sclerodermatous changes rarely involve the feet With progression the sclerosis of the skin and subcutaneous tissues eventually involves the *toes, feet and legs, and in the more severely progressive instances the entire surface* of the body including the mucous membranes is affected. As the skin or the mucous membrane becomes involved the patient complains of sensations of stiffness therein

The patient may complain of dysphagia The constricting effect of scleroderma of the thoracic wall, changes in the larynx, and pulmonary fibrosis eventually produce considerable respiratory difficulty Pleural effusion, pericardial effusion and heart failure as the result of scleroderma have been recorded In rare instances, in *the midst of the disease, hydrarthrosis may supervene.*

EXAMINATION Sclerodermatous skin is tight but not necessarily thickened It may be difficult to wrinkle it by pinching The underlying tissue is stiff and hard. In the late stages the fingers become stiff, puffy and fixed and the hands may have a clawlike appearance. The pulsation of peripheral arteries is often *variable and* may be difficult to palpate on account of rigidity of the tissues.

Disturbances of skin pigments are present Hyperpigmentation and depigmentation of the skin may result in the presence of brown pigmentation and vitiligo in the same region The subcutaneous tissues become thinner and atrophic The nails become deformed, shrunken, cracked and lusterless. Gangrene of the end of a finger or toe may appear. The distal ends of the bones of the fingers may become fragmented and may form *sequestra with resulting draining sinuses.*

The roentgenologic examination of the esophagus may reveal loss of peristalsis and dilatation of the distal segment with ulceration. As the disease advances ulceration and stricture may be demonstrated.

In the more advanced stages there may be pulmonary fibrosis and cardiac enlargement

DIAGNOSIS. No other disease produces the hard, tight skin over the fingers, hands and arms, and the expressionless face, thin lips and difficulty in fully opening the mouth as does scleroderma

In most instances of Raynaud's disease the sclerodermatous changes are absent or appear only late in the disease. However, in some instances sclerodermatous changes precede the Raynaud's phenomenon. In rare instances scleroderma proceeds without vascular changes.

Occasionally rapidly progressive scleroderma simulates dermatomyositis and lupus erythematosus. In dermatomyositis the changes are deeper and involve largely the muscle and its fibrous sheath. In lupus erythematosus the skin does not undergo changes in tension and appearance such as occur in scleroderma.

According to O'Leary, Waisman and Harrison scleroderma of the acrosclerotic type reaches a stage where it may remain more or less stationary, but usually it is progressive

Sarcoidosis. Sarcoidosis is called also Boeck's sarcoid, Besnier-Boeck disease, Besnier-Boeck-Schaumann disease, Hutchinson-Boeck disease, lymphogranulomatosis benigna, Darier's sarcoid, erythema induratum, lupus pernio, tuberculosis nodularis, angiolipoid, uveoparotid fever, and osteitis tuberculosa multiplex cystoides.

Boeck's sarcoid is a generalized disease often associated with obscure pathologic processes such as cystic formations in small bones and the syndrome of uveoparotid fever The disease affects the reticuloendothelial system in the lymph structures, spleen, liver, skin and bones The lungs, cardiac muscle, salivary glands and nervous tissue also may be affected. Sarcoidosis is considered by some to be a benign lymphogranulomatosis, by others, a noncaseating form of tuberculosis. Outstanding features of sarcoidosis are an absence or a paucity of tissue caseation, an absence of acid-fast organisms unless frank tuberculosis coexists, and anergy to tuberculin The lesions show a marked tendency to regress The course often is benign, but not always so Death is usually caused by progressive pulmonary tuberculosis or cardiac failure.

Sarcoidosis according to Longcope is neither a new nor a rare disease. The sexes and the races are equally susceptible. Those from rural districts are more frequently affected than urban dwellers, and the disease does occur in more than one member of a family Many authorities believe that it is an infection or that it is related to an infection in some such relationship as rheumatic fever to streptococcus type A infections

In the presence of sarcoidosis active tuberculosis frequently develops, and because of this many have believed that sarcoidosis is an atypical form of tuberculosis

Sarcoidosis bears some clinical similarities to Hodgkin's disease, though histologically it is distinct from it

There are points of similarity to lymphopathia venereum Lymphopathia venereum can be ruled out, however, by the preponderance of negative reactions to the Frei skin test and the failure to isolate this or any other virus from sarcoid either by culture or by animal inoculation

Syphilis, though bearing many resemblances to sarcoid, has been excluded by the usual examinations, including therapeutic tests. There has been no evidence to support the view that sarcoidosis is due to brucella infection.

PATHOLOGY. The sarcoid lesions may occur in all organs of the body but usually are limited to one or two organs or systems. The tissues most frequently involved are the lymph nodes, lungs, eyes, skin, spleen and liver. The cut surface of sarcoid tissue has a

homogeneous appearance, firm, or soft, but never caseous or purulent The lesions vary in size. In some instances there are small nodules in the iris or on an eyelid, or in a lymph node with only slight enlargement of that node. At times the lesions form masses of lymph nodes, cause great enlargement of the spleen, or infiltrate densely throughout the lungs

The lungs in sarcoidosis are large and emphysematous; the visceral pleura is thickened On section, there is a generalized dissemination of millimeter-sized grayish spots as well as larger nodules and patches similar in structure Emphysematous blebs are often present on the surface and small bullae within the lung substance The hilar lymph nodes may reach considerable size

SYMPTOMS. The complaints of a patient who has sarcoidosis depend on the organs involved It is only when a vital organ is involved that there is anything more than a minor discomfort The discomfort in no way indicates the widespread distribution of the lesions. In spite of the number of lesions the patient seems well and has suffered no great loss of body weight If there has been any fever it has not exceeded 101 to 102 F (38 3 to 38 8 C)

EXAMINATION The skin lesions are the commonest and usually the only complaint of the patient These lesions are nodular in type. The nodules are firm and situated deep in the skin and present a semitranslucent, slick or sometimes scaly appearance The lesions are sparsely scattered over all parts of the body The nodules show progression and regression, depending on the progress of the disease, they often have been observed to disappear completely

Enlargement of the lymph nodes may be limited to the hilar nodes or may involve the superficial lymph nodes In the superficial enlargements only a few nodes may be affected or there may be general enlargement.

Lesions of bone may be present in the small bones of the hands and feet. When there are large sarcoid nodules in the hands, there is an irregular enlargement of the phalanges with disability and deformities

Ocular lesions occur in one half of all of those who have the disease Ocular lesions, however, are more regularly associated with thoracic involvement than with involvement of other organs Some patients have enlargement of the lacrimal glands, some have nodules on the lids; often the whole uveal tract is involved with nodules and generalized uveitis Nodules in the iris are irregular in outline, and are larger and more vascular than those due to tuberculosis Ophthalmologists see these lesions best with slit lamp illumination The nodules are situated in the stroma toward both the ciliary and the pupillary borders The first diagnostic suggestion of sarcoidosis comes from the ophthalmologist in some instances.

Sarcoid infiltration may cause nasal obstruction which in appearance resembles carcinoma. A biopsy of this tissue is the only means of diagnosis

An enlargement of one or both parotid glands, involvement of the uveal tract, lacrimal glands and facial nerve with transitory peripheral facial paralysis may be associated with fever (uveoparotid fever). The syndrome of uveoparotid fever has been declared to be characteristic of sarcoidosis

In uveoparotid fever transitory facial nerve paralysis is common. When the central nervous system is involved, the signs and symptoms are unpredictable. [illegible] urine, upper motor neuron lesions, chronic meningo-encephalitis, compression of the [illegible] convulsions and transitory hemiplegia have been recorded as being caused by sarcoidosis

Sarcoidosis frequently involves the hilar lymph nodes without giving clinical symptoms and often without giving findings on examination by physical means. Extensive involvement of the lungs may be revealed by roentgenologic examination A roentgenogram of the thorax is made of every patient who has sarcoid lesions anywhere. Cutaneous, lymph-node, and nasal lesions are the expected findings. There is a tendency for pulmonary lesions to show improvement

The heart and pericardium may be involved and enlarged in widespread sarcoid lesions. The cardiac muscle may be deeply invaded and bundle-branch blocks may be present

The liver may be moderately enlarged and hepatic functional activity may be impaired Jaundice is rarely present. The spleen often is palpable.

Invasion of the pituitary gland with resultant diabetes insipidus, Simmonds' disease, renal lesions and lesions in the muscles has been recorded

Eosinophilia is more likely to be absent than to be present. Tuberculin tests will eliminate tuberculosis if tuberculin anergy is not present. Skin tests for histoplasmosis may be necessary when the lungs are involved

In sarcoidosis usually there is an increased concentration of serum protein, the increment being due to serum globulin of the gamma fraction

DIAGNOSIS The diagnosis depends on the microscopic study of cutaneous nodules or affected lymph nodes In those who have a uveitis the ophthalomogists may make the diagnosis. It is not an easy task for the pathologist to distinguish the hard tubercle of sarcoidosis from the lesions due to true tuberculosis. The tuberculin skin reaction is usually negative in sarcoidosis The roentgenographic appearances of the process in the lungs and bones are distinctive enough to be of value in the differential diagnosis. Active tuberculosis may of course complicate the making of a diagnosis

Sarcoidosis uncomplicated by tuberculosis runs a long course with remissions and exacerbations ending after years in recovery In some instances the uveitis may result in permanent loss of vision Active tuberculosis is prone to develop and to pursue its usual course

Specific treatment is not known, but it would seem best to institute the general hygienic measures which are employed in treatment for tuberculosis.

Amyloidosis. Amyloid is an insoluble protein substance present as an abnormal deposit in the various organs of the body It is homogeneous, translucent and colorless, and is apparently a compound of albumin and chondroitin-sulfuric acid It gives a blue color when treated with iodine and retains Congo red dye

The term lardaceous disease formerly was applied to this condition The disease amyloidosis occurs in both a primary and a secondary form

Primary Amyloidosis. Primary amyloidosis is an unusual disease Dahlin enumerated the differences of primary amyloidosis from the commoner secondary amyloidosis as follows (1) absence of the generally considered specific etiologic factors such as tuberculosis or chronic suppuration, (2) often minimal involvement of the liver, spleen, kidneys and adrenal glands, which are ordinarily the sites of maximal deposition in secondary amyloidosis, (3) usually considerable deposition of the substance in the heart, lungs, skin, striate muscles and other tissues not often involved in the secondary type, (4) often atypical reactions to the specific amyloid stains and (5) the occasional occurrence of amyloid tumors

The etiology is entirely unknown The lardaceous deposits are found diffusely distributed in mesodermal structures It is therefore classed with the collagenous diseases

In the liver the lardaceous deposits are closely applied to the reticulum fibers between the sinusoids and the cords of hepatic cells The same site of deposition is observed in the adrenal gland In the heart the amyloid is situated on the reticulum between the [illegible] blood vessels of [illegible] where it encases [illegible] gastrointestinal [illegible] othelial cells of [illegible] d gland and the pancreas the material appears to be in the connective tissue The adipose connective tissue near the adrenals in some instances shows the amyloid to be deposited on the surface of fat cells, giving their walls a thickened appearance

homogeneous appearance, firm, or soft, but never caseous or purulent. The lesions vary in size. In some instances there are small nodules in the iris or on an eyelid, or in a lymph node with only slight enlargement of that node At times the lesions form masses of lymph nodes, cause great enlargement of the spleen, or infiltrate densely throughout the lungs

The lungs in sarcoidosis are large and emphysematous, the visceral pleura is thickened On section, there is a generalized dissemination of millimeter-sized grayish spots as well as larger nodules and patches similar in structure Emphysematous blebs are often present on the surface and small bullae within the lung substance. The hilar lymph nodes may reach considerable size

SYMPTOMS. The complaints of a patient who has sarcoidosis depend on the organs involved It is only when a vital organ is involved that there is anything more than a minor discomfort The discomfort in no way indicates the widespread distribution of the lesions. In spite of the number of lesions the patient seems well and has suffered no great loss of body weight. If there has been any fever it has not exceeded 101 to 102 F (38 3 to 38.8 C)

EXAMINATION The skin lesions are the commonest and usually the only complaint of the patient. These lesions are nodular in type. The nodules are firm and situated deep in the skin and present a semitranslucent, slick or sometimes scaly appearance. The lesions are sparsely scattered over all parts of the body. The nodules show progression and regression, depending on the progress of the disease; they often have been observed to disappear completely

Enlargement of the lymph nodes may be limited to the hilar nodes or may involve the superficial lymph nodes In the superficial enlargements only a few nodes may be affected or there may be general enlargement

Lesions of bone may be present in the small bones of the hands and feet When there are large sarcoid nodules in the hands, there is an irregular enlargement of the phalanges with disability and deformities.

Ocular lesions occur in one half of all of those who have the disease Ocular lesions, however, are more regularly associated with thoracic involvement than with involvement of other organs Some patients have enlargement of the lacrimal glands, some have nodules on the lids, often the whole uveal tract is involved with nodules and generalized uveitis Nodules in the iris are irregular in outline, and are larger and more vascular than those due to tuberculosis Ophthalmologists see these lesions best with slit lamp illumination The nodules are situated in the stroma toward both the ciliary and the pupillary borders The first diagnostic suggestion of sarcoidosis comes from the ophthalmologist in some instances

Sarcoid infiltration may cause nasal obstruction which in appearance resembles carcinoma. A biopsy of this tissue is the only means of diagnosis

An enlargement of one or both parotid glands, involvement of the uveal tract, lacrimal glands and facial nerve with transitory peripheral facial paralysis may be associated with fever (uveoparotid fever). The syndrome of uveoparotid fever has been declared to be characteristic of sarcoidosis

In uveoparotid fever transitory facial nerve paralysis is common When the central nervous system is involved, the signs and symptoms are unpredictable. Argyll Robertson pupils, incontinence of urine, upper motor neuron lesions, chronic arachnoiditis, internal hydrocephalus, meningo-encephalitis, compression of the spinal cord resulting in paraplegia, and convulsions and transitory hemiplegia have been recorded as being caused by sarcoidosis

Sarcoidosis frequently involves the hilar lymph nodes without giving clinical symptoms and often without giving findings on examination by physical means. Extensive involvement of the lungs may be revealed by roentgenologic examination. A roentgenogram of the thorax is made of every patient who has sarcoid lesions anywhere. Cutaneous, lymph-node, and nasal lesions are the expected findings There is a tendency for pulmonary lesions to show improvement.

ripheral nerves where there is extensive degeneration than elsewhere Amyloidosis of the nervous system cannot be clinically diagnosed

Secondary Amyloidosis. Secondary amyloidosis follows long, wasting illnesses, often a suppurative process such as an old osteomyelitis, tuberculosis, actinomycosis, syphilis or protracted intoxication such as a chronic nephritis, cancer or myeloma.

In the secondary form of amyloidosis the spleen, kidneys, adrenal glands and liver are the organs most frequently involved.

The clinical signs and symptoms of amyloidosis in the secondary form of the disease are usually those due to involvement of the kidneys. The kidneys manifest amyloidosis by the signs and symptoms of nephrosis (see Diseases of the Kidneys, Chapter 11). In an occasional instance of the disease, hepatomegaly due to infiltration of the liver with amyloid may be present Even when no hepatic enlargement is present, minimal signs of hepatic failure, apparently the result of amyloidosis, may be present.

Adrenal cortical insufficiency may be present in amyloidosis of the adrenals

Amyloidosis of the intestine may be present without manifest symptoms of disturbed intestinal functions If symptoms should be present, the patient complains of diarrhea

In lipoid nephrosis from 40 to 60 per cent of the Congo red disappears from the blood in an hour However, if the urine reveals the presence ot the dye with the disappearance of more than 40 per cent in the blood, nephrosis is a probable diagnosis

Amyloid and Myeloma Those who have myeloma are prone to the development of deposits of amyloid The distribution of this peculiar material in myeloma is often similar to that observed in primary systemic amyloidosis. Deposits of amyloid may occur within the nodular proliferations of the myeloma cells themselves.

Dahlin and Dockerty expressed the belief that the appearance of amyloid deposition is so characteristic in a myeloma that when amyloid is recognized, an underlying myeloma should be sought if it is not immediately obvious. Similar deposits of amyloid rarely, if ever, occur within other neoplasms The nature of material suspected of being amyloid must be confirmed by the use of special staining reactions The variability of the affinity for Congo red by the amyloid in myeloma is pointed out by Dahlin and Dockerty The van Gieson connective tissue stain is of great value in differentiating amyloid from dense collagen or bone, which stains a brilliant red

DIAGNOSIS OF AMYLOIDOSIS The diagnosis of amyloidosis in the primary form depends on the awareness that the first symptoms in many cases are edema, breathlessness and nocturnal dyspnea Precordial pain may be present Often there is just breathlessness In some there are muscular weakness and limitation of motion of the muscles Difficulty in walking from muscular stiffness may be marked.

A primary amyloidosis may be solely manifested as hepatic insufficiency.

The diagnosis of the secondary form of amyloidosis depends on an awareness that this form of the disease frequently follows a chronic suppurative process present anywhere in the body It is usually manifested as a chronic nephrosis

The diagnosis can be established with certainty by means of histologic examination after the tissue has been stained by a special stain (iodine, methyl violet or Congo red) In accessible areas biopsy is made and the tissue studied by special staining methods

The primary form of amyloidosis is always fatal. The secondary form of the disease may in rare instances become quiescent

Primary amyloidosis appears about equally in the sexes, but, unlike secondary amyloidosis, it occurs more frequently in older patients than in young persons A pronounced asthenia is common Because of the frequently diffuse extent and the varying degree of amyloid deposit in the different organs the myocardium and the lungs may be heavily infiltrated. There may be the symptoms of congestive heart failure In other instances the clinical manifestations are referable to hepatic failure due to the deposits in the liver The association of signs of hepatic disease and renal disease in some may be an outstanding feature. In well-developed renal amyloidosis the manifestations may be those of a nephrosis. A rather rapidly progressive and fatal termination is frequent in a renal amyloidosis being manifested as a nephrosis

In about one third of these patients a loss of body weight is present In others there is a gain of body weight due to subcutaneous edema In some patients there are hydrothorax and ascites

The heart is not enlarged until congestive failure is present. As heart failure develops there may be murmurs, pulsus alternans and gallop rhythms. The electrocardiogram is helpful in detecting, if present, occult cardiac infarction In amyloidosis of the heart there is a low voltage of the QRS complexes.

The liver and the spleen are often palpable

In all forms of primary amyloidosis macroglossia may be present. It is observed in about one third of those who have the disease Dysarthria and discomfort from swallowing are common

Cutaneous changes consist of areas which are opalescent, papular, nodular or diffusely eczematous in appearance When large areas of skin are involved, these changes may be sclerodermatous in appearance. Focal cutaneous lesions of the above-mentioned varieties often occur about the nails of the fingers and toes. Lesions comparable to those of the skin may appear on a thickened enlarged tongue or on the mucous membranes of the throat.

Hypochromic or normocytic anemia is usual The sedimentation reaction is moderately or greatly increased and the leukocytes are normal

The Congo red test is useful The procedure consists in the parenteral administration of 1 ml. of a 1 per cent aqueous solution of Congo red per 10 pounds of body weight In normal persons less than 40 per cent of the dye disappears from the blood in 1 hour In amyloidosis the disappearance of 60 to 100 per cent in 4 minutes is a consistent finding Since small amounts of amyloid may not absorb more than 40 per cent of the dye in 1 hour, the absorption of 40 per cent or less does not exclude amyloidosis The results of the Congo red test may be misleading in individual cases.

The cause of death is renal or cardiac failure, terminal infection and gastrointestinal hemorrhage

Amyloid Neuritis Kernohan and Woltman have observed the infrequency of amyloidosis of the nervous system. Damage to the nervous system, when caused by amyloid, seems to be the result of compression or of arterial obliteration In a few instances the brain may be invaded It is well to remember that corpora amylacea and amyloid are unrelated substances. Small amounts of amyloid have been described in the large vessels of the base of the brain and their branches It is still rarer to observe involvement of the peripheral nerves.

When involvement of the nervous system occurs, it is a part of the general primary or nonseptic form of amyloidosis. As has been noted, the disease process in this form is limited to the media of the smaller arteries and arterioles The amyloidosis of these blood vessels may produce narrowing of the lumina of the vessels or may occlude them The changes in the parenchyma of organs is the result of ischemia subsequent to the narrowing or occlusion of the blood vessels by the amyloid. The results of the ischemia are more specifically observed in the pe-

DISEASES DUE TO TRAUMA, PHYSICAL AGENTS AND CHEMICAL AGENTS

TRAUMA

The term trauma as employed here indicates an agent which, when violently applied, is capable of immediate infliction of a rupture of the continuity of an internal or an external organ or a surface of the body. A gross wound ensues

Classification of Wounds. An *abrasion* is a skin wound caused by scraping or scratching or wearing away of the skin

When an abrasion is inflicted by sliding on the ground or pavement, the direction of the slide is revealed by the angle at which the skin strikes the ground on the starting edge of the injury and tags of skin along the finishing edge Changes in the direction of the body are indicated by curving of the lines of the scratches. Abrasions also may be caused by direct impact by a blunt object Abrasions from falls often affect parts of the body which are made prominent by bony elevations such as the knee or the elbow

A *bruise* or *contusion* is an injury from a blow without an ensuing laceration It causes a spreading extravasation of blood into the tissues from an area crushed by the blow. The skin may be injured by the direct impact. A blow or a fall may leave the skin intact but beneath it the tissues have been crushed sufficiently to tear the capillaries and smaller blood vessels Blood escaping from these will spread and the area will become discolored purple These discolorations are the characteristic manifestations of a bruise

Bruising is manifested more easily in soft, vascular, lax tissues like the eyelids than in tough and less vascular ones like the palm of the hand The young and the old bruise more easily than do persons of other ages

The length of time required for the color changes and the other manifestations of bruises to resolve varies according to their situation Bruises, for instance, seldom resolve when situated under the dura and are slow to resolve in the aged, while those around the eyes or on the scalp resolve in a few days.

A bruise discoloration may shift its position For instance, a deep bruise in the fasciae of the hip may finally discolor the skin at the knee.

A bruise can be caused after death as long as fluid blood is present in the capillaries and veins. The amount of blood escaping in this way can only be very small.

A *laceration* originates from splitting or tearing of the whole skin and is likely to be attended by either abrasions or bruises The extra force which splits the skin is aided by the projection and partial fixation of skin over bony prominences, as with the scalp, cheek, nose, elbows or knees. The edges of such splits are likely to be jagged.

A wound by *incision* is made by a cutting instrument, and incisions vary according to the character of the cutting instrument and the sort of stroke made. A blow with an axe effects a wound with straight but torn edges, whereas a sharp knife or razor inflicts a split-edged wound.

Incised wounds are common in accidents involving broken glass, in accidents

The *exit wound* consists of a hole in the skin—torn to a degree dependent on the momentum of the bullet leaving the body, and on whether or not it leaves the body straightway, wobbling, or turning over and over, and the amount of bone splinter it may carry away with it. At close range the entry wound is larger than the exit wound.

The course of the projectile is traced by a line commencing at the entry wound and running into the body along the track of the bullet As soon as the bullet meets dense tissue, such as bone or teeth, capable of deflecting it, the jacket may be torn off in the impact, and it with the other solid material may be dispersed in different directions.

A bullet passing through the plates of the skull leaves a hole the margin of which is shelved or beveled from the outside toward the inside of the skull plate. The exit of a bullet from the skull causes a hole in the skull plate with the shelving and beveling from the inside out.

Entry wounds from *shot* at close range differ in no material way from entry wounds from bullets except in being of larger size The body sustaining the force of the muzzle blast is split open There is not likely to be an exit wound of any kind The tissues are torn and blown away, and if the part hit is covered with clothing, shreds of cloth are blown into the adjacent tissues As the range increases, the charge of shot spreads so that a shot spread of 18 to 20 inches will have been fired from a 12-gauge shotgun with modified choked bore at a range of 20 yards However, no exact opinion should be given until trial shot patterns are made by trial shots fired from a particular weapon and recorded The tattooing distance of a shotgun is the same as that of a rifle It is about 1 yard

The wounds inflicted by small arms are most frequently caused accidentally by "unloaded" arms The brief descriptions of these wounds as given here will be helpful in the recognition and treatment In cases of suicide and of murder the physician may be expected to give an opinion in answer to such questions as: Could a particular wound be inflicted by a certain weapon which is at hand? If so, at what range and direction was it fired?

A suicidal wound can only be inflicted from a range within the subject's reach (except when some string or cord is rigged up to pull the trigger). This range, for practical purposes, is 3 feet This range of 3 feet is also the range of the powder tattooing The length of shotgun and rifle barrels varies from 26 to 32 inches and therefore, for practical purposes, unless some sort of preparations for firing these arms is made, suicidal wounds will be made with muzzle against the part and from angles of fire not likely to be obtainable in a homicidal wound If a suicidal wound is inflicted at greater ranges, evidence such as a stick, string or some object used to pull the trigger will be found The significance of these objects in making the diagnosis of suicidal wounds is great and they and the method in which they may have been used should be looked for The significance of these objects may naturally escape the inexperienced police officer, and the doctor should ask about them himself

Self-inflicted wounds of a deliberate suicidal character are almost always contact wounds, situated in the sites of election, the right temple (or the left temple in left-handed persons), center brow, the roof of the mouth, and over the heart. An entry wound situated off an elective site always arouses suspicion of foul play. When, in addition, such a wound is inflicted from a range outside arm's reach, suspicion grows stronger Only the addition of some circumstantial evidence can decide the problem of the single wound not bearing the stamp of suicide It is rare for a suicide to be able to fire twice in any of the sites of election, for each is vital Two or more wounds almost certainly mean homicide.

Wounds inflicted by shotguns are greatly modified by sawing off a part of the

while using sharp instruments, in homicidal attacks and in suicide or suicidal attempts. Accidentally incised wounds from broken glass have no topographic preferences Wounds inflicted while using sharp instruments occur on the face, hands and feet. Homicidal wounds occur on the hands, face, neck, back and abdomen of the opponent, whereas suicidally incised wounds are topographically situated.

The person with suicidal intent often makes several superficial stroking cuts over wrists, neck, chest, abdomen, groins and legs in the belief that vital arteries lie superficially in these regions. Often these wounds do not even divide the skin After the disappointment of finding out that these vital structures are more deeply situated, a determined stroke is made which severs every tissue down to bone in a wrist, neck, chest, groin or leg Often in suicide by cutting the throat the carotid arteries may not be cut, for in the greatly extended neck the carotid arteries are displaced laterally to the spinal column and thus are spared because the knife impinges on the vertebrae before it can reach them.

Stab or *penetrating* wounds may be made with but little effort with sharp-pointed or sharp-edged weapons or with considerable effort with blunter-pointed instruments such as knives, forks and nails. The entry wound in either case is a slit Rocking of the weapon or twisting of the victim may tear such slits more widely. The deepest wound inflicted by a rotary movement provides an estimate of the minimal length of the blade.

It is the depth of the stab or penetrating wound which makes the injury dangerous Such a wound furnishes poor drainage and is susceptible to infection by the various clostridia (*Clostridium tetani*). A vital injury or a lethal infection by *Clostridium tetani* may have entered the body through a very small entry wound

Stab wounds are common to both suicides and homicides. Stab wounds inflicted by one with suicidal intentions are situated in the region of the heart or the epigastrium where the heart beat can be felt The suicidal stab is a single, deep penetrating wound made without rocking of the knife after entry. The homicidal wound is often finished with a rocking movement. The homicidal wound rarely is situated directly over the heart. It may be situated in the epigastrium or anywhere over the thorax. Multiple deep stab wounds in the back are homicidal.

The two types of *firearms* of small caliber commonly used for hunting of small game inflict accidental wounds as well as the wounds resulting from crimes of violence. These arms include those with rifled barrels (pistols and rifles) and the smooth-bored barrels, or shotguns.

A bullet wound from a rifled barreled gun consists of an entry wound and often an exit wound. The *entry wound* made by a *bullet* at close range bears the marks of everything that is discharged with explosive force from the muzzle. Its size varies with the caliber of the weapon

The entry wound which is made with the muzzle of the firearm from 6 inches to 2½ feet from its mark is split and scorched; the hairs are singed, maybe slightly blackened, and there are finely tattooed, unburned particles of powder embedded in the surrounding skin. The tissues beneath the skin are often torn away from their supporting structures. They may be tinted cherry red by the carbon monoxide in the gases which have been forced into them.

A discharge made more than a yard from the body will inflict the same sort of wound for ranges up to some 60 (pistol) to 200 (rifle) yards; the entry hole is split and soiled by the irregular vibratory course of the blunt end of the bullet in its trajectory. These entry wounds are soiled by the spin of the bullet. The oncoming bullet produces a *soiling ring* which distinguishes its entry from its exit When the momentum of the bullet is small, it may remain inside far removed from its *normal* trajectory.

Diagnosis is based on the history and the short duration of the illness, from 2 to 10 days The fever subsides within a period of a few hours up to two days

Bagassosis. The inhalation of bagasse dust, derived from the pulp of sugar cane after it has been crushed and the juice extracted, incites a pathologic process which has been called bagasse disease of the lungs or bagassosis Bagasse or sugar cane pulp is being used extensively in the manufacture of insulating building materials and refractory brick It constitutes a serious hazard unless properly handled

The etiologic basis for bagassosis is obscure Whether or not the pathologic reaction is due to fungi, bacteria or a virus associated with the pulp dust, to an allergic response to the bagasse or its possible infectious agents or their products, to some chemical or physical property of the dust or to any combination of these factors has not been determined.

Pulmonary changes incited by the inhalation of bagasse dust consist in a diffuse infiltration and consolidation, an acute bronchiolitis or a pneumonia which is similar to that seen in pneumoconiosis but which in one respect is greatly different It is a reversible reaction, with the process undergoing resolution and the lung regaining its normal appearance on the roentgenogram, a phenomenon which is not observed in pneumoconiosis

About 2 months of exposure to the dust are required before symptoms develop The onset is insidious and gradual The disease manifests itself as an acute febrile illness with extreme shortness of breath, a persistent cough with scanty mucoid sputum, and profound weakness.

Examination reveals a bronchopneumonia

The diagnosis is made on the basis of the history, findings on physical and roentgenologic examination, and the final clearing of the process in the absence of other causative factors

Thresher's Lung (Bronchomoniliasis) Thresher's lung is caused by the inhalation of dust from molded ("burned") grain Cultivation of samples of sputum on Sabouraud's medium yields *Monilia,* a yeastlike fungus In the severe instances of the disease the onset is sudden, accompanied by shivering, fever, malaise and cough with mucopurulent or sanguinolent expectoration, and dyspnea Ocular symptoms and rhinitis also may be present The clinical signs include a bronchial catarrh at the bases with dry subcrepitation, mild leukocytosis and an increased sedimentation rate The findings resemble those of miliary tuberculosis. In severe illnesses the densities increase and merge into a disseminated patchy fibrosis with bronchiectasis

Lipid Pneumonias Young children who resist the administration of oily vitamin preparations often inhale these substances into the lungs These oily preparations are often composed of fish oils irritating to the lungs However, these oils can be absorbed into the body from the lungs. Mineral oil is a saturated hydrocarbon It cannot be ingested into the body tissues and consequently it remains in the lungs indefinitely, except for the small amounts which appear in the sputum

Anatomic defects in the mouth, palate, tongue, larynx or esophagus, neurologic disturbances that interfere with swallowing, the use of forced feedings, and the fact that mineral oil, being bland, does not initiate the cough reflex, are factors that predispose to the aspiration of oil. Mineral oil pneumonia in adults often results from nose drops or nasal sprays When mineral oil reaches the dependent portions of the lungs, it first remains free in the alveoli Then some of it is phagocitized by the macrophages, some is disposed of in the sputum, and a small amount reaches the lymph nodes, but the bulk remains indefinitely in the lung, where it provokes the development of fibrous tissue The lower lobes, particularly the right, are most likely to be involved

The symptoms are those of a chronic pulmonary affection.

On examination there may be the physical evidence of consolidation The oil may be discovered in the sputum

The diagnosis of lipid pneumonia depends on the history and on roentgenologic

barrels or by removing the shot from the cartridge and reloading with slugs (irregular-sized pieces of lead or steel). These wounds are almost always homicidal wounds.

PHYSICAL AGENTS OF DISEASE

A physical agent, as defined here, is a material perceptible to the senses which produces disease by its presence It remains aloof from the chemical processes of the body and does not depend on the body for sustenance

Particulate Matter. Finely divided physical material may cause injury to the skin, to the mucous membranes and, particularly when inhaled, to the lungs.

Organic Particulate Matter. *Large quantities of organic dust, such as corn* meal, wheat flour, and coal dust, may be inhaled, sometimes causing clogging of the smaller air passages and resultant regions of atelectasis.

The inhalation of dust and smoke of cities may cause a mild form of pneumoconiosis In fact, evidence of it may be found on roentgenologic examination or at postmortem examination of the lungs of many adult dwellers in cities. The older such persons become, the more marked are these findings.

Smokes such as diphenylaminechlorarsine and diphenylchlorarsine may produce irritation of the nose and throat. The nasal accessory sinuses also are involved The symptoms consist of pain and a feeling of fullness in the nose and sinuses with severe headache. Later there is intense burning of the throat, with tightness and pain in the chest There are lacrimation, violent sneezing and marked nasal secretion. Nausea and vomiting also may occur Mental depression may be so severe as to cause the sufferer to inflict self-injury. All symptoms usually disappear in one or two hours, leaving no permanent injury Prevention consists of the use of the gas mask.

There are organic contaminants which cause coniotoxicosis, irritation of the respiratory tract, resulting in bronchitis, hay fever and asthma. Organic dusts are not indicated as being harmful unless a person becomes sensitized to them. For example, the pollens of various trees and plants, and vegetable dust, including that of wheat, corn, oats and barley, may cause asthma when inhaled by sensitized persons (see Chapter 18)

However, there are organic dusts which may cause irritation from the physical properties of the dust or from bacteria contained within the particulate matter, for example, the cotton bacterium in raw cotton

Byssinosis or Cotton Disease An acute illness, the cause of which has not been completely elucidated, occurs among rural mattress makers who use cotton in their manufacture. Probably the same disease is the so-called *mill fever* or *Monday fever* formerly found in workers in cotton mills The disease or diseases follow the inhalation of dusty cotton during the initial stages of cotton processing

The symptoms and physical manifestations described for this disease indicate that the severity of the illness is dependent on the presence and concentration of the cotton bacterium or its products in the cotton dust inhaled, and on the duration of exposure Neither age nor sex seems to influence the incidence of the disease.

These illnesses commence from 1 to 6 hours after work is begun. The initial symptoms are fatigue and generalized aches, followed by anorexia, headache, nausea and vomiting, the latter lasting 6 to 9 hours in some instances About 6 hours after exposure a sense of chilliness supervenes, followed usually by definite chills, fever and headache. In some patients the temperature may be 102 F (38.8 C) or more. Fatigue and generalized aches last from 2 to 4 days Many patients complain of abdominal pain or cramps and of substernal discomfort or pressure, varying in intensity and duration. The patient may be unable to take a deep breath

On examination the lungs are clear. There is a moderate leukocytosis. Results of roentgenologic examination of the chest are negative.

Diagnosis is based on the history and the short duration of the illness, from 2 to 10 days The fever subsides within a period of a few hours up to two days.

Bagassosis. The inhalation of bagasse dust, derived from the pulp of sugar cane after it has been crushed and the juice extracted, incites a pathologic process which has been called bagasse disease of the lungs or bagassosis Bagasse or sugar cane pulp is being used extensively in the manufacture of insulating building materials and refractory brick. It constitutes a serious hazard unless properly handled

The etiologic basis for bagassosis is obscure Whether or not the pathologic reaction is due to fungi, bacteria or a virus associated with the pulp dust, to an allergic response to the bagasse or its possible infectious agents or their products, to some chemical or physical property of the dust or to any combination of these factors has not been determined

Pulmonary changes incited by the inhalation of bagasse dust consist in a diffuse infiltration and consolidation, an acute bronchiolitis or a pneumonia which is similar to that seen in pneumoconiosis but which in one respect is greatly different It is a reversible reaction, with the process undergoing resolution and the lung regaining its normal appearance on the roentgenogram, a phenomenon which is not observed in pneumoconiosis

About 2 months of exposure to the dust are required before symptoms develop. The onset is insidious and gradual The disease manifests itself as an acute febrile illness with extreme shortness of breath, a persistent cough with scanty mucoid sputum, and profound weakness

Examination reveals a bronchopneumonia

The diagnosis is made on the basis of the history, findings on physical and roentgenologic examination, and the final clearing of the process in the absence of other causative factors.

Thresher's Lung (Bronchomoniliasis) Thresher's lung is caused by the inhalation of dust from molded ("burned") grain Cultivation of samples of sputum on Sabouraud's medium yields *Monilia*, a yeastlike fungus In the severe instances of the disease the onset is sudden, accompanied by shivering, fever, malaise and cough with mucopurulent or sanguinolent expectoration, and dyspnea Ocular symptoms and rhinitis also may be present The clinical signs include a bronchial catarrh at the bases with dry subcrepitation, mild leukocytosis and an increased sedimentation rate The findings resemble those of miliary tuberculosis In severe illnesses the densities increase and merge into a disseminated patchy fibrosis with bronchiectasis

Lipid Pneumonias Young children who resist the administration of oily vitamin preparations often inhale these substances into the lungs These oily preparations are often composed of fish oils irritating to the lungs However, these oils can be absorbed into the body from the lungs Mineral oil is a saturated hydrocarbon It cannot be ingested into the body tissues and consequently it remains in the lungs indefinitely, except for the small amounts which appear in the sputum.

Anatomic defects in the mouth, palate, tongue, larynx or esophagus, neurologic disturbances that interfere with swallowing, the use of forced feedings, and the fact that mineral oil, being bland, does not initiate the cough reflex, are factors that predispose to the aspiration of oil Mineral oil pneumonia in adults often results from nose drops or nasal sprays When mineral oil reaches the dependent portions of the lungs, it first remains free in the alveoli Then some of it is phagocitized by the macrophages, some is disposed of in the sputum, and a small amount reaches the lymph nodes, but the bulk remains indefinitely in the lung, where it provokes the development of fibrous tissue. The lower lobes, particularly the right, are most likely to be involved

The symptoms are those of a chronic pulmonary affection

On examination there may be the physical evidence of consolidation. The oil may be discovered in the sputum.

The diagnosis of lipid pneumonia depends on the history and on roentgenologic

examination of the chest when there are no other causes for the findings. The presence of fat in the sputum is not necessarily diagnostic, for fat may be demonstrated in almost any unfixed sputum stained with Sudan III and examined microscopically. The average concentration of fat is greater in bronchial sputum than in that obtained from the mouth. There is no correlation between the amount of fat and the type of pulmonary disease which may or may not be present. Recent ingestion of oil will cause no increase in concentration of fat, but increased amounts of fat are present shortly after intake of food.

Inorganic Particulate Matter. The term pneumoconiosis designates a chronic fibrous reaction in the lungs due to the inhalation of particulate matter (dust). It is attended by fibroid induration and pigmentation The condition in the lung may be designated according to the kind of dust inhaled, for instance anthracosis, asbestosis, siderosis, and silicosis Illnesses due to mixed dusts are designated by terms indicating the offending dusts, for instance anthracosilicosis and siderosilicosis.

Coniofibrosis is a form of pneumoconiosis characterized by a profuse growth of connective tissue due to a specific irritant It embraces silicosis, silicotuberculosis and asbestosis

Anthracosis and *siderosis* act principally by obstructing the lymphatic structures and impairing lymphatic drainage. An impaired drainage of lymph lowers the resistance of tissue and thus enhances any infection which may be present at the time or which begins thereafter.

Persons exposed to field, farm and road dust can, but rarely do, inhale enough dust to result in changes in the respiratory tract.

Silicosis Silicon dioxide is abundantly present everywhere. The natural defense mechanism of the lungs protects them against even high concentrations of silica dust. Those whose nasal passages have been injured by trauma, surgical operation or disease are more readily susceptible to silicosis than others.

The ciliated epithelium of the trachea and bronchi directs much of the dust lodged in these tubes to the pharynx where it is swallowed or expectorated Particles larger than 10 microns in diameter cannot enter the terminal bronchioles It is therefore the particles of silicon of less than 10 microns in diameter which can pass into the smallest bronchioles and lodge in them

Silicosis produces a wide range of lesions, all of which serve to retard the flow of lymph with an attending extensive fibrosis in both lungs.

In most instances of rapidly developing silicosis the lesions of pulmonary tuberculosis are present. Grossly the appearance of the lungs is not that of silicosis but suggests the induration of organized pneumonia The tracheobronchial lymph nodes are not enlarged No nodules are visible on the cut surface of the lung or on the pleura. There is diffuse thickening of the alveolar septa

There is present a high incidence of cardiac failure in silicosis

There is no evidence to indicate that pulmonary malignant disease develops more frequently among silicotic patients than among other persons.

Silicosis is not necessarily a progressive disease. Workers in dusty trades often have been frightened by what they have heard and read about silicosis and few consequently are those who do not have symptoms. Symptoms will surely follow if these persons are made aware that the roentgenograms reveal changes in the lungs.

The symptoms of silicosis depend on the stage of development of the disease. A history of 2 or more years of exposure to dust (10,000,000 or more particles of dust less than 10 microns in diameter, of which 25 to 35 per cent is free silica, per cubic foot of air) is required for the acquirement of silicosis In most persons silicosis never gives symptoms

As silicosis progresses sufficiently to cause symptoms, there are *shortness of breath* on exertion and a slight nonproductive cough. As silicosis *advances further*, the shortness of breath becomes severer. When the pleura is involved, pleural pain

occurs. A dry cough is frequently present. If any sputum is present, it is in small amounts.

Rapidly developing silicosis or *acute silicosis* occurs in those who are exposed to large numbers of finely divided particles of almost pure silica dust, as may occur in sandblasting or pulverizing plants. The symptoms of a rapidly developing silicosis are those of bronchopneumonia As the pneumonia lingers on, it is then found that there is present in addition to the acute silicosis some other pulmonary infection, usually tuberculosis

Silicosis may be suspected from the physical signs plus roentgenologic findings indicating silicosis.

On examination there may be limitation of movement of the thoracic wall during forced respirations This limitation of motion is confirmed by palpation The percussion note may be dull over localized regions of the thorax. Scattered rhonchi are sometimes heard on auscultation, and expiration is prolonged. On examination by physical means the findings in those who have a rapidly developing silicosis are those of bronchopneumonia.

The diagnostic requirement of silicosis is the presence of shadows on the roentgenogram which might be due to silicosis Diagnosis of disabling silicosis without disabling symptoms is impossible

The diagnosis of clinical or disabling silicosis is based on the degree of dyspnea, thoracic pain and cough The roentgenologic findings may or may not be far advanced in those who have clinical manifestations of silicosis.

Silicosis and Pneumonia A patient who has symptomless silicosis may have pneumonia, but perhaps is no more likely to have it than anyone else of the same age group The severity of the pneumonia may not be enhanced by the presence of silicosis though there is no agreement on this point

Silicosis and Tuberculosis. Pulmonary tuberculosis in the presence of silicosis is known as silicotuberculosis The patient who has silicotuberculosis can live and get along, with proper care, the same as anyone else who has tuberculosis

Tuberculosis is more prevalent among industrial workers, even in the absence of hazardous dusts, than among the general population. Until recently, however, almost no attempt was made to protect individuals in industry against their tuberculous fellow workers For this reason alone the incidence of tuberculosis should be higher among persons in dusty occupations than among the general population.

Siderosis Excessive iron in the lungs is termed siderosis. Iron may accumulate in the lungs to such an extent that approximately 8 per cent of the weight of the moist lung will be iron The source of iron in the lungs is often electric arc welding.

The steel electrode consists of approximately 99 per cent ferrous material with extremely small amounts of such alloy substances as carbon, manganese, nickel, phosphorus and silicon The coatings are composed of such materials as aluminum, borates, chromium, fluorides and silicates The fumes arising from coated rods consist largely of extremely small particles of iron oxide

As in silicosis, symptoms rarely occur. If symptoms are present, they are dyspnea, thoracic pain, and perhaps a cough

There is a great similarity of the roentgenologic appearance due to the deposit of iron oxide and that due to silicotic nodulation

Silicatosis The dust responsible is talc in the form of tremolite (calcium magnesium silicate) or soapstone (hydrous magnesium silicate), or both, since free silica or other dust in a high concentration is not found Tremolite talc is chemically much the same as asbestos The principal difference is in the physical rather than the chemical structure

The symptoms of the workmen consist of dyspnea, cough, thoracic pain, and weakness After disability occurs, recovery apparently is impossible. On roentgenologic examination there is diffuse haziness, but general nodulations are absent.

Asbestosis. Asbestosis is characterized by diffuse interstitial pulmonary fibrosis and the presence of asbestos bodies in the lungs.

When particles and fibers of asbestos are inhaled a pulmonary fibrosis results from their entrance As the condition progresses, extensive fibrosis develops. Walls of the alveoli become thick enough to reduce the alveolar capacity. The visceral pleura is thickened

At first there are no symptoms, but as the condition progresses, shortness of breath may occur which late in the disease may be distressing. Cough at first is mild, but later it becomes severe and is productive of tenacious sputum which at times is blood streaked There is substernal thoracic pain.

Examination by physical means reveals no important findings until the advanced stages of the disease are reached In the advanced stages a dull percussion note may be elicited over the lower two thirds of the lung fields Auscultation reveals diminished or feeble breath sounds and expiration is prolonged. Dry, crackling, or even moist, rales may be heard over the lower half or two thirds of the lungs.

The diagnosis of asbestosis requires a history of long-continued inhalation of asbestos dust in addition to the roentgenologic findings in the lungs.

Irradiation Injuries. The term radiation hazard is indicative of the dangers associated with ionizing radiations and the radiant energy from heat and light. The injury from radium is comparable to that arising from the roentgen rays The undesirable effects of ionizing radiation rarely become apparent after the use of the roentgen rays in diagnosis Undesirable effects are more likely to become apparent from the use of roentgen rays and radium in therapy

All types of ionizing radiations produce destruction of cells. From a biologic viewpoint, roentgen rays, gamma rays, alpha and beta particles and neutrons differ essentially only in the distribution and the magnitude of the destruction produced

Radiation Reactions. Incidence of sickness due to roentgen rays varies with the patient and also with the kind of disease for which treatment is being administered Patients receiving treatment for the lymphoblastomas occasionally complain of a disagreeable taste in the mouth almost immediately with the start of treatment Nausea and vomiting may follow the administration of but 100 r. Other patients with other tumors frequently withstand 400 r doses without being upset. Profound fatigue also occurs as a sequel to radiation treatment The roentgenologist is aware of the danger and does all that is possible to prevent severe reactions.

Edema following irradiation may be manifested early or late Early edema may be manifest from an hour to several hours after irradiation Late edema due to obstruction of lymph drainage is a serious sequel to irradiation Edema indicates that the irradiation reaction has advanced beyond the desirable limits

Erythema after irradiation has a latent period of 2 to 10 days Varying amounts of roentgen rays, depending on the method of application, when administered in a single dose will produce erythema, as well as epilation, in many skins

A *factitial dermatitis* may follow the erythema Such a dermatitis is characterized by progressive ulcerations of the skin The affected skin is a hard, thickened scar Over the scarred skin course numerous dilated veins

Severe radiation ulcers are the late results of overdosage or are due to an increased sensitivity of the patient or both. These ulcerations are due to the ischemia resulting from destruction of vascular endothelium. They are painful, indolent, and may be permanent Indurated ischemic tissue may become nonviable and ulcerate 2 or 3 years after the last treatment Epithelioma may arise as the last complication of irradiation injury

A distinction is made by the roentgenologist between severe radiation reactions of skin or mucous membrane which are intentionally caused in carrying fractionated radiation dosage to a high level, and painful, deep, nonhealing ulcers that are the result of gross unintentional overdosage or of ill-advised repetition of massive doses

In the administration of a protracted course of roentgen therapy the roentgenologist plans to obtain epidermal effect, epithelitis, epidermitis, and mucositis, without irreparable injury to cutis and subcutis This means a prominent hyperemia, frequently with blisters, denudation, and formation of false membrane. However, recovery from these reactions will ensue without undue induration, and the epithelium will regenerate rapidly.

Irradiation Injury to the Intestine From Treatment for Carcinoma of the Cervix. The intestinal mucosa is so susceptible to injury from irradiation that it sometimes is difficult to deliver a sufficient amount of radiation to destroy the malignant process in the uterus and still prevent excessive, harmful, secondary effects of irradiation from developing in the rectosigmoid and ileum.

Conditions predisposing to excessive exposure of the intestines to irradiation include retroverted uterus, uterus with a thin muscle wall, and peritoneal adhesions fixing one or more loops of intestines in the pelvis where they are likely to receive a concentrated dose of irradiation Irradiation therapy is given cautiously to those who have had pelvic infections or previous surgical operations in the pelvis

The mucosa of the intestines usually manifests irradiation injury by an acute inflammatory reaction consisting of edema, hyperemia, and spasm This change may occur at any time during the course of therapy, or 1 to 2 weeks after completion of the treatment There may be direct injury of the blood vessels manifested by endarteritis, thrombosis, and subsequent infarction of the involved portion of bowel The mucosa may then ulcerate The ulcerations consist of single or multiple, irregular, superficial erosions which progress to deep, discrete ulcers The surrounding mucosa becomes thickened and indurated, and telangiectasis ensue

As the lesions heal, bands of scar tissue form which may constrict the bowel and produce obstruction In some the primary irradiation injury may involve the perirectal tissues, with subsequent production of a diffuse mass of fibrous tissue involving all pelvic structures and producing a condition difficult to differentiate from a pelvis filled with carcinoma

The symptoms of irradiation injury to the rectosigmoid or the ileum may appear within the first month after the institution of therapy, or years afterward.

In many, however, there is only mild rectal discomfort with very little or no bleeding When the symptoms are severe they consist of: (1) those arising from proctosigmoiditis and (2) those referable to obstruction of the lower part of the small intestine

The symptoms referable to the proctosigmoiditis are first of all blood in the bowel motion, which is attended by pain, tenesmus and frequent rectal discharges of bloody mucus. In instances of severe injury the rectal hemorrhage is uncontrollable by ordinary means and requires many blood transfusions in order to sustain life

In a great many pain in the pelvis and rectum is severe, and often drug addiction is acquired

Ileal involvement is rarely present without rectosigmoidal changes When ileal symptoms are present, they are manifestations of obstruction of the distal small intestine

On digital examination of the rectum the lumen of the bowel may be contracted and the walls of the rectum scarred When an ulcer or ulcers are present, they are oval or circular with discrete indurated margins On digital examination one of these ulcers is hard and indurated like a malignant ulcer. These irradiation ulcers sometimes perforate and lead to peritonitis, or to external fistulization or to fistulas into the vagina or the bladder

On sigmoidoscopic examination in the first weeks after treatment the mucosa is red and edematous Later, the mucous membrane becomes atrophic Telangiectases and contraction of scar tissue ensues

The diagnosis of irradiation injury to the intestines from treatment of carcinoma of the cervix is usually established by endoscopic examination In occasional in-

stances, however, it may be difficult to determine whether or not there is recurrence or extension of the cervical carcinoma. If there is considerable perirectal fibrous tissue, it may be impossible to know whether there is recurrence or metastasis of the carcinoma

The Nervous System. Therapeutic irradiation over the pelvis during pregnancy is dangerous to the fetus. Often microcephaly and idiocy are present at birth, seemingly from the effects of irradiation of the fetus.

Extensive and prolonged irradiation of the head after birth may also cause destructive changes in the brain There is an early inflammatory reaction which begins to recede in 4 or 5 weeks A late reaction may begin as long as 1 to 7 years after the irradiation This reaction may appear in widespread regions of the brain It consists of necrosis apparently due to injury to the blood vessels.

Malignant tumors of the nose, mouth, pharynx, cervical lymph nodes, esophagus, middle ear, parotid gland, and lesions of vertebrae often require irradiation treatment. In instances of increased susceptibility or overtreatment injury from irradiation may be as dangerous as the lesions themselves. Because of the long latent period between the irradiation and the appearance of symptoms, the cause of the condition may not be immediately apparent.

The manifestations of irradiation injury seem to be due primarily to injury to the blood vessels rather than to the neurons, and the eventual neurologic lesions seem to be the result of gradual impairment of blood supply.

Symptoms may be ascribed, without proof, to metastatic lesions from the original tumor or to cerebrovascular accidents The symptoms commence with numbness and tingling in the hands or feet precipitated by flexion or extension of the neck and often associated with pain in the neck and shoulders In mild injuries these symptoms are transient and disappear in 3 to 9 months In the more seriously affected spinal cords the paresthesias are followed by weakness or spastic paralysis and later by dysfunction of bowel or bladder. Death results often from bronchopneumonia or ascending infection of the urinary tract Cranial nerve palsies, ataxia, and hemiplegias in older patients cannot be differentiated from those due to cerebrovascular accidents.

The lesions of irradiation myelitis often can be distinguished from those of metastasis to the spinal column or to the cord by the absence of roentgenographic changes in the vertebrae and the absence of changes in the spinal fluid

Acute Radiation Syndrome. The acute radiation syndrome is caused by sudden exposure to the actions of the roentgen rays or of the penetrating radiations liberated by radium or the atomic bomb The resulting changes depend on the inherent sensitivity of the exposed tissues and the type of radiation and are attributable to injury to formed elements of the blood and the blood-forming organs, the endothelium of blood-vessels, and the digestive tract and the uterine cervix These particular tissues all show a tendency toward ultimate regeneration, and it is on this fact that present therapeutic programs for the supportive treatment for malignant disease of these tissues are based.

The effect of irradiation on the body is a cessation of mitotic activity and death of cells which are not immediately replaced The time required for this destruction depends on the susceptibility and the life span of the cell in question. Cessation of mitotic activity by the leukopoietic tissues results in leukopenia within 24 hours The lymphoid cells also rapidly disappear, but less rapidly than the granulocytes. Destruction of the erythrocytes is the last of the hematologic alterations to appear. Subsequently the marrow may assume a hyperplastic appearance with arrest of maturation

Changes in the oral and pharyngeal membranes and the gastrointestinal tract are restricted to the mucosal surface and consist of ulceration and sloughing These changes result from a combination of the effects of radiation and the rapid invasion of microorganisms

The gonadal epithelial tissues of boys and men are extensively destroyed. The female gonads are less easily affected.

Three forms of radiation sickness are categorized. 1 *Initial shock* occurs in those who have received overwhelming injury, as from an atomic bomb. Vomiting appears within 12 hours after exposure and within 24 hours, owing to the effects of vomiting and radiation, prostration, fever and diarrhea follow.

On examination weakness, tachycardia and hypotension may be present in the extremes. Petechiae and purpura are present after about 5 days. Toward the end of the first week after the injury the fever increases rapidly and the temperature may reach 104 F (40 C) The pulse rate is fast and the pulse is enfeebled. The weakness is extreme. *The profuse and often bloody diarrhea contributes to the dehydration* Examination of the blood reveals progressive leukopenia that may reach levels of 400 to 500 cells per cubic millimeter. The erythrocytes usually remain normal, but the platelets are depressed in numbers

Death occurs in from 1 week to 10 days

2. The *acute form* occurs in those who have incurred extensive but often not fatal injury Within 24 hours after exposure, nausea, vomiting and diarrhea with prostration usually appear and persist for a day or two The patient is then generally well for 10 days to 2 weeks, at the end of which time great weakness, malaise, petechiae, purpura of skin and mucous membranes, and epilation of the scalp and perhaps of other areas of the body occur These lesions of the mouth and pharynx resemble the lesions of agranulocytic angina Gastrointestinal disturbances, of which diarrhea is the most pronounced, reappear and there is fever Death often occurs in 3 or 4 weeks. Those who survive the exposure enter a more chronic course with continuing ulcerative lesions and anemia Recovery slowly progresses, or the patient succumbs to infection

3. The *subacute form* of radiation sickness occurs in persons who have been less severely exposed than those who have the acute form This subacute form of the disease consists of the severe reactions which occur in those who have had large exposure to roentgen rays for treatment and are more susceptible to the effects of irradiation than is expected Often such sickness cannot be avoided Three to 5 weeks after initial exposure, epilation occurs, to be followed by mild inflammation of the oral and pharyngeal membranes and weakness with malaise A watery diarrhea develops The hematologic changes in these patients are often those of severe and increasing anemia If death occurs, it is due to aplastic anemia, occurring 2 to 4 months after the initial exposure A large number of patients in this group recover

Injuries and Death from Electric Currents and Lightning. ***Electrocution.*** A voltage of 60 may cause death if the amperage is high, but it is seldom that a fatal result ensues from a current of less than 230-260 volts

Shock from the sudden passage of a current of low voltage (60 V) and high amperage, when the head or the chest is imposed between the contact and the ground, as may be present in the home, may cause death Instances of death from low voltages are likely to occur in the bathroom or in the basement of the home. Death there is produced by prolonged contact and ventricular fibrillation

In instances of shock and death from contact with a high-voltage current, the fatality is likely to be caused by the discharge of current through the body and ventricular fibrillation rather than by burns If resistance through the body is low, burns will not ensue.

When a cutaneous burn is present, it may be so small as to be difficult to locate in the area of cold white skin which surrounds the point of contact of the current with the skin Cutaneous wounds of fantastic configuration may be sustained when there is a sudden or an intermittent contact with high-voltage electric currents

The postmortem findings away from the points of contact may be entirely absent

In those who have died from cardiac ventricular fibrillation there are dilatation of the chambers of the heart, sometimes with petechiae under the pericardium and ventricular endocardium, and gross pulmonary and afferent venous congestion and cyanosis.

Lightning. Lightning stroke or death from lightning is economically important from the standpoint both of loss of human life and of the loss of livestock Nine hundred to 1,000 persons die in the United States each year from lightning The number of livestock lost by this means is much greater.

Injury or death from lightning is attributable (1) to the direct effect of a current of enormous voltage, (2) to burning by the flash, (3) to the compression force of air displaced around the flash and (4) to the tremendous force of impact of compressed air thrust in front of the flash The high-voltage electric current of lightning may cause cutaneous burns of complex configurations. Metallic articles, such as buttons, keys, and belt and suspender buckles, are magnetized—a useful sign in making a postmortem diagnosis Arms and legs may be broken and blown from the body by the tremendous forces exerted by the rarefied or compressed air.

Death may occur from the force exerted by the rarefied air near the point of the lightning stroke

Multiple fractures of bones and necrotic areas of bones may be present There may be bubbles of gas and petechial hemorrhages and small cavities around blood vessels, especially of the meninges, brain and spinal cord

Often death from lightning stroke is instantaneous. A few who are struck by lightning are severely injured, the rest of those experiencing lightning stroke or shock recover immediately

Instant death is the result of either paralysis of respiration or fibrillation of the ventricles of the heart In instances of serious shock, even though artificial respiration is maintained for hours, death may ensue

In those who survive, there may be unconsciousness for a variable period In some cases consciousness is never regained and death occurs during convulsions days later. If the patient survives, there may be various mental disturbances, blindness, and palsies, probably from a prolonged cerebral anoxia which follows the shock.

The site of contact is characterized by cutaneous burns The skin may be scorched yellow in color or it may be burned just sufficiently to cause blistering. The blisters are often of considerable length. Penetrating wounds are common There may be hemiplegias associated with regions of necrosis of the skull

Lesions and detachments of the retinas, blindness, rupture of the choroid, and paralysis of the oculomotor muscles are ocular sequelae of lightning stroke. Deafness may result Rarely other cranial nerves may be affected.

Transient and persistent paraplegias may result from shocks from currents transmitted through the spinal cord. As a rule, the paralysis lasts only a few hours and disappears completely Electric shocks from any source may give rise to delayed muscular atrophy and flaccid paralysis. Muscular atrophy may be delayed for months after the shock The atrophy may extend to involve all four extremities.

The diagnosis depends on the history or evidence of lightning stroke. In those who have been struck by lightning there may be physical evidence of injury to the skin, to the nervous system and to the bones Multiple fractures are commonly present. In lightning stroke burned metallic objects contained in the clothing in the line or near the point of strike reveal the effects of the heat of the electric current They become magnetized, even if there is no evidence of excessive heating.

Effects of Excessive Sunlight. The effects of sunlight, due to the differences in the amount of pigment in the skin, vary greatly in different persons The albino has no pigment in the skin and thus is very susceptible to short exposures to the sun of summertime

Sunlight may cause sun erythema, sunburn, ephelides and reticular pigmentations. It is difficult to differentiate between a physiologic and

of the skin, but if the threshold value is greatly reduced, the sensitivity is usually regarded as pathologic. A photosensitizing substance may be present in the individual or it may enter artificially in the form of medicine or food or may come from contact The photosensitivity dermatoses may be divided into photo-allergic cutaneous reactions and photodynamic manifestations.

The *photo-allergic reactions* are observed rarely away from temperate climates, where in some persons the allergy recurs every year with the onset of the sunny season. The terms urticaria solaris, eczema solare and prurigo aestivalis indicate their seasonal incidence. Photo-allergic reactions are not conditioned by previous exposure to light; that is, allergy to light is defined as one in which the allergic manifestations occur on the uncovered skin

The photodynamic manifestations depend on a photosensitizing substance naturally present, such as porphyrin On exposure of the sensitive person to sunlight, hydroa vacciniforme, hematoporphyrinuria or xeroderma pigmentosum ensues.

The local forms of light dermatitis are characterized by a temporary erythema and a subsequent persistent pigmentation The form of the light effect indicates previous contact with a sensitizing substance in fluid state

[illegible]

drie [illegible]

ran [illegible]

at first only in the height of summer. As the degree of sensitization increases, the disease appears earlier year by year, until even in winter some trace remains

Hydroa aestivale (hydroa puerorum) is a genuine hypersensitiveness to sunlight The disease begins in childhood and is characterized by erythematous, papular and pustular lesions on the exposed skin, for instance, the face and the dorsa of the hands These lesions recur annually in the same season, but they tend to recede in early youth Adult persons may have a similar disease which continues for years

In a susceptible person *solar urticaria* may result from a brief exposure of the skin to sunlight Exposure is followed in a few minutes by development of intense itching and erythema limited precisely to the areas exposed to the sunlight Soon small urticarial lesions form in the erythematous area and these quickly coalesce to form a continuous urticarial wheal confined to the exposed area When the urticarial edema has developed, a flare of diffuse erythema surrounds the wheal of the exposed skin

Hematoporphyrinuria is discussed in association with the disease porphyria (Chapter 22)

Xeroderma Pigmentosum. This rare, and fatal, disease occurs in red-haired persons The disease is due to an altered reaction of the skin to light. The disease may commence in childhood or after adulthood is attained. The manifestations are the same in either children or adults

In children the dark brown freckles persist after summer is over. The skin begins to atrophy, telangiectasis appears and the skin begins to look old As the senile appearance of the skin develops the muscles become atrophic and weak, completing the appearance of old age In a few years warty growths arise, some of which turn malignant By the time adolescence is attained the patient dies from a disseminated highly malignant epithelioma

A more rapidly progressive form of the disease, beginning in adult life, may occasionally be encountered after undue exposure to sunlight. Often the disease occurs after undue exposure of the skin to sunlight by visitors to winter resorts Muscular atrophy is absent in the adult form of the disease.

Decompression Sickness. Caisson Disease. The term decompression sickness refers to an illness which follows a too rapid decrease in barometric pressure. A rapid decrease in barometric pressure may occur from (1) a rapid transfer of the

In those who have died from cardiac ventricular fibrillation there are dilatation of the chambers of the heart, sometimes with petechiae under the pericardium and ventricular endocardium, and gross pulmonary and afferent venous congestion and cyanosis

Lightning. Lightning stroke or death from lightning is economically important from the standpoint both of loss of human life and of the loss of livestock. Nine hundred to 1,000 persons die in the United States each year from lightning The number of livestock lost by this means is much greater.

Injury or death from lightning is attributable (1) to the direct effect of a current of enormous voltage, (2) to burning by the flash, (3) to the compression force of air displaced around the flash and (4) to the tremendous force of impact of compressed air thrust in front of the flash. The high-voltage electric current of lightning may cause cutaneous burns of complex configurations Metallic articles, such as buttons, keys, and belt and suspender buckles, are magnetized—a useful sign in making a postmortem diagnosis Arms and legs may be broken and blown from the body by the tremendous forces exerted by the rarefied or compressed air

Death may occur from the force exerted by the rarefied air near the point of the lightning stroke.

Multiple fractures of bones and necrotic areas of bones may be present There may be bubbles of gas and petechial hemorrhages and small cavities around blood vessels, especially of the meninges, brain and spinal cord

Often death from lightning stroke is instantaneous A few who are struck by lightning are severely injured; the rest of those experiencing lightning stroke or shock recover immediately

Instant death is the result of either paralysis of respiration or fibrillation of the ventricles of the heart. In instances of serious shock, even though artificial respiration is maintained for hours, death may ensue.

In those who survive, there may be unconsciousness for a variable period. In some cases consciousness is never regained and death occurs during convulsions days later If the patient survives, there may be various mental disturbances, blindness, and palsies, probably from a prolonged cerebral anoxia which follows the shock.

The site of contact is characterized by cutaneous burns The skin may be scorched yellow in color or it may be burned just sufficiently to cause blistering The blisters are often of considerable length Penetrating wounds are common There may be hemiplegias associated with regions of necrosis of the skull.

Lesions and detachments of the retinas, blindness, rupture of the choroid, and paralysis of the oculomotor muscles are ocular sequelae of lightning stroke Deafness may result Rarely other cranial nerves may be affected

Transient and persistent paraplegias may result from shocks from currents transmitted through the spinal cord As a rule, the paralysis lasts only a few hours and disappears completely Electric shocks from any source may give rise to delayed muscular atrophy and flaccid paralysis Muscular atrophy may be delayed for months after the shock. The atrophy may extend to involve all four extremities

The diagnosis depends on the history or evidence of lightning stroke. In those who have been struck by lightning there may be physical evidence of injury to the skin, to the nervous system and to the bones. Multiple fractures are commonly present In lightning stroke burned metallic objects contained in the clothing in the line or near the point of strike reveal the effects of the heat of the electric current They become magnetized, even if there is no evidence of excessive heating

Effects of Excessive Sunlight. The effects of sunlight, due to the differences in the amount of pigment in the skin, vary greatly in different persons. The albino has no pigment in the skin and thus is very susceptible to short exposures to the sun of summertime.

Sunlight may cause sun erythema, sunburn, ephelides and reticular pigmentations It is difficult to differentiate between a physiologic and a pathologic sensitivity

of the skin, but if the threshold value is greatly reduced, the sensitivity is usually regarded as pathologic. The photodynamic manifestations depend on a photosensitizing substance naturally present, such as porphyrin. On exposure of the sensitive person to sunlight, hydroa vacciniforme, hematoporphyrinuria or xeroderma pigmentosum ensues.

The local forms of light dermatitis are characterized by a temporary erythema and a subsequent persistent pigmentation The form of the light effect indicates previous contact with a sensitizing substance in fluid state

Sun and wind combined produce a prolonged irritation to the skin which thickens, dries and wrinkles it This type of weather-beaten skin is observed in farmers, ranchers and sailors. If such a skin becomes hypersensitive to light, symptoms occur at first only in the height of summer. As the degree of sensitization increases, the disease appears earlier year by year, until even in winter some trace remains

Hydroa aestivale (hydroa puerorum) is a genuine hypersensitiveness to sunlight. The disease begins in childhood and is characterized by erythematous, papular and pustular lesions on the exposed skin, for instance, the face and the dorsa of the hands These lesions recur annually in the same season, but they tend to recede in early youth Adult persons may have a similar disease which continues for years.

Lesions and detachments of the retinas, blindness, rupture of the choroid, and paralysis of the oculomotor muscles are ocular sequelae of lightning stroke Deafness may result Rarely other cranial nerves may be affected

Transient and persistent paraplegias may result from shocks from currents transmitted through the spinal cord As a rule, the paralysis lasts only a few hours and disappears completely Electric shocks from any source may give rise to delayed muscular atrophy and flaccid paralysis Muscular atrophy may be delayed for months after the shock The atrophy may extend to involve all four extremities

The diagnosis depends on the history or evidence of lightning stroke In those who have been struck by lightning there may be physical evidence of injury to the skin, to the nervous system and to the bones Multiple fractures are commonly present. In lightning stroke burned metallic objects contained in the clothing in the line or near the point of strike reveal the effects of the heat of the electric current They become magnetized, even if there is no evidence of excessive heating

Effects of Excessive Sunlight. The effects of sunlight, due to the differences in the amount of pigment in the skin, vary greatly in different persons. The albino has no pigment in the skin and thus is very susceptible to short exposures to the sun of summertime

Sunlight may cause sun erythema, sunburn, ephelides and reticular pigmentations. It is difficult to differentiate between a physiologic and a pathologic sensitivity

and the arrhythmias which are produced tend to remain during recovery until the myocardium is again well oxygenated. However, the brain is affected by anoxemia before the heart is, and peripheral circulatory collapse can result from a deficient supply of oxygen to the central nervous system.

The effects from the progressive reduction in atmospheric pressure at higher altitudes result from the effects of the expansion of gases, from the pressure on the ear, or if great changes in pressure occur, from the changes in the volume of gases contained within the body. The coefficient of the expansion of gas under reduced pressure is such that a volume at 18,000 feet is double the size it was at sea level, four times that of sea level at 34,000 feet, and six times as much at 42,000 feet

Aero-otitis Aero-otitis is due to rapid changes in pressure difference between the cavities of the ears and the surrounding atmosphere.

Aero-otitis Externa Aero-otitis externa occurs when a person has used tight ear plugs in descent from high altitude flying or when one has severe rhinitis associated with postnasal infection. It is characterized by hyperemia and ecchymotic hemorrhages affecting the tympanic membranes and perhaps the soft tissues of the external auditory canal

Those who have flown despite the presence of a rhinitis should be treated if the pain in the ear or ears persists for more than an hour or two after landing

Aero-otitis Media. Aero-otitis media occurs when there has been rapid change in pressure differences between the middle ear cavity and the surrounding atmosphere. Usually the eustachian tubes are not patent or are partially obstructed. It is a traumatic inflammation of the middle ear

The well-known devices of keeping the pressure difference equalized by keeping the eustachian tubes open are gum-chewing, swallowing, yawning, eating and drinking. In children the same end is attained by having them inflate small balloons, and feeding infants during descent

Aerosinusitis may develop in those who have sinus disease.

Airsickness. One of every 10 adults may be affected by airsickness It is the same as motion sickness

As preventive measures against airsickness, pregnant and neurotic women and persons with gastrointestinal disease and those who are convalescent after abdominal operations are advised to have adequate sleep on the preceding night, bowel evacuation, a light meal one hour before flight, small light meals during flight, warm clothing, ear plugs to minimize noise, to assume a recumbent position, and to look up to minimize stimulation of utricles by otoliths

Abdominal Distention Persons contemplating flights at high altitudes are advised to abstain from ingestion of foods which they think form gas and not to partake of carbonated beverages The precautions already mentioned, of adequate rest, easily digested foods, and good bowel evacuation, are also good prophylactic measures against abdominal distention Patients who have intestinal obstruction generally should not be transported by air

Mountain Sickness. On ascending the mountain side to heights of from 12,000 to 15,000 feet, owing to a low atmospheric pressure of oxygen which occasions oxygen want in the tissues, cyanosis, nausea, headache, intestinal disturbances and hyperpnea develop If exercise is continued, syncope may ensue

After acclimation at these altitudes, symptoms are not present unless physical exercise is performed During and after even mild physical exercise there are dyspnea, blue lips and ears, and often periodic breathing When acclimation is present, the alveolar carbon dioxide pressure is reduced to 25 to 30 mm., which increases by about 50 per cent in the ventilation of the lungs. This process of acclimation is associated with a great increase in the number of erythrocytes and in the hemoglobin Hemoglobin of 120 to 150 per cent may be attained (see Polycythemia, Chapter 12)

body from low altitudes to higher ones, as in airplane flight and (2) removal of the body from a high barometric pressure, as is present in a caisson, to a lower one, the surface atmosphere

The cause of the disability in the decompression sickness of divers, caisson workers and fliers is the same, namely, bubbles, consisting chiefly of nitrogen, which occlude veins, capillaries and, more rarely, arterioles, collect in tissues, especially fatty tissue, and cause pain by distorting nerves or nerve endings.

Decompression disease most commonly affects older persons and those who are fat. There is a *varying susceptibility to decompression disease among the young and* fit, and apparently this susceptibility varies in each individual from time to time. An occasional person seems to become more susceptible on subsequent decompression Likewise an occasional person seems to become somewhat adapted to decompression. There is some evidence to indicate that the incapacity is less likely to occur when the incentive is high One hour of preoxygenation prior to ascent decreases the incidence of incapacity.

In caisson workers exercise is the most important factor predisposing to bends and chokes

Owing to the rapidity of decompression in fliers on rapid ascent the symptoms come on more quickly than in caisson workers In the latter workers, since decompression is carried out more slowly, the symptoms often do not occur until some time after decompression (one-half hour to an hour and a half).

Often the symptoms are mild, with headache and uncertainty of gait which soon pass away In severe injuries the symptoms commence with pains in bones, joints (bends) and abdomen On inspiration there is a cough (chokes) Paralysis of the legs may ensue with disturbances of sensation Monoplegia or hemiplegia resembling apoplexy is rare In most patients these symptoms pass away, but in a few the coma deepens and death occurs Some of those severely injured who survive may be disabled by a persistent hemiplegia, monoplegia or other disability from injury to the spinal cord

On examination there may be coughing almost with each breath. *The coughs or* the chokes are apparently due to the collection of bubbles in the small branches of the pulmonary artery, and at times some enlargement of the right side of the heart may be detected Distention of the abdomen is not common The abdominal gas pains and distention are due to the expansion of gas in the stomach and colon and do not occur if the subject can readily expel the gas *There may be some fullness about* the joints which stiffens (bends) them and causes pains, especially if attempts are made to use the joints Bends are usually associated with collections of gas or bubbles in the veins or in the tissue of the fascial planes about the joints, tension being a factor in their production.

In more severe injury there may be neurologic findings the same as in monoplegia or hemiplegia Coma may be present

The diagnosis is usually obvious, and it is confirmed by the response to recompression The symptoms may occasionally recur or occur after recompression The prevention of the symptoms is the same in divers and in fliers, namely, *denitrogenation* or the removal of most of the liter of dissolved gaseous nitrogen, contained within the blood of normal persons, by the inhalation of pure oxygen for several [illegible] prior to exposure

[illegible]titudes. The stresses encountered during flight [illegible] 10,000 feet are not important Above 10,000 feet, supplementary oxygen is required in *increasing amounts.* At 40,000 feet, 100 per cent oxygen is inadequate unless it is supplied under pressure.

In persons whose ability to oxygenate tissues is hampered by respiratory or cardiovascular disease, the *effects of hypoxia* may become more apparent at higher altitudes than in normal persons, and the consequences may be serious. Anoxia dilates the heart,

The appearance of the body dead from asphyxia indicates to a certain degree the type and the duration of the asphyxia suffered. When asphyxia has developed gradually, there is a livid color of lips, face and ears When excessive carbon dioxide has accumulated, there is present a dark bluish tint. When death has followed anoxemia, the face may be pale. The tongue may lie in normal position, or the tip may be pressed against the back of the teeth. When asphyxia has been severe, as in acute pulmonary edema or in hanging, the tongue is protruded either between the margins of the teeth, or beyond them. A frothy and frequently blood-stained fluid may be present at the corners of the mouth and at the nostrils The conjunctivae are congested and speckled with small punctate hemorrhages.

The larynx and the trachea contain a varying amount of frothy watery secretion. The lungs are engorged and edematous. Petechial hemorrhages are commonly present in the parietal, pulmonary and pericardial pleurae, pericardium, heart muscle and endocardium. On section, a copious, frothy, dark-colored, blood-stained exudate is observed

The cavities of the right side of the heart and the venae cavae are engorged. The cavities on the left side of the heart are often comparatively empty.

The cranial sinuses are usually filled with dark-colored blood The brain is often congested and speckled with hemorrhages. An excess of serous fluid is present in the lateral ventricles

Asphyxia and Drowning The physician may be called upon to give an opinion in regard to death from drowning Usually the circumstances make the cause of death obvious, but not always A person may be said to have died from drowning into whose air passages and lungs air has been prevented from entering by the presence of any watery or viscid fluid which has been aspirated into the air passages and has caused asphyxia

The duration of the process of drowning varies from about 2 to 5 minutes. Occasionally a person on entering the water may die suddenly before the process of drowning has been properly initiated These deaths may be due to the sudden entry of water into the larynx or to the impinging of cold water on the nasal or postnasal mucous membrane, with ensuing powerful stimulation of the glossopharyngeal and vagus nerves, cardiac inhibition and death

When a person falls into water during a fatal syncopal attack in which respiration had ceased before submersion, the water will not be inspired, and the signs of asphyxia will be absent When a person falls into water as the result of an apoplectic or epileptic fit or a serious traumatic injury to the body, the immediate death will be due to drowning, the respiratory function having continued. The lesion which precipitated the fall and whether or not death was due to injury or to drowning can be discovered only by postmortem examination

The external signs found on a body recovered from water immediately after drowning consist of the presence of a fine foam or froth at the mouth or the nostrils or both Objects from beside the water or that were floating in it, or material from the bottom of the water, may often be found clutched in the victim's hands.

When a person who is unable to swim, or one who can swim but who is laden with heavy clothing or is fatigued, falls into water he sinks and inspires a mixture of air and water. Usually he rises to the surface again and expels the water and air This increases the specific gravity of his body, and he again submerges. Under water, he inspires more air and water. This initiates coughing, air and water are expelled, more water is inspired, and the lungs become progressively heavier, with the result that the tendency to sink becomes greater as this often repeated process of expiration and inspiration continues Finally the lungs become filled with water and the body sinks to the bottom, head downward

The blood passes to the head and neck. Since decomposition is enhanced by the presence of blood, it proceeds in the head and neck more rapidly than elsewhere,

Diseases Which May Contraindicate Flight by Air. Patients who have intestinal obstruction or impending obstruction, those who have cardiac or pulmonary conditions in which a reduction of oxygen or pressure may be detrimental, those in shock, and those who have severe anemia, maxillofacial injury, or cerebral injury should not be transported by air unless special attention can be provided and unless air pressure within the cabin is adjusted in relation to the altitude at which the plane is to fly.

Patients with angina pectoris should have an electrocardiogram to exclude an infarct, since infarction is a contraindication to flight by air for at least 60 days, preferably 6 months

Hypertension is not a contraindication to flight if the diastolic pressure is less than 110 mm. of mercury.

If a pulmonary disease has seriously reduced pulmonary reserve, flight is hazardous Many patients with disorders of the lungs, however, tolerate moderate altitudes if given oxygen during the flight.

Mild asthma is not a contraindication to flying. Tuberculosis usually is a contraindication. Rapid contraction and expansion of collapsed lungs are deleterious to healing, and tearing of adhesions attached to diseased lungs may cause hemorrhage or permit dissemination of the infection to new sites or to distant parts. If flight is necessary, sputum must be negative and cavities adequately controlled by collapse. Pneumothorax is an absolute contraindication, particularly if the volume of air is large and the area recently has been filled.

Patients who have undergone lobectomy or pneumonectomy do not travel well, especially within the first 3 months postoperatively Patients with pulmonary foreign bodies may fly but must be grounded at once if pulmonary edema is threatened.

Patients who have anemia are permitted to fly if hemoglobin is at least 60 per cent, leukemic patients should have at least 80 per cent hemoglobin

A diabetic person not readily subject to insulin shock or coma may fly. The attendant should be informed at the beginning of flight if a passenger has severe diabetes and has taken large doses of insulin

Agitated patients who might be dangerous, or obnoxious, or irritating should be absolutely forbidden to fly

Epileptic patients have a tendency to seizures aloft, and must be individually evaluated for the conditions anticipated during a specific flight.

Women may be flown without question during the first 8 months of pregnancy, provided there is no history of premature birth or habitual abortion

During the first 10 days of life the respiratory system is not sufficiently established to permit exposure to respiratory stress

Asphyxia. Asphyxia is essentially a state, or series of states, induced by deprivation of oxygen An asphyxia may proceed slowly and be characterized by gasping for breath and marked cyanosis with retention of carbon dioxide and depletion of oxygen In contrast to this type of asphyxia is that due to depletion of oxygen, or anoxia, characterized by skin pallor due to little or no retention of carbon dioxide.

Asphyxia originates from many causes, such as occlusion of the air passages, impediment to respiratory function by pressure on the thoracic wall, strangulation, suffocation, hanging, throttling, drowning, electrocution, and the inhalation of toxic gases; paralysis of the respiratory nerves or muscles; and from causes operating from the lungs or from the pulmonary circulatory system

When the asphyxial process is slight and prolonged, the congestive component will be diminished, when acute, lividity and congestion are extreme, and when, during the process of asphyxia, heart failure precedes respiratory arrest, the asphyxial signs may be less pronounced, depending at which stage in the asphyxial process cardiac arrest occurred.

This is more often used in resuscitation of children than of adults. Mouth-to-mouth insufflation is an ancient method of artificial respiration since it was possibly employed by Elisha in resuscitating the son of the Shunammite (II Kings, Chapter IV, Verse 34).

In recent years investigative work has been done to determine the relative efficacy of the various methods employed in artificial respiration In 1951 Gordon, Sadov, Raymon and Ivy recommended for general use the Nielsen method. These investigators seem to believe, however, that the Schafer-Emerson-Ivy (hip lift-prone pressure) method was the most effective of all methods. Since 1951 various organizations, such as the American National Red Cross, have approved or adopted the Nielsen method.

The preferable method of artificial respiration is determined by the circumstances under which it is to be employed and the experience and the physical condition of the operator. For instance, on removal of a body from the water of a swollen stream to a brushy, muddy, slippery bank, by one who is alone and exhausted it is well for him to know the importance of placing the asphyxiated person in a position so that his head is somewhat lower than his thorax, face down, the forehead placed in the palm of the victim's hand as in the Nielsen method. Despite exhaustion, the operator can usually muster enough strength intermittently to elevate the elbows and to push downward 10 to 20 times per minute on the lower back and ribs

The most important accomplishment to be obtained in resuscitation after immersion is removal of water from the lungs as rapidly as possible As the water is removed from the lungs the space occupied by it is filled with air. Therefore, artificial respiration is immediately urgent.

The *Nielsen method* (Fig 19-1) of artificial respiration requires that the victim be placed in the prone position with the forehead resting in the palm of one hand which is resting on the other. Percussions with the fist are administered between the scapulae to force the tongue back into position. The elbows are grasped and raised to cause active inspiration, they are then released, and pressure is exerted over both scapulae to produce active expiration The maneuver is performed rhythmically 10 to 20 times per minute. Undue pressure may fracture the ribs

After Gordon Fainer and Ivy, J A M A, 144 1455, 1950

Fig 19-1 The Nielsen method of artificial respiration.

The *Schafer (prone pressure) method* (Fig 19-2) is the simplest and for this reason it has been widely used as a method of artificial respiration. The patient is placed in the prone position with arms extended and face to one side Pressure is exerted with the hands close together on the lower portion of the thorax The pressure is rhythmically applied and relaxed at about the rate per minute of normal quiet respiration. The pressure on the thorax causes active expiration and passive inspiration as the result of elastic recoil of the lungs when the pressure is relaxed. The maneuver requires little muscular exertion by the operator.

The *Schafer-Nielsen-Drinker method* (Fig 19-3) requires that the patient be placed in the Nielsen position One operator performs the prone pressure procedure of the Schafer method while another operator alternately raises the elbows or arms. The Drinker method thus eliminates the pressure exerted over the scapular area in the

but the color changes which usually are observed in the lower quadrants and si
of the abdomen on the second or third day when the body is not immersed, m
not appear at all In the immersed body, however, on the fifth or sixth day,
comparable discoloration will appear in the head and neck. The generation of ga
in the immersed body may not be sufficient to cause the body to float until t
sixth to the tenth day. In warm water the body may float in 2 days; in cold wa
it may not float for several weeks.

Soon after immersion the skin of the hands and feet begins to wrinkle and m
become detached The hair loosens more quickly than do the nails of the han
and feet

The condition known as saponification may take place in an immersed bo
as well as in buried bodies or in those exposed to rain, sun and warmth In sapo
ification the affected fat becomes swollen, whitened and greatly stiffened and oft
constitutes the bulk of the tissue clinging to the bones after the skin and muscl
have gone

When the thoracic cavity of a drowned person is opened, the lungs bulge ou
ward and appear moderately congested, but sometimes are pale, owing to air an
water which have been trapped in the alveoli When the lungs are voluminous, re
and gray patches may be seen on the surfaces On section an edematous conditio
due to the presence of a copious, watery, frothy, blood-stained exudate, will b
observed This fluid is readily expressed on pressure of the cut surfaces or ma
exude spontaneously The presence of this fine, clear or, occasionally, blood-tinge
foamy or frothy fluid unmistakably points to death by acute pulmonary edema
by drowning

The stomach contains water, or liquid, corresponding to the drowning mediu
or to substances found in it

When putrefaction has become established, many of the signs which have bee
described are masked

The Heart and Blood in Fresh-Water Drowning and in Salt-Water Drownin
Swann, Brucer, Moore and Vezien found that there is abrupt and pronounce
hemodilution in drowning in fresh water as shown by rapid falls in plasma protei
hemoglobin, chloride and other constituents of the blood They found the convers
a strong hemoconcentration, in drowning in sea water Their data reveal that i
fresh-water drowning the blood may dilute to as much as twice its volume Con
versely, in sea-water drowning, nearly one third of the water of blood may b
removed These sudden alterations in the concentration of blood might be expecte
to have significant effects on the heart During sea-water drowning the heart ma
retain fair functional activity for nearly twice as long as in fresh-water drowning

METHODS OF ARTIFICIAL RESPIRATION (DROWNING) The methods for artifi
cial respiration are classified as manual and mechanical The term mechanica
according to Gordon, Famer, and Ivy indicates that some sort of apparatus o
device, even though only a board or stretcher, is used during the administration o
artificial respiration.

The application of a method of artificial respiration is a lifesaving measure to
those who have been submerged in water but in whom life still remains. The
methods of manual artificial respiration may be divided into four groups depending
on the manipulations used in the procedure. (1) The methods which give forced
expiration. These are termed push methods, the classic example of which is the
Schafer method of artificial respiration (2) The methods which give forced
inspiration. These are the pull methods, represented by the first-stage Silvester and
the hip lift manipulations. (3) The methods which combine the manipulations of
forced expiration and inspiration. These are termed push-and-pull methods, for
instance, the Nielsen, the Silvester and the modification of the Schafer method
known as the hip-lift Schafer method. (4) The mouth-to-mouth insufflation method.

This is more often used in resuscitation of children than of adults. Mouth-to-mouth insufflation is an ancient method of artificial respiration since it was possibly employed by Elisha in resuscitating the son of the Shunammite (II Kings, Chapter IV, Verse 34).

In recent years investigative work has been done to determine the relative efficacy of the various methods employed in artificial respiration. In 1951 Gordon, Sadov, Raymon and Ivy recommended for general use the Nielsen method. These investigators seem to believe, however, that the Schafer-Emerson-Ivy (hip lift-prone pressure) method was the most effective of all methods. Since 1951 various organizations, such as the American National Red Cross, have approved or adopted the Nielsen method

The preferable method of artificial respiration is determined by the circumstances under which it is to be employed and the experience and the physical condition of the operator For instance, on removal of a body from the water of a swollen stream to a brushy, muddy, slippery bank, by one who is alone and exhausted it is well for him to know the importance of placing the asphyxiated person in a position so that his head is somewhat lower than his thorax, face down, the forehead placed in the palm of the victim's hand as in the Nielsen method Despite exhaustion, the operator can usually muster enough strength intermittently to elevate the elbows and to push downward 10 to 20 times per minute on the lower back and ribs

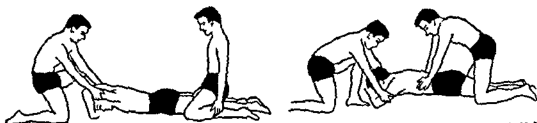
The most important accomplishment to be obtained in resuscitation after immersion is removal of water from the lungs as rapidly as possible. As the water is removed from the lungs the space occupied by it is filled with air. Therefore, artificial respiration is immediately urgent

The Nielsen method (Fig. 19-1) of artificial respiration requires that the victim be placed in the prone position with the forehead resting in the palm of one hand which is resting on the other. Percussions with the fist are administered between the scapulae to force the tongue back into position The elbows are grasped and raised to cause active inspiration, they are then released, and pressure is exerted over both scapulae to produce active expiration The maneuver is performed rhythmically 10 to 20 times per minute. Undue pressure may fracture the ribs.

After Gordon Fainer and Ivy J.A.M.A., 144 1455, 1950

Fig 19-1 The Nielsen method of artificial respiration

The *Schafer (prone pressure) method* (Fig 19-2) is the simplest and for this reason it has been widely used as a method of artificial respiration The patient is placed in the prone position with arms extended and face to one side Pressure is exerted with the hands close together on the lower portion of the thorax. The pressure is rhythmically applied and relaxed at about the rate per minute of normal quiet respiration. The pressure on the thorax causes active expiration and passive inspiration as the result of elastic recoil of the lungs when the pressure is relaxed. The maneuver requires little



(Fig 19-3) requires that the patient be placed performs the prone pressure procedure of the Schafer method while another operator alternately raises the elbows or arms. The Drinker method thus eliminates the pressure exerted over the scapular area in the

Nielsen method and consequently avoids possible fractures of the ribs. At the same time it retains the well-known features of the Schafer method.

After Gordon, Fainer and Ivy J A M A 144 1455, 1950

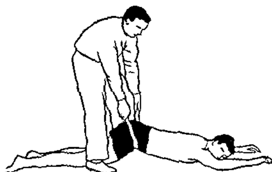


Fig 19-2 The Schafer (prone pressure) method of artificial respiration

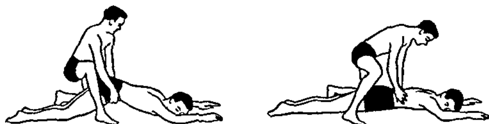
After Gordon Fainer and Ivy, J A M A 144 1455, 1950

Fig 19-3 Schafer-Nielsen-Drinker method of artificial respiration

The *Emerson method* is performed by raising and lowering the hips with the patient in the prone position as in the Nielsen method Raising the hips several inches causes active inspiration because of descent of the inert diaphragm and hyperextension of the spinal column. Lowering of the hips results in passive expiration. Mechanical devices are available for executing this method A belt employed as shown in Figure 19-4 may be of great help.

After Gordon, Fainer and Ivy J A M A 144 1455, 1950

Fig. 19-4 Emerson method when belt is used for the hip-raising maneuver



The *Schafer-Emerson-Ivy (hip lift-prone pressure) method* (Fig 19-5) is employed with the patient prone. This method alternates the lifting and lowering of the hips as in the Emerson method with pressure exerted on the lower part of the thorax as in the Schafer method Early muscular exhaustion of the operator may be avoided by the use of a piece of cloth, a shirt or a belt passed beneath the patient's hips, so that the lifting may be conducted by one or two persons while another carries on the prone-pressure maneuver. This method can be employed for a short interval in the treatment of acute paralytic poliomyelitis

Gordon, Fainer, and Ivy found that often the supine position results in respiratory obstruction. The "push" or "pull" methods alone do not ventilate. The manual methods [illegible] which the subject lies prone or supine and which utilize a "push-and-pull" principle [illegible] which [illegible] person [illegible] yield

method) is added [illegible] (Schafer-Emerson-Ivy method), it is as effective in restoring a "push-and-pull" method [illegible] Schafer-Nielsen-Drinker method. respiration as either the Nielsen method or the [illegible] (Fig 19-6), in order to reduce the fatigue

In the *hip roll-prone pressure method* [illegible] the victim is grasped at the distant hip and repeatedly is incident to lifting the hips, [illegible]

"rolled" onto and off the rescuer's knee. This can be accomplished alone or in conjunction with Schafer prone pressure.

After Gordon Fainer and Ivy, J.A.M.A., 144 1455, 1950

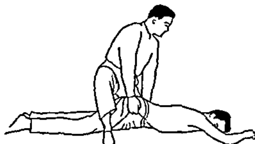


Fig 19-5 Schafer-Emerson-Ivy method of artificial respiration.

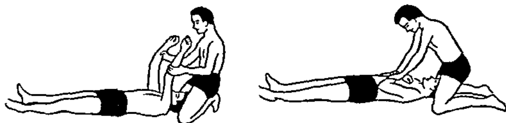
The simple method employed by Silvester (Fig 19-7) is not often used.

Mechanical Methods. In the *Eve (rocking) method* the patient is placed in the prone position and is rocked in a head-down and then feet-down position. Unlike the manual methods, the rocking method depends solely on the up-and-down motion of the diaphragm produced by the movements of the abdominal viscera during rocking

The *automatic intermittent positive pressure method* expands the chest by intermittently introducing air or a gas mixture under pressure (up to 20 cm of water or 14 7 mm of mercury) into the upper respiratory passages via a face mask A Burns valve may be used as a positive pressure device.



In the *alternating negative and positive pressure (suck and blow) method* a positive pressure of +14 mm. of mercury and a negative pressure of approximately −9 mm. of mercury via a face mask are applied rhythmically.

After Gordon, Fainer and Ivy, J.A M A, 144 1455, 1950

Fig 19-6 Modification of hip-lift method

Gordon, Fainer and Ivy concluded that except for the equipment of the anesthetist and the fire, police and rescue emergency crews, all mechanical devices must always be considered as adjuncts and not substitutes for the manual method, preferably of the "push-and-pull" type. The mechanical resuscitator operating at a maximal mask pressure of +14 mm of mercury is no more effective than a properly performed "push-and-pull" manual method On the other hand, the

After Gordon, Fainer and Ivy, J.A M A, 144 1455, 1950

Fig 19-7. Silvester method of artificial respiration.

properly employed mechanical resuscitator requires less skill than a properly executed "push-and-pull" manual method, is not fatiguing, and can furnish 100 per cent oxygen; herein lie the most important advantages of a good mechanical resuscitator There are other advantages, however. Since a resuscitator need be applied only once to a patient's face, it can be employed where physical manipulation of the body is impossible or would be harmful, as during major surgical procedures, for victims of accidents with extensive

burns, broken vertebrae, ribs or arms, for victims trapped under debris of excavations or overturned vehicles, and during transportation to a hospital. Some resuscitators signal when the airway is obstructed and provide an aspirator.

ASPHYXIA AND HANGING. Hanging is that form of death which is caused by suspension of the body by a line or rope which encircles the neck, the constricting force being the weight of the body. The proximate cause of death is asphyxia.

When the ligature is not tight, death may come slowly. The point of application of the force is an important factor not only in the time occupied in dying but also in the subsequent postmortem appearances. As the result of the constriction of the neck, entry of air to the lungs is hindered or prevented, the cerebral circulation is impeded and the phrenic and vagus nerves are compressed. Apart from implication of respiration a person may die from the effects of suspension on the circulation and from nerve injury. Pressure on the vagus nerves may cause cardiac inhibition and sudden death before asphyxial manifestations are established This possibility is always considered at the postmortem examination of bodies of persons found hanged.

As in other forms of death from asphyxia, the heart continues to beat for a few minutes after the cessation of respiration, and, therefore, artificial respiration on a suspended person may prove successful if the body is cut down within 5 or 6 minutes after the commencement of suspension After 5 minutes there is little chance of success in the re-establishment of breathing by any means

On examination of a body found suspended by the neck, when the ligature itself is not available for inspection, indications in the vicinity of a ligature mark, such as scratches or small bruises, may be suggestive of the nature of the ligature used. These marks may have been produced by a ligature or by the finger nails of the victim or those of an assailant in throttling, prior to suspension of the body to simulate suicide by hanging In doubtful cases, to eliminate the possibility of the body having been suspended after death, a piece of tissue from the ligature mark should be excised so that histologic examination may determine the presence or absence of vital reaction from trauma. Bruising associated with the ligature mark indicates either that the violence responsible was operative during life or that it was applied immediately after death while there was continuance of molecular life of the tissues

ASPHYXIA AND STRANGULATION Strangulation is that form of death caused by a constricting force applied around the neck by means of a ligature without suspension of the body. The constricting mark is usually found at a lower level on the neck than in hanging, but may be found at any level, and frequently direct pressure is exerted upon the larynx. The mark in some cases may be continuous around the neck; in others it may be invisible at some part of the neck.

Homicidal strangulation is common. It occasionally is associated with violation of a female victim

Under favorable circumstances, *asphyxia from any cause*, if life remains, may be relieved by institution of artificial respiration

Infant Deaths from Suffocation. At a conference on sudden death in infants which was held under the auspices of the Children's Bureau and the National Institutes of Health (November 30, 1949), Dr. Katherine Bain summed up the situation as follows:

Each year in the United States a large number of babies under 1 year of age die of what is classified as "accidental mechanical suffocation" The story behind the death is usually this: An infant, in apparent good health and usually between the ages of 2 and 5 months, is put to bed in a crib or baby buggy, or in bed with his parents Several hours later the infant is found dead Sometimes he is lying on his face; sometimes bedclothes are over his head Often in the excitement of the discovery the exact conditions are

unnoted The physician, the coroner or the medical examiner, confronted with such a death, is likely to assume that the baby has smothered. And without an autopsy, or at best after a sketchy one, he writes on the birth certificate that the baby's death was due to "accidental mechanical suffocation." The mother and father of a baby who has died in this way develop a great sense of guilt, which may disturb their lives for years But there is now abundant evidence that most of these deaths are not due to any external cause but may be the result of a sudden overwhelming infection with which a young baby is not able to cope. When a careful postmortem examination is made, including a microscopic study, evidence of infection is often found in the baby's respiratory tract, though sometimes elsewhere in his body, as in the membranes of the brain When a careful history is taken, information is often brought out concerning respiratory infection in the family, and there may be some indication that the baby himself had not been up to par.

Sudden Death in Status Lymphaticus. Status lymphaticus is regarded in the United States of America as a clinically recognizable entity consisting of a combination of hereditary constitutional anomalies, entering into which are certain peculiarities of configuration, with preservation or even hyperplasia of the thymus at an age when involution is to be expected, hyperplasia of the lymphoid cells in the spleen, intestine and elsewhere, changes in the distribution of hair, hypoplasia of the vascular system, developmental deficiencies in the genitalia, and visceral defects of uncertain occurrence and irregular distribution

In children who have expired suddenly with the physical attributes of status lymphaticus, the lymphoid tissues in various parts of the body reveal on postmortem examination myriads of necroses in the cells of the germinal follicles. These changes are believed to result in the release of sensitizing nucleoproteins. After the expiration of the anaphylactic incubation period the lymph nodes, according to this theory, are again subjected to the action of destructive substances which now serve to bring about further disintegration of nuclei, thus providing the requisite quantity of specific proteins to complete the sensitizing process.

Many do not believe that such an entity as status lymphaticus exists.

CHEMICAL AGENTS OF DISEASE

In industry and in everyday life a person may be subjected to exposure to injurious chemical agents and to their effects. In order to discuss the diseases caused by these chemical agents, some reference is made to their composition, manufacture and how contacts with them may be made.

A chemical may injure by contact with the skin, by inhalation, and by ingestion into the alimentary tract The injuries from chemical agents may be largely limited to the places of local contact On the other hand, the chemical may be absorbed from the skin, the lungs, or the stomach and intestines and may cause systemic disease after absorption.

From those suspected to be suffering from the ill effects of a poison a detailed account is obtained of precisely the work done, its relationship to chemicals and the possibility of having been exposed to poisonous materials An account is elicited of the habits of eating and drinking, and what has been eaten and drunk Inquiry is made in regard to accidents, medications, new household equipment, plumbing, new clothing, or the purchase of new cooking utensils, *ad infinitum*.

If the patient has been employed where there is the possible chance of exposure to the effects of chemicals, it should be recorded whether or not medical examinations were made (1) before beginning the work, (2) at regular intervals after being employed and (3) at the termination of employment or at the time of transfer from one job to another.

The pre-employment examinations in many of the industries are comprehensive and include a history, physical examination, roentgenologic examination of the

thorax, and laboratory examinations of the blood and urine. The results of these investigations are kept for future reference

After an employee has been selected *for a job, the frequency and thoroughness* of his physical examination depend on the hazards present. Each time an employee is transferred from one job to another, or when he is released from work, examination is made. The release examination is as comprehensive as the pre-employment examination.

At the time of examination at intervals during employment and at the time of discharge it is kept in mind that the common manifestations of being chronically affected by many different poisons are the same. These manifestations are easiness of fatigue, headache in one not accustomed to headaches, nausea, loss of appetite, sensation of fullness of the stomach, gas on the stomach, pain in the epigastrium, dizziness, precordial pain, pain or tingling of the extremities, and dyspnea on slight exertion.

The first signs of exposure to toxic chemicals are changes in pulse rate and in *diastolic blood pressure.* The blood pressure should be measured with the patient sitting, according to the recent recommendations of the Committee for Standardization of Blood Pressure Readings of the American Heart Association It is best to take measurements on both arms as well as to record the two levels of diastolic blood pressure

Acute exposure to toxic chemicals sufficient to cause a fall in diastolic and systolic blood pressures may lead to circulatory collapse. Collapse is due, in most instances, to a failure of the circulation to overcome the effects of gravity, so that insufficient blood is returned to the right side of the heart. If this condition is detected immediately, rest in the supine position, with the head lower than the legs, can restore normal circulation. If circulatory collapse is not detected, and the man falls, he may automatically reach the horizontal position and so restore circulation to normal; but, should he fall in a cramped position, sudden death may ensue

In the practice of medicine away from industry the possibilities of acute or *chronic poisoning are more remote than in industry,* and often a history of exposure to chemicals is absent or indefinite. Under these more adverse conditions, if poisoning is suspected, there are certain evidences in the history or on examination of the patient which will be diagnostically helpful

The *general appearance of the patient* is not characteristic of poisoning without a definite history of exposure to a noxious substance. Fear, anxiety, and a state of excitation are most commonly observed in those who have not been poisoned but who fear the presence of an impending disaster from disease or who may doubt their own ability to convince the physician of the validity of their complaints and to gain his agreement with their diagnosis of their ailments.

The Skin. *Changes in the color of the skin* consisting of pallor, or variations thereof, and cyanosis are most commonly due to systemic diseases Pallor, if due to *poisoning, is rarely present without other manifestations.* Pallor, however, may be present in acute poisoning by many substances, notable among them is the acute poisoning due to ergot, ether or lead

A cyanosis may result from bronchial spasm (constriction) or from an increased demand for oxygen Severe bronchial irritation may follow the inhalation of chlorine or ammonia gas and may prevent adequate breathing and thus create a need for oxygen as is observed in poisoning by dinitrophenol

Some poisons, su [illegible] and
prevent oxygenation, [illegible]
cause cyanosis, while [illegible]
from the combination of a foreign substance with the hemoglobin is [illegible]
poisoning by sulfides, and there is sulfhemoglobinemia. An example of poisoning causing a lividity of the skin is that of benzol.

An *artificially darkened skin* may be differentiated from a skin darkened by cyanosis by pressure on it with a glass slide. The artificially darkened skin will not blanch from pressure

An *excessive pink color of the skin* is most commonly observed in alkalosis from deep breathing due to hysteria It indicates the presence of an excessive amount of oxyhemoglobin and when due to poisoning, it may be caused by cyanides, atropine or carbon monoxide.

A *yellowish discoloration of the skin* is commonly due to excessive amounts of serum bilirubin—jaundice. When the discoloration is due to a poison, the common offending substances are picric acid, atabrine, and yellow dyes This yellow color is of a darker shade than the bronze coloring observed in poisoning by arsenic or arsenic compounds such as arsine

A *dry scaly skin* is present in many of the contact dermatitides (see Chapters 18 and 20) A *wet skin,* in the absence of a subsiding fever, may be occasioned by an increased activity of the sweat glands such as is observed from the effects of aspirin, insulin, and bites of snakes and spiders.

Fever. *Fever is the common manifestation* of the mechanisms of body defense from such a great variety of injuries that it may be misleading by its presence. It is well, however, to remember that an increased body temperature is frequently a manifestation of a poison Particularly important is the presence of fever in instances of poisoning by metals, the so-called metal fever. Chills and fever may occur after a poison has been given by mouth or intravenously (see Body Temperature, Chapter 22)

Nausea and Vomiting. Nausea, vomiting, anorexia, and abdominal pain are among the commonest symptoms of poisoning. The amount of abdominal pain present is usually indicative of the dosage of a poison or of whether or not the patient
[illegible] The presence of these symptoms, associ-
fear of impending death by the patient
onment in which the physician finds the victim of accidental poisoning if such has occurred in the patient's home. The next most frequent general observation of a victim of poisoning is to find the patient asleep in the midst of an apprehensive family.

The Mouth. Nausea, vomiting and abdominal pain arise from irritation, ulceration, and corrosions of the gastrointestinal tract. The examiner may help himself toward identifying the nature of a poison by observing the inflammation and edema of the lips which are present after contact with irritant materials. Likewise the oral cavity may be immediately affected from caustics, but its involvement more commonly is a secondary inflammatory stomatitis which is less immediately associated with acute poisoning The classic example of a stomatitis from poisoning is that known as salivation from the effects of calomel, a compound of mercury Other drugs and chemicals may invoke stomatitis, and many of them cause severe deep ulcerations of the gingivae

In the absence of stomatitis the mucous membranes of the mouth may be cyanotic from hypoxemia, or pink from carbon monoxide and cyanide. Yellow mucous membranes are caused by dyestuffs, picric acid, atabrine, chromates and, in the late stages of poisoning, from phenol On surfaces of the teeth there may be deposits of various nonmetallic or metallic substances such as carbon, copper, nickel, iron, mercury, lead and manganese These deposits are usually associated with a line along the gingival margins, for instance, the "lead line"

The changes in the mouth incident to poisons are greatly influenced by the amount of saliva present Therefore the effects of the noxious agent on the salivary [illegible]
ber of com-
or instance,

The secretions of the salivary glands are stimulated by physostigmine, prostigmine (neostigmine), pilocarpine, quinine, strychnine and iodides. The chemicals which stimulate these glands may give rise to inflammations in them. The chemicals which commonly originate inflammation of the salivary glands are iodides, lead, and arsenic. Often parotitis is originated by botulism.

The Esophagus and Stomach. The esophageal symptoms from immediate poisoning or following the ingestion of corrosives are not immediately distinct. They are overshadowed by the symptoms arising in the mouth and stomach The symptoms of esophagitis are described with the disorders of the esophagus (Chapter 13). Corrosive ulcers of the esophagus or the stomach may arise which may cause free perforation or become chronic indolent ulcerations.

Aside from the immediate irritative and corrosive effects of poisons when they reach the stomach, little can be said with certainty concerning the production of subacute or chronic gastritis of prolonged duration The immediate irritation of the stomach by foreign substances which provokes vomiting is a protective mechanism which saves many lives

The Intestines. Diarrhea, like vomiting, is a protective mechanism. Bloody dysentery may originate from injury to the mucous membranes of the intestines Metallic substances, such as compounds of antimony, arsenic, barium, bromine, copper, and mercury more commonly than other poisons cause diarrhea Many of the vegetable substances cause diarrhea, and some, a very severe diarrhea.

Constipation may originate from spasm of the intestine, particularly the colon, or from atony or paralysis Constipation arising from spasm of the bowel is difficult to interpret. Many times spasm of the colon is prolonged and severe from tension and anxiety, caused by the fear of an impending disaster. Constipation occurs immediately from the action of the alkaloids of opium Chronic constipation is characteristically present in poisoning from some of the metals, particularly from lead.

The Liver. Owing to the circulatory arrangement of the liver in association with the gastrointestinal tract, the liver is next in order to be affected by poisons being absorbed from the intestines Poisons received by the liver may be stored there or excreted through the liver in the bile The liver therefore is thoroughly exposed to noxious materials arriving from the intestines.

The liver is injured by chemicals and drugs by (1) idiosyncrasy, an individual peculiarity of metabolism which results in exceptional susceptibility; (2) cumulation, in which the effects of repeated small doses are identical with those of a single larger dose. This may be the result of direct chemical effect, of storage of the substance in the body with continuous injury, or of continued organic change as the result of scar formation after the drug has been eliminated; (3) nonallergic sensitivity, in which a usually harmless agent injures the liver because the organ has received some previous injury which lowers its resistance to any toxic substance; and (4) allergic sensitivity, in which previous exposure to the causative agent has produced sensitivity in certain susceptible persons, the average person not being sensitive to the drug despite the use of large doses

The subject of toxic hepatitis is considered in association with diseases of the hemic system (Chapter 12), diseases of the liver in Chapter 13, and in association with descriptions of the poisons which may injure the liver, in this chapter.

The Heart. The blood pressure is often affected secondarily from the effects of poison. Palpitation, pain in the chest, fainting spells, and circulatory collapse if present are often reflex in origin and not due to primary effects of poisoning. Auricular fibrillation may originate from poisoning by digitalis or quinine which ... occur from

cardial disease ... methemoglobinemia.

Respiration. Changes in respirations are very common manifestations of systemic disease or diseases of the body as a whole. The type of the respiratory response to a poison varies with the toxic substance, its action, its intensity, and the length of time during which the patient was exposed to it The rate, volume and vigor of the respiratory movements depend on the responsiveness of the medullary centers to the dissolved toxic agent, on the quantity of carbon dioxide or on disturbances of oxyhemoglobin concentrations, since they all may effect changes in the respiratory rate and in the blood pressure

The common initial respiratory response to a poison is an increase in the rate and depth of respiration as the result of hypoxia due to a replacement of oxygen in the inspired air by an inert gas such as carbon dioxide, nitrogen, nitrous oxide, helium, or methane or marsh gas, which may be present in old abandoned wells and caves There are many and varied poisonous compounds, such as the aromatic and aliphatic nitro compounds as well as the inorganic nitrites, which increase the rate and often the depth of the respiratory movements These nitro compounds cause a vasodilatation which may slow down the rate of blood flow and consequently decrease the supply of oxygen to the medullary centers. Similar disturbances of the medullary centers may be originated if a poison hampers the normal functioning of the oxidative enzymes. Such an effect occurs in cyanide and hydrogen sulfide poisoning

Slowed and difficult respiratory movements are usually indicative of acidosis. The acidosis, if due to a poison, may have originated in various ways; for instance, by a poison having displaced the normally present, easily dissociable amphoteric substances of the blood by more stable compounds and by engorgement of the lungs However, the more important toxicologic reasons for slow respiration ensue upon the accidental or intentional administration of chemicals which depress the activities of the central nervous system such as the alkaloids of opium, carbon tetrachloride, chloroform, barbiturates and hyoscyamine.

In poisoning by gases or easily volatile compounds such as ammonia, and the aromatic and aliphatic compounds, including gasoline, the odor on the breath may be the same as that of the toxic agent

The mucous membrane of the upper part of the respiratory tract may be irritated by the inhalation of either gaseous or particulate solid matter, and rhinitis and coryza may result Prolonged irritation of the nasal mucous membrane may cause hypertrophy and increased nasal secretions Epistaxis may be incident to such a condition of the nasal membranes Perforation of the nasal septum occurs in exposures to arsenic, copper, zinc, and chromic acid Irritating gases may induce edema of the glottis, while the accidental aspiration of caustic alkalies or acids may cause corrosion of the glottis. The same kind of irritants as those which produce edema and corrosion of the glottis may extend these processes into the larynx and down the trachea to the bronchi Irritation of the air passages from toxic substances may become infected, and thus pneumonitis may ensue Often, however, a pneumonia occurs as the result of aspiration of saliva or vomitus while the patient is unconscious from anesthetization or from other toxic action of the poison

Whenever the lower part of the respiratory system is severely injured from direct action by a toxic substance, pulmonary edema may ensue The edema may not develop until some time after the acute manifestations of the injury have subsided. In those injuries severe enough to originate pulmonary edema directly or as an allergic manifestation, pulmonary hemorrhages may be observed

Pulmonary hemorrhages may occur as a part of the acute injury by gases or they may come on late. All pulmonary hemorrhages from irritating substances are preceded by hard spasmodic coughs

The critical and dangerous respiratory manifestations of injury from toxic or irritating substances are pulmonary hemorrhages, edema, and sudden respiratory

arrest. A sudden respiratory arrest occurs as the result of overstimulation of the medullary centers Sudden overstimulation may result from severe irritation of the respiratory passages, as when flames of fire are inhaled; also an anoxia or a paralysis of the respiratory muscles from the administration of curare.

The Kidneys and Bladder. A poison, once in the body, may be excreted by any of the excretory systems, for instance, the integumentary, the respiratory, the digestive, or the urinary system Aside from the injury which may be sustained by the kidneys, the toxic material may injure the ureters or bladder.

The kidneys have the main responsibility for excretion of those noxious materials which are absorbed into the blood The blood renders many poisons innoxious to the body and to the kidneys. The kidneys may be injured directly by attempting, or by accomplishing, the task of excretion of poisons They may suffer indirectly from changes and variations of the blood pressure secondary to the effects of poisons.

Renal changes of sufficient degree to be diagnosable are manifested as either a nephrosis or a nephritis.

In the exit of urine containing poisons excreted from the kidneys the bladder may be affected and stranguria may ensue. Common examples of poisons causing stranguria are turpentine, toluidine, santonin, ergot, strychnine, and overdoses of morphine.

Urinary incontinence is incident to paralysis of the sphincters of the bladder and is common in overdoses of barbiturates, bromide, and sulfonal

The Endocrine Glands. Measurable effects of poisoning can rarely be assigned as the cause of dysfunction of the endocrine glands. In former times there were drugs offered which were thought to have the power of increasing the libido The libido if affected at all by a poison is first increased and then decreased. Decreased libido is common in various chronic poisonings just as it is common in all debilitating diseases.

The thyroid gland and the adrenal glands are rarely injured by poisons Lead, mercury and carbon monoxide may reduce thyroid functions The prolonged use of *iodides may injure the thyroid gland The adrenal glands may be injured by various* substances, but little is known about such injuries.

The effects of poisons on parturition are most commonly directly associated with injury to the fetus, with or without subsequent abortion It is much commoner to observe systemic poisoning from the use of a drug with the intention of causing abortion than of taking the life of the mother Abortion may be caused by poisoning with substances such as lead, arsenic, mercury, and phosphorus It is more commonly caused by organic substances such as ergot, quinine, nitrobenzene, turpentine, carbon tetrachloride and benzene

The Muscles. The muscles may be affected by direct action of a poison or they may be affected indirectly through the nervous system or circulatory disease A common example of the direct action of a poison causing paralysis is that of curare, while strychnine causes hypertonicity of the muscles with its central action is limited to the spinal cord.

Flaccid paralysis of the muscles follows certain chronic poisonings by both metallic and nonmetallic substances Common examples of metallic substances causing flaccid paralysis are arsenic, lead, and mercury. This paralysis is the result of peripheral neuritis Choreiform movements performed by the muscles originate from injury of the basal ganglia *Tremors usually characterized by rapid movements* of muscle groups of the hands and head are, as a rule, of hereditary origin and not due to a poison. Ataxia is a common muscular disturbance in poisoning, particularly by the alcohols

Convulsions often arise as a part of a convulsive state such as idiopathic epilepsy, and the apprehension in regard to having been poisoned intentionally or accidentally may increase the number of convulsions if a convulsive state is present. If a

convulsion arises from the action of a poison, there is nothing characteristic about it. Such fits occur as clonic convulsions and tonic convulsions of the musculature. The muscular convulsive response originates in the central nervous system or from the destruction of enzymes of the muscles. Stimulation of certain nerve centers with ensuing convulsions may be due to asphyxia, to circulatory disturbances, or to the formation of toxic substances in the body fluids

The Nervous System. The manifestations of the action of a poison on the central nervous system are central and peripheral. Variations in these manifestations are dependent on the susceptibility of the nervous system to injury and on its ability through anxiety, fear and apprehension to feign injury.

The manifestations of injury to the central nervous system may be headache, restlessness, confusion, disorientation, delirium, excitement, irritability, insomnia, fatigue, lassitude, somnolence, stupor, unconsciousness and coma. Hallucinations, catatonia, psychosis, mental deterioration and dementia all may occur in various sorts of poisoning, but these cannot be the assigned effects of poisoning until proved.

Pain in the extremities in the course of peripheral nerves is a most important manifestation of chronic poisoning of various sorts If the pain is associated with both sensory changes and motor disturbances, a peripheral nerve is affected. Peripheral neuritis may be accompanied by degrees of myalgia and arthralgia. Notable among the poisons causing peripheral neuritis are lead, arsenic, mercury and thallium Other important causes for peripheral neuritis are benzene, the monoxide and disulfide of carbon, oil of chenopodium, emetine, penicillin, and the sulfonamides

Vision and Hearing. The eyelids and the conjunctivae are frequently injured by poisonous or corrosive substances Von Oettingen lists 120 substances which have caused conjunctivitis, and no doubt this list could be greatly lengthened. Many of these and other substances may cause severe damage to the external structures of the eye by chemosis and corrosion

On contact of an irritant with the external structures of the eye, blepharospasm, lacrimation, and often photophobia ensue

In poisoning which acts through the central nervous system, but on rare occasions on the ocular nerves to the ocular muscles, the function of the oculomotor muscles may be impaired and be manifested by weakness of these muscles and the resulting abnormal position of the eyeball For instance, there may be exophthalmos, strabismus and nystagmus

Pupillary disturbance consisting of mydriasis alone or associated with rigidity is often the result of severe pain from any cause.

Common poisons which cause dilatation of the pupil are atropine, cocaine, ergot, insulin, and procaine The common drugs or poisons causing miosis or small pupils are caffeine, morphine, physostigmine, pilocarpine and chloroform.

Visual disturbances from poisoning may exist in all degrees from impaired vision, double vision, restriction of the visual field, disturbances in color vision, and yellow vision, to complete blindness The common poisons which may cause double vision are digitalis, ergot, insulin, morphine, quinine and ethanol (alcoholic beverages) The visual field is restricted by atropine, caffeine, epinephrine, ergot, morphine, quinine, salicylates and chloroform Disturbances in color vision are caused by barbiturates, digitalis, bromides, methyl alcohol (wood alcohol), quinine, salicylates and mercury (calomel) The common causes for yellow vision are digitalis, amyl nitrite, atropine, wood alcohol, and particularly santonin, when administered as a vermifuge

Poisons may injure both parts of the eighth cranial nerve. Defects in hearing, ranging from impairment to deafness, may follow poisoning from aspirin, atropine, quinine, streptomycin, cortisone, cocaine, the oxides and sulfides of carbon, and benzene. Vestibular disturbances may be caused by wood alcohol and amyl alcohol,

atropine, codeine, digitalis, kerosene, mercury, nitrites, opium, phenol, prostigmine, ethyl alcohol, lead, sulfonamides, thymol and many others.

ORGANIC COMPOUNDS

Benzene (Lethal Dose ⅓ Ounce to 1 Ounce). The symptoms of acute benzene poisoning are headache, dizziness and a feeling of intoxication.

In *acute benzene (benzol) poisoning* the most characteristic change is dark red blood which is very slow to clot but which does not show hemolysis. Hemorrhages, usually punctate, are found in the lungs and pancreas and in the gastric and intestinal mucous membranes. The abdominal organs are congested and there are *many bright red spots on the skin*

Treatment for acute poisoning consists of gastric lavage, followed by the administration of milk, tea and, if necessary, heart stimulants

Chronic benzene poisoning is more frequent, more important and more difficult to diagnose and treat than the acute form

When benzene vapors enter the body in the acute poisoning, about one third is absorbed in the blood Of this absorbed benzene some is oxidized to phenol and diphenols such as catechols and hydroquinone and eliminated as such. More of the benzene is eliminated as esters of sulfuric and glycuronic acids than is oxidized. In chronic poisoning more of the benzene is absorbed by the blood and is fixed in the bone marrow, fatty tissue, and liver.

There is individual but variable susceptibility to benzol poisoning. Also, there is an individual variation in the time required for symptoms of the poisoning to develop. The anemia may be discovered in from a few weeks to many years after exposure

The tendency of men to react with hyperplasia of the bone marrow, and of women to react with aplasia, suggests that women are more susceptible to benzene than are men

The influence of benzene on the course of infections reveals a lack of response on the part of the patient to infection Severe lesions of the mouth, such as Vincent's angina, are the most frequent manifestation of this action of benzene. Osteomyelitis of the lower jaw and gangrenous stomatitis may ensue.

The symptoms of chronic benzene poisoning are progressive weakness, malaise and fatigue. Then oozing of blood from the gums, throat, and nose occurs, and petechial hemorrhages from the stomach, intestines, and uterus ensue There may be chills, fever, delirium, heart failure with pulmonary edema, or toxemia following suppurative lesions in the throat, and death.

In benzol poisoning the results of a general examination by physical means are normal or are in accordance with the symptoms just outlined. *The characteristic* blood findings of severe poisoning are leukopenia, thrombocytopenia, and a high-grade anemia As the anemia develops in severe poisoning, there are macrocytosis, thrombocytopenia and leukopenia Leukopenia may develop first if it is present at all. Other manifestations of benzol poisoning are eosinophilia, immature elements of marrow in the circulating blood, and evidence of increased destruction of blood. The serum bilirubin values may be increased

Erythropenia sometimes is present to the point at which there are no young erythrocytes in the circulating blood Leukopenia may advance to the stage in which not only is the number of polymorphonuclear cells low but there is an absence of myelocytes, myeloblasts, and lymphoblasts The platelets are decreased, *sometimes to very* low levels Coagulation of the blood is decreased in time, with no retraction of the clot ensuing on standing.

Typically, the erythrocytes should present a perfectly normal appearance

Of great aid in the diagnosis of early benzene poisoning is the urinary test devised by Schrenk, Pearce and Yant of the Bureau of Mines They found uniformly

that an early sign of benzene poisoning is a decrease in the proportion of inorganic sulfates to total sulfates, this decrease being marked in accordance with the severity of the intoxication. The same decrease may be present in the urine of benzene workers.

Normally the inorganic sulfates make up 85 to 95 per cent, the organic, ethereal or conjugated, 5 to 15 per cent, but in cases of benzene absorption the phenolic products that are formed take up the sulfur, and the result is an increase in the conjugated sulfates which reverses the foregoing proportions. The decrease occurs rapidly on exposure to benzene and well in advance of leukopenia or anemia or other evidence of injury.

Derivatives of Benzene. The derivatives of the benzene ring are numerous and it is not always possible to predict, from the chemical composition of the simpler members of the group, what the physiologic action probably will be.

A chief use of *phenol* (hydroxybenzene) is the production of plastics, especially bakelite, for which it is combined with formaldehyde. Complaints of disagreeable effects in the making and use of bakelite are usually referred to the formaldehyde. Severe burns may be caused by phenol (carbolic acid) or by cresol. Phenol is readily absorbed through the skin Extensive burns of the skin by picric acid (trinitrophenol) may cause collapse and death.

Dinitrophenol 1-2-4, or *alpha-dinitrophenol*, is a powerful stimulant to metabolism This excessive oxidation affects metabolism and nutrition and damages hepatic and renal cells The use of alpha-dinitrophenol for the treatment of obesity may cause serious poisoning with symptoms such as fever, profuse sweating, and restlessness, associated with agranulocytosis, polyneuritis, rapidly developing cataract, blindness, and dermatitis exfoliativa

Trinitrophenol (picric acid) on the skin results in a dermatitis, sometimes severe, abdominal cramps, vomiting, and diarrhea.

Tricresyl phosphate is used as a plasticizer in the plastics industry. Tricresyl phosphate may be present in the alcoholic drink Jamaica ginger. Ingestion of Jamaica ginger may be followed by "jake paralysis" in which there are bilateral drop foot and wristdrop as the result of degeneration of peripheral nerves and corresponding anterior horn cells. A similar condition may arise from the use of an abortifacient, apiol, adulterated with *tri-ortho-cresyl phosphate* Soya bean oil used for salads and cooking has been known to be contaminated with tri-ortho-cresyl phosphate, the use of which causes a lower motor neuron paralysis.

Diphenyl is two benzene rings linked together. *Chlorinated diphenyls* are toxic. The *diphenylamine* and *para-amino-diphenyl* have the toxic action characteristic of amido compounds and are absorbed chiefly through the skin *Tetryl* or *trinitrophenylmethylnitramine* causes a dermatosis which is the principal toxic disturbance if not the only form of poisoning present in those who handle tetryl products.

Pure *chlorbenzene* produces systemic poisoning with methemoglobinemia and the resulting oxygen starvation *Paradichlorbenzene* is a constituent of antimoth mixtures and insecticides and often gives rise to dermatitis Nitrochlor compounds are irritating to the skin *Nitrochlorobenzene* is toxic and first causes anoxemia, flushed face, pressure in the head which increases to a violent throbbing headache, with dizziness, weakness and perhaps dyspnea. In severe poisoning the lips, tongue, and ears are deeply cyanosed Nausea, sometimes vomiting, a complaint of cramps in the abdomen, a staggering gait, and extreme weakness are present Such attacks always occur several hours after exposure The livid color persists for several days after acute poisoning, and in chronic poisoning it is plainly obvious all the time. The livid color, breathlessness on exertion and attacks of vertigo and gastric upset simulate cardiac disease. These symptoms may cause a serious disability with slow recovery.

Dinitrobenzene passes rapidly through the skin and also is inhaled as vapor.

If a sufficient dose is obtained, death may ensue in 1 to 2 days. In chronic poisoning there is a severe form of anemia, the skin is dusky yellow, and the conjunctivae are jaundiced, the muscles waste, sensation is dulled, and paresis of the hands with paresthesias, hyperesthesia and defects of vision are present. The effect on the bone marrow is at first stimulation of active erythrocyte production, as shown by polycythemia and then inactivity of the marrow follows. There are evidences of effort at regeneration: stippled erythrocytes, polychromatophilia, nucleated forms, variation in size of cells, and diminished platelets and lymphocytosis.

Trinitrotoluene ($C_6H_2(NO_2)_3CH_3$), TNT, is capable of causing dermatitis Workers with TNT and aniline dyes have an increased susceptibility to alcohol A small amount (a single drink) of whiskey may be enough to cause acute intoxication Anilinism is the term used to designate poisoning from aniline fumes

Paranitraniline is used with beta naphthol for the production on fabric of a bright red dye called parared. This, like other aniline compounds, may cause dermatitis, and even fatal sytemic poisoning Instances of the latter are rare. When they do occur, they result from exposure of a large part of the body to the dust of the dry compounds. A few hours after exposure there is unconsciousness, and death may ensue Often recovery may be hastened by intravenous injections of methylene blue

Paraphenylendiamine (ursol) is a dye for fur and felt. Poisoning from paraphenylendiamine is comparatively common among those who wear fur dyed with this compound The dye causes a severe dermatitis and, in some, bronchial asthma, an allergic reaction which is explained by the acute edema of the bronchial tubes. The patch skin test is often diagnostic.

Ethanolaniline or *2-anilinethanol* (phenylethanol amine) is toxic in the same way as the compounds of the aniline group. It produces methemoglobinemia The symptoms are headache, dizziness, pains in the muscles of the legs, breathlessness, and cyanosis. The blood is a deep brownish blue and the urine is dark. The cyanosis subsides after 24 hours

Toluene and Xylene. Toluene is methyl benzene, xylene is dimethyl benzene Owing to the inclusion of the methyl radical in the molecule, both toxicity and volatility are reduced Commercial toluene and xylene are very likely to contain benzene If the benzene content is high, benzene poisoning may ensue from handling

The affinity of benzene and toluene for the lipase substances present in the cells of the central nervous system attracts the ill effects of these chemicals on this system The poisoning characteristically causes inebriation, narcosis and psychosis Headache, vertigo, nausea, fatigue and giddiness are the predominant complaints, and disturbance of equilibrium (with a positive Romberg sign), ataxia, paresthesia and staggering gait the chief manifestations Psychotic disturbances manifest themselves in restlessness, disorientation, loss of memory, fugues, hallucinations and irritability, culminating in loss of consciousness. The wearing of respirators should be rigidly enforced in those working for even a short period in heavy concentrations of benzene and toluene.

In either toluene or xylene poisoning, there may be a decrease in the number of erythrocytes after exposure to high concentrations, a proportionately lowered hemoglobin, marked leukocytosis, and a considerable fluctuation in the proportion of lymphocytes to granulocytes

Toluene does not cause a reduction in the ratio of inorganic sulfates to the ethereal sulfates excreted in the urine, it does cause an increased excretion of hippuric acid which is roughly parallel to the intensity of the exposure.

Derivatives of Toluene and Xylene. The *toluidines* are amino derivatives of toluene. These compounds are irritating to the urinary system, causing strangury and hematuria. The para-toluidine seems to be more toxic than ortho-toluidine, despite the fact that it is a solid, while ortho-toluidine is a liquid.

Trinitrotoluene poisoning causes breathlessness on exertion, dizziness on stooping over, persistent headache, fatigue, anorexia, bad taste, and nausea in the morning. The conjunctivae smart and secrete excessively. The nose and throat burn and often there is nosebleed. The urine becomes clear brown in color. The Webster reaction of the urine is positive. This color test reveals a reduction product of trinitrotoluene which is proof only of absorption and not of poisoning, whereas the presence of *porphyrinuria* may indicate intoxication. In all instances of severe poisoning, the liver, the bone marrow and the vascular endothelium are affected simultaneously. The symptoms may be those of acute toxic hepatitis, if the liver is most involved, or of aplastic anemia or of acute toxic purpura.

Naphthalene fumes may cause headache, nausea, and vomiting and if hot and concentrated, injury to the cornea and bilateral optic neuritis *Tetralin*, tetrahydronaphthalene, is used as a degreaser and as a substitute for turpentine in paint or floor finishes The vapors are irritating to the mucous membranes and conjunctivae and also cause nausea, headache, and stupor. A dark, olive green coloration of the urine is present The color is attributed to the hydrolysis of tetralin, which is excreted as conjugated glycuronic acid.

The *naphthols* vary in solubility and isomeric arrangements. Beta naphthols give rise to skin irritation, cyanosis, frequent micturition and evidence of irritation of the bladder. Nitronaphthol (Marius yellow) is likewise a skin irritant. Alpha naphthol is harmless

The simpler compounds of chlorinated naphthalenes are commercially known as *halowax*. They are a cause of severe forms of acne, cable itch or blackhead itch

For many years the only recognized industrial injury from the use of halowax was a form of acne which differed from the ordinary form because itching was present The men called it blackhead itch and it appeared on the exposed skin It was often severe in type and secondary infections sometimes caused permanent scars. Vapors condensing on the skin act more quickly than does direct contact, and the melting temperature is around 240 to 260 F (115 5 to 126.6 C) at which point vapors are given off

The higher [illegible]
cally by jaundic [illegible]
are sufficient tc [illegible]
of the scleras Jaundice with anorexia, nausea, and severe abdominal pains ensue.

The Aniline Dyes. The aniline dyes are harmless. Dermatoses that sometimes affect dyemakers and dyers should be attributed to overharsh methods of cleaning the hands Cicatricial shrinkage of the conjunctivae of dye workers may occur.

Petroleum. The distillates of petroleum such as gasoline, naphtha, petroleum ether, and benzine and dry-cleaning fluids (Stoddard's solvent) have an acute anesthetic action Exposure to the fumes of these volatile solvent substances results in headache, blurred vision, dizziness, mental confusion, nausea, abdominal pain and, in extreme cases, loss of consciousness. These symptoms pass off promptly when fresh air is breathed, though occasionally there is a temporary exacerbation on coming into the open air. Massive doses result in sudden collapse, coma, and death.

Gasoline. Gasoline is a mixture of petroleum hydrocarbons having a distillation range of from less than 100 to about 400 F (204 C). Its composition in general comprises naphthenes, paraffins, aromatics and olefins All straight-run gasolines contain naphthene hydrocarbons. Straight-run gasoline made from petroleum pro- [illegible]

[illegible] at the filling station can be a possible source of poisoning The other sources of poisoning are the added constituents such as tetraethyl lead

Gasoline intoxication, as emphasized by Machle, occurs outside the petroleum industry when there is substitution of gasoline for solvents. Severe chronic gasoline poisoning has occurred in dry-cleaning plants; the pressing of clothes still damp with gasoline is dangerous because high temperatures volatilize the more toxic, heavier fractions, which are inhaled, and the toxicity is said to be likewise increased Cutaneous absorption is an insignificant means of absorption.

Gasoline is sometimes ingested accidentally, usually by children but also by motorists attempting to siphon it from tanks. The single oral dose usually fatal to man is approximately 7.5 gm per kilogram of body weight but death has been caused by a total dose as little as 10 gm., and recovery has followed the ingestion of 250 gm This divergence is due in part to the variability both in absorption and in the chemical composition of the gasoline It is absorbed most rapidly if it contains a high concentration of benzene and other aromatic hydrocarbons. The time interval between the ingestion of the gasoline and the occurrence of emesis and the possibility of aspiration are also of great toxicologic importance, since these factors influence the effective dose retained Individual susceptibility and the presence of food and fats in the stomach, tending to delay absorption, are factors in delaying or reducing poisoning

If the concentration of gasoline vapor in air is high, absorption through the lungs may be extremely rapid and symptoms may appear after a few minutes of exposure There is no agreement as to the amounts of volatile gasoline necessary to cause intoxication Susceptible persons may show symptoms after short exposures.

There are no characteristic general morbid anatomic changes incident to acute poisoning by gasoline The lungs are hyperemic There are petechial hemorrhages, subpleural extravasations and, in some instances, gross pulmonary hemorrhages Pleural effusion may be present Some degree of pneumonitis is usually present, especially if the gasoline has been ingested and aspiration has occurred, or as the result of its excretion by the lungs

Hemorrhages in the liver, kidneys and spleen and hemorrhages into the serous cavities are common The liver may be enlarged and contain cloudy swelling, and there may be fatty changes In the kidneys, edema may be present The proximal convoluted tubules are injured and the glomeruli contain lipid degenerative changes.

Hyperemia and edema of the brain and meninges and edema of the myelin and peripheral nerves may be persent

In chronic poisoning the anatomic changes are neither pronounced nor specific.

SYMPTOMS *Acute Intoxication* On exposure to very high concentrations of gasoline vapor in air, the highly susceptible victim falls to the ground in a comatose state and may die at once or within a few hours without regaining consciousness In a less susceptible person the onset of coma may be less rapid and the acute anesthetic action of the gasoline may cause initial symptoms like those of acute alcoholic intoxication, a brief period of in-co-ordination, restlessness and great excitement, with combativeness and abusiveness, mental confusion, disorientation, ataxia and possibly disturbances of speech and of swallowing. Delirium and finally coma ensue.

Unsaturated hydrocarbons, particularly the aromatic series, cause convulsions, tremors and motor disturbance Meningismus and epileptiform fits may continue for some time after recovery from the coma

EXAMINATION On examination evidence of the symptomatic manifestations may be observed. The skin may be moist and cyanotic. Coma often is present The pulse is enfeebled and rapid in the early stages of coma; it is often full in the presence of considerable motor unrest. Bradycardia, however, may be present. The pulse returns slowly to normal with recovery The temperature is usually subnormal but a rise in temperature may occur and in very sick patients and in terminal states it has reached 10o F (about 41 C). Respirations are usually shallow, rapid, and irregular. Sudden apnea may occur.

In quiet coma the superficial and deep reflexes are weak or absent. In the

presence of jactitation, meningismus and convulsions the reflexes may be greatly increased and plantar extension may be obtained. The pupils are dilated, often fixed, and may be unequal. Conjugate deviation and strabismus are frequent. Vomiting and singultus sometimes are observed during coma and may persist.

Subacute Intoxication Under most conditions of exposure in the ranges that cause subacute poisoning, the concentrations of volatile gasoline vary widely within wide limits. Individual susceptibility seems to be an important etiologic factor

If sickness has occurred as the result of ingestion, with no aspiration of the gasoline, symptoms develop more slowly than in poisoning by inhalation. There are various premonitory symptoms headache, usually described simply as a feeling of pressure over the head, blurred vision, vertigo, ataxia, tinnitus, nausea and anorexia, weakness and in some cases general abdominal pain. With these symptoms there develops a state of intoxication like that produced by alcohol, known as naphtha jag The sensation may be pleasurable and persons have been known to inhale gasoline vapors intentionally

Chronic Intoxication. This term is applied to poisoning which results from exposure to low concentrations of gasoline vapor for long periods of time.

The first symptoms to appear in chronic intoxication are those of a general nature and closely resemble psychasthenic and neurasthenic manifestations They are followed by muscular weakness and cramps, listlessness and a feeling of fatigue, and loss of body weight Hayhurst's patients slowly lost from 10 to 60 per cent of their body weight Irritative properties of the vapor usually cause conjunctivitis with lacrimation and cough with expectoration. Pulmonary hemorrhage has been reported but is uncommon When pulmonary hemorrhage occurs causes other than gasoline fumes should be found

Symptoms due to the effect of chronic intoxication on the central nervous system are mental confusion, loss of memory, a sense of impaired mental faculties, depression, irritability and nervousness

Indigestion, anorexia, nausea, but rarely vomiting, may be complaints Generalized abdominal pain is frequent and there may be either constipation or diarrhea.

There is often evident loss of body weight These patients often present physical appearances and behavior comparable to those observed in persons who have chronic alcoholism.

The specific effect of gasoline, or benzene, on the blood seems to be present only in chronic intoxication In cases of chronic gasoline poisoning some degree of anemia is usual. Hemoglobin may vary from 60 to 90 per cent, with 3,000,000 to 4,000,000 erythocytes per cubic millimeter The number of leukocytes is little changed, usually slightly increased In those cases in which leukopenia has been reported there has usually been exposure to gasoline of high benzene content Thrombopenia, purpura and epistaxis may also occur

Chemical changes in the blood are not significant

Albuminuria caused by gasoline poisoning occurs in some cases and usually appears 3 or 4 days after exposure

The commonest complications of gasoline poisoning are peripheral neuritis, impairment of memory, dullness of intellect, paresthesias in the extremities, cranial nerve palsies, retrobulbar neuritis and epileptiform fits. The neuritis and paresthesia do not usually persist, in some, however, severe spinal cord or neuritic symptoms have persisted.

DIAGNOSIS In acute poisoning there is a history of exposure or ingestion, and the odor of gasoline on the clothes and skin If poisoning has been by ingestion, both vomitus and washings from lavage will have the odor of gasoline. The odor will also be detected in the expired air for hours if exposure has been to high concentrations.

Gasoline intoxication, as emphasized by Machle, occurs outside the petroleum industry when there is substitution of gasoline for solvents. Severe chronic gasoline poisoning has occurred in dry-cleaning plants; the pressing of clothes still damp with gasoline is dangerous because high temperatures volatilize the more toxic, heavier fractions, which are inhaled, and the toxicity is said to be likewise increased Cutaneous absorption is an insignificant means of absorption.

Gasoline is sometimes ingested accidentally, usually by children but also by motorists attempting to siphon it from tanks. The single oral dose usually fatal to man is approximately 7.5 gm per kilogram of body weight but death has been caused by a total dose as little as 10 gm., and recovery has followed the ingestion of 250 gm This divergence is due in part to the variability both in absorption and in the chemical composition of the gasoline It is absorbed most rapidly if it contains a high concentration of benzene and other aromatic hydrocarbons. The time interval between the ingestion of the gasoline and the occurrence of emesis and the possibility of aspiration are also of great toxicologic importance, since these factors influence the effective dose retained. Individual susceptibility and the presence of food and fats in the stomach, tending to delay absorption, are factors in delaying or reducing poisoning

If the concentration of gasoline vapor in air is high, absorption through the lungs may be extremely rapid and symptoms may appear after a few minutes of exposure There is no agreement as to the amounts of volatile gasoline necessary to cause intoxication Susceptible persons may show symptoms after short exposures.

There are no characteristic general morbid anatomic changes incident to acute poisoning by gasoline. The lungs are hyperemic There are petechial hemorrhages, subpleural extravasations and, in some instances, gross pulmonary hemorrhages. Pleural effusion may be present Some degree of pneumonitis is usually present, especially if the gasoline has been ingested and aspiration has occurred, or as the result of its excretion by the lungs

Hemorrhages in the liver, kidneys and spleen and hemorrhages into the serous cavities are common The liver may be enlarged and contain cloudy swelling, and there may be fatty changes In the kidneys, edema may be present The proximal convoluted tubules are injured and the glomeruli contain lipid degenerative changes.

Hyperemia and edema of the brain and meninges and edema of the myelin and peripheral nerves may be persent

In chronic poisoning the anatomic changes are neither pronounced nor specific

SYMPTOMS *Acute Intoxication* On exposure to very high concentrations of gasoline vapor in air, the highly susceptible victim falls to the ground in a comatose state and may die at once or within a few hours without regaining consciousness. In a less susceptible person the onset of coma may be less rapid and the acute anesthetic action of the gasoline may cause initial symptoms like those of acute alcoholic intoxication a brief period of in-co-ordination, restlessness and great excitement, with combativeness and abusiveness, mental confusion, disorientation, ataxia and possibly disturbances of speech and of swallowing. Delirium and finally coma ensue.

Unsaturated hydrocarbons, particularly the aromatic series, cause convulsions, tremors and motor disturbance. Meningismus and epileptiform fits may continue for some time after recovery from the coma

EXAMINATION On examination evidence of the symptomatic manifestations may be observed The skin may be moist and cyanotic. Coma often is present. The pulse is enfeebled and rapid in the early stages of coma, it is often full in the presence of considerable motor unrest Bradycardia, however, may be present. The pulse returns slowly to normal with recovery. The temperature is usually subnormal but a rise in temperature may occur and in very sick patients and in terminal states it has reached 10o F (about 41 C). Respirations are usually shallow, rapid, and irregular. Sudden apnea may occur

In quiet coma the superficial and deep reflexes are weak or absent. In the

EXAMINATION. The distinctive odor of methyl alcohol or acetone is detected on the breath The pupils are dilated and sluggish in response to light in serious poisoning The conjunctivae are injected, and there is photophobia. There is reduction of central vision, developing 24 hours after ingestion. This is usually in the form of a negative central scotoma of the relative type. However, the scotomas may be anywhere in the visual fields. Night blindness, color impairment and yellow vision may occur.

The fundi may show generalized hyperemia The disks are hyperemic and the borders blurred owing to papillitis Secondary optic atrophy may occur in patients whose vision improved for four to six weeks

There are varying degrees of acetonuria. The levels of methanol in the blood may reach 40 to 50 mg. per 100 ml. and still recovery may ensue.

The pathologic changes in the eye are attributed to an optic neuritis. As the initial inflammation subsides, there is an improvement of vision which lasts until the scar tissue contracts, and atrophy of the optic nerve and permanent blindness ensue.

Combating the intense acidosis is the most important single feature of therapy. In severe poisoning 250 ml. of a 5 per cent solution of sodium bicarbonate can be administered intravenously and then continued measures to combat the acidosis may be used if necessary.

The diagnosis of methyl alcohol intoxication can be surmised from the evidence obtained from the history and the examination. Identification of methyl alcohol requires the services of the chemist.

Ethyl Alcohol. Ethyl alcohol (CH_3CH_2OH) has an *irritant action* owing to the partial precipitation of the proteins of the cells and to its dehydrating property.

[illegible]

unprotected surfaces the irritant action is much greater, and the application is attended with pain and smarting. In the mouth strong alcohol produces a burning, unpleasant sensation which passes to the throat and stomach when it is swallowed, and if the concentrated vapor is inhaled, it causes irritation and reflex closure of the glottis and cough or strangling.

Alcohol is absorbed rapidly, about 20 per cent of that ingested being taken up in the stomach and 80 per cent in the small intestine. The rate of absorption varies with the concentration, strong alcohol appearing more quickly in the blood than does the same amount in greater dilution, food delays the absorption when taken at the same time, especially if it contains fat The concentration of alcohol in the blood reaches its maximum about 2 hours after the alcohol is swallowed, and then the level falls slowly, the amount in the blood being determined by the balance between that which is being absorbed and the amount undergoing oxidation and excretion The course of intoxication follows the curve of the concentration in the blood fairly closely.

The most constant *pathologic changes* are severe meningeal and cerebral congestion, pulmonary edema, acute gastritis, visceral congestion and acute pancreatic necrosis Most of these changes are found in other conditions, especially those characterized by anoxemia Postmortem determinations of blood, urine and tissue alcohol are of diagnostic value only when death has taken place within a few hours after the onset of the alcoholic coma Acute alcoholism should be suspected in all cases of suicide, homicide, accident, trauma and poisoning and as a complicating or precipitating factor in other medical or surgical fatalities.

The *effects* of alcohol differ in different persons as well as in a given person at different times When drinking is indulged in in company, the stage of excitement is a common phenomenon, but if alcohol is taken in solitude, the excitement does not occur.

In small quantities, alcohol produces a feeling of well-being and good fellowship

Gasoline poisoning occurring in a room where gasoline combustion engines are operating may be confused with coma and convulsions from carbon monoxide intoxication. The color of the skin and mucous membranes and the finding of carbon monoxide hemoglobin in the blood will serve to identify the poisoning of carbon monoxide. In most cases of acute intoxication there is recovery without serious after-effects Severe sequelae are uncommon. It is to be emphasized that most of those who have gasoline poisoning or intoxication, in either the acute or chronic forms, recover completely. The manifestations which have been alleged to be the result of complications and which persist can rarely be proved to be due to gasoline *intoxication.*

Alcohols. The common alcohols, methyl, ethyl, isopropyl, butyl and amyl, increase in toxicity as the series becomes chemically more complex from methyl alcohol.

The acute effects of the alcohols, *methyl* and *ethyl,* do not differ except that the duration of intoxication with methyl alcohol is more prolonged than with ethyl alcohol. Ethyl alcohol is rapidly oxidized to carbon dioxide and water, which are disposed of quickly, whereas methyl alcohol is difficult to excrete and it is by this property that it is rendered so poisonous when ingested.

Methyl Alcohol. Methyl alcohol (CH_3OH) is properly known as methanol, and more commonly is called wood alcohol. It is an important industrial solvent and the major ingredient of many inexpensive antifreeze preparations

Acute or chronic poisoning may be produced by ingestion, cutaneous absorption or inhalation Atmospheric concentrations of 0 2 per cent may cause systemic complaints. The erroneous use of methyl for ethyl alcohol as a skin rub, or its criminal incorporation in cheap hair tonics or hand lotions, may produce poisoning Most commonly, however, intoxication occurs after using it for a spiritous beverage There is extreme variability in individual tolerance to this agent, but permanent blindness has been reported after ingestion of as little as 4 ml and death has occurred after drinking 30 ml.

One third of the assimilated dose of methanol may remain in the body unaltered for 48 hours, and traces may persist for a week in serious poisoning Twenty to 70 per cent may be excreted through the lungs and 3 per cent through the urine.

Chronic poisoning is made possible by the cumulative effect from slow elimination.

Formaldehyde may be produced from methanol oxidation If so, it too is more toxic than is methanol, and persons poisoned with it may become profoundly acidotic.

Methyl alcohol produces poisoning by direct destruction and irritation of tissues and by a disturbed acid-base balance Methyl alcohol has unlimited miscibility with water but a very low solvent power for fats

Among all body fluids, the aqueous and vitreous of the eye have the highest percentage of water Thus it happens that intra-ocular fluid and unmedullated nervous tissues are sites of greatest damage from methanol

The direct local action of methanol and formic acid damages the gastrointestinal tract (especially the stomach), the lungs, the kidneys, the liver, the pancreas, the brain and, most markedly, the eyes The general action results in acidosis This is thought to be due largely to the formation of formic acid, and perhaps secondarily to the accumulation of carbon dioxide The latter is a consequence of the alveolar damage of methanol

Symptoms In general, patients who are mildly poisoned have symptoms indistinguishable from those of patients suffering the aftermaths of ordinary ethyl alcoholism. The symptoms consist of headache, dizziness, nausea, lassitude and slight abdominal pain Some patients on admission have violent epigastric pain, vomiting, delirium and various degrees of blindness.

Sometimes the symptoms of inebriation partially clear, just prior to coma, giving a false impression of recovery Coma frequently is accompanied with Kussmaul breathing, cyanosis, noisy gurgling respirations and, usually, respiratory arrest, circulatory collapse and death.

moderately, but is overcome by the irresistible impulse to drink excessively, even when he knows that drinking is injurious to his body and mind.

In chronic alcoholism there is often a chronic catarrh of the throat, larynx and stomach. There are an injection of the cutaneous vessels of the face and acne, or pustular eruptions Fatty degeneration occurs in the liver and in the arterial walls throughout the body. The heart may undergo fatty changes accompanied by dilatation and weakness Cirrhosis of the liver, which is common in alcoholics, develops in part because of thiamine deficiency. But repeated excessive doses of alcohol may also cause acute hepatic damage

Drunkards often appear to be healthy, of good color, well nourished and strong. Depending on their inherent physical stamina, sooner or later alcoholic cachexia will overtake them In alcoholic cachexia there are emaciation, pallor, cyanosis, tremulousness and unsteadiness, and an indifference and incapability.

Dipsomania In dipsomania, periodically there is an irresistible impulse to excessive drinking of alcoholic liquors After the first drink the patient begins to drink rapidly, of whiskey, brandy, or gin, without choice or purpose A single attack lasts, in most cases, about 3 days, but it may extend to a week or to two Subsequent to an attack, the patient is depressed and self-accusatory; he resolves never to take another drink, and he may be industrious and abstinent until the occurrence of the next attack The succeeding attacks occur more regularly and more frequently as time passes.

Dipsomania is manifested as a form of chronic alcoholism, but in reality it is a sign of a periodically recurring abnormal mental state.

Delirium Tremens This is a delirium of chronic drunkards, usually after many years of excess, it usually appears after a temporary abstinence from alcohol, due to gastric catarrh, to infection or to lack of access to alcoholic beverages.

The delirium comes on suddenly, lasts from 2 to 10 days, and is characterized by a dreamy alteration of consciousness, with visual hallucinations and illusions. The patients are especially prone to have visual hallucinations of a large number of small, moving, dark objects such as flies, mice, lice and snakes, and are greatly terrified by them

During an attack of violence there may be fever, tachycardia, tremor, anorexia and sweating. At the end of the attack the patient, if he is to recover, falls into a deep sleep and awakes with a clear consciousness, again fully oriented Death may occur from heart failure, from a complicating pneumonia, or from gastrointestinal manifestations.

If the patient's habits are known, there is usually little difficulty in arriving at the diagnosis If not, delirium tremens may be confused with other twilight states, hysteria and epilepsy, traumatic psychoses and infectious or toxic deliria.

Korsakoff's Psychosis (Polyneuritic Psychosis) This is a psychosis accompanied with polyneuritis which is commonest in alcoholism, though it occurs in other conditions that give rise to multiple neuritis The same psychosis may occur without the neuritis

There is an impairment of the recording faculty of the cerebral hemispheres which is manifested by forgetting immediately all new impressions and the most [illegible] emory falsifi- [illegible] iese falsifica- [illegible] liar has no [illegible] memory disturbances.

Cure is rare, chronic mental disease usually ensues.

Paranoid States Related to Alcoholism. In chronic alcoholism paranoid states are frequent These states are stages of alcoholism, for instance, the acute alcoholic paranoid state incident to acute alcoholism, and the jealous insanity of drunkards. The acute alcoholic paranoid state was discussed with acute alcoholic intoxication,

along with increased confidence in the powers, mental and physical. Larger quantities are followed by laughter, loquacity and gesticulation. The face becomes flushed and hot, the pupils become dilated, the eyes brighter and livelier; the pulse is accelerated Self-control is partially lost, the will power is weakened Movements are undignified, and there may be outbursts of anger, unreasonableness, and sensual fancies. The sense of responsibility, the power of judgment, and the regard for the feelings of others or the ordinary conventions of life are lost. The ingestion of more is followed by ataxic movements; the speech becomes difficult and stammering

The gait and locomotion resembles that observed in cerebellar ataxia. A deep sleep follows. On awakening from slumber, there are mental depression with nausea, vomiting and anorexia, which may last for several days, associated with the symptoms of acute gastrointestinal irritation and physical weakness.

The ingestion of 50 ml of alcohol induces irritation of the gastrointestinal tract with a profuse secretion of mucus The nausea and vomiting encountered may arise in part from this local irritation, but it is probable that the nervous centers are also involved directly as in the case of the general anesthetic agents which induce similar symptoms

Alcohol in moderate doses has a depressant effect on the motor and mental faculties Work requiring skill is done with decreased endurance, more slowly and with more errors than without it In some persons alcohol removes nervousness, self-consciousness and anxiety by depression of the higher inhibitory centers and in these it may contribute to better performance.

The stimulation observed following the ingestion of alcohol is a result of the removal of the inhibitory action of the cerebral cortex and the weakening of the will and self-restraint. The drug appears to act most strongly on the most recently acquired faculties, the power of self-control and the sense of responsibility. Alcohol is a narcotic which depresses first the highest cerebral center, and then the lower ones including the cerebellum and spinal cord

The manifestations of alcohol are characterized by a flushed, hot, perspiring face. The pulse is accelerated during the excitement of alcoholic intoxication Even small amounts of alcohol may cause a transient acceleration of the pulse and cardiac output and a slight rise in arterial pressure In moderate drinkers, slightly larger amounts cause appreciable increases in both blood pressure and cardiac output Alcohol is believed by some to augment the strength of the heart, but the change is small in extent and inconstant in its appearance. Larger quantities weaken the auricular and later the ventricular systole and induce dilatation and slowing of both chambers

Large quantities of alcohol lead to a deep sleep which eventually passes into total unconsciousness The respiration is stertorous and slow, and the face becomes pale or cyanotic. The pupils are dilated This condition may last for several hours and end in death from failure of the respiration When the stage of anesthesia is reached, it lasts much longer than that produced by chloroform or ether If unconsciousness lasts longer than 10 to 12 hours, recovery is unlikely. Death occurs, likely from edema and paralysis of the medullary centers

In the blood and urine of normal persons there is less than 0 1 per cent of alcohol Concentrations of 0.1 to 0.2 per cent in the blood and 0 25 per cent in the urine are accompanied by emotional instability and slight motor in-co-ordination. When the concentration reaches 0.2 to 0.35 per cent in the blood and 0 25 to 0 45 per cent in the urine there is confusion and ataxia of speech and gait Stupor is established with concentrations of 0.3 to 0 4 in the blood and concentrations of 0 5 to 0 7 in the urine It is in this range of alcoholic concentration in the blood and urine that death ensues Analyses of the blood and urine from the dead one are of no value unless made within an hour or two after death

Chronic Alcoholism. Men and women who become chronic alcoholics are predisposed by the inheritance of a bad nervous system. A drunkard cannot drink

the olefins, unsaturated, for example ethylene, propylene; and the naphthalenes. They are strong solvents, used as cleaners of metal and textiles, as solvents for rubber, tar and gums; as thinners of cellulose lacquers; for treatment of garbage, tankage and bones; in the production of high grade lubricating oils from inferior ones; and in the production of vegetable oils. They are used in fire extinguishers and refrigerators.

Monochlormethane (methyl chloride) (CH_3Cl) is used in refrigeration. It is a weak narcotic and a severe nerve poison. Refrigerator repairmen after chronic exposure may have attacks of dizziness and drunkenness, apathy, anorexia, persistent somnolence, loss of power in the legs, uncertain gait and disturbances of vision There may be anemia, jaundice and impaired or disturbed function of the kidneys.

Trichlormethane (chloroform) is no longer used extensively as a general anesthetic agent and therefore it is not an important cause of disability

Tetrachlormethane, known as carbon tetrachloride, is a noninflammable fluid used in chemical fire extinguishers and as a dry cleaner It is a narcotic with an action very like that of chloroform The after-effects of severe narcosis are more serious than are those of delayed chloroform poisoning

In man, poisoning by carbon tetrachloride produces symptoms of hepatic and renal injury Persistent headache, nausea, vomiting, diarrhea, pain, and tenderness in the hepatic region and jaundiced scleras characterize the early stages The renal injury is manifested by oliguria, the urine is heavy with albumin and casts. These manifestations follow those from hepatic injury Soon uremia, increasing in severity as the suppression of urine becomes complete, ends in death.

The recovery of renal function following acute renal failure due to carbon tetrachloride poisoning is characterized by three clinical phases The first phase starts with the cessation of oliguria and is associated with rising concentrations of creatinine and urea in the blood despite an adequate excretion of urine It lasts 1 to 3 days The second phase begins with a rapid decline in the concentrations of urea and creatinine After 5 to 6 weeks the renal functional activity begins to improve and slowly regains normal limits.

Chronic poisoning by carbon tetrachloride seems to be well established as an entity The symptoms are headache, vertigo, loss of appetite, gastric distress, loss of strength and, in some, jaundice

Monochlorethane (ethyl chloride) (C_2H_5Cl) is used as a local anesthetic agent, as a refrigerant, and as a solvent in making perfumes It is less toxic than methyl chloride (monochlormethane) but similar in its action

Dichlorethane (ethylene dichloride) is an excellent solvent and a dangerous poison It is used in dry cleaning, in the production of photographic films and as a thinner of lacquers, especially for coating the interior of beer vats. It is a narcotic poison and causes a severe dermatitis of the hands, leukocytosis and hepatic disturbance, but no evidence of renal involvement Fatal injuries are rare

Trichlorethane ($C_2H_3Cl_3$) when made from grape pips which are crushed and dried and distilled may endanger those near by its rapidly acting anesthetic fumes and by causing acute congestion of the lungs and kidneys and to a less extent of the liver and spleen Lesions of the skin are formed which resemble burns

Tetrachlorethane ($C_2H_2Cl_4$) is a solvent for the fats and gums and best of all for cellulose acetate It is a dangerous narcotic poison. It acts more slowly than chloroform but the effects are more last[illegible]

[illegible] causes acute yellow atrophy of the l[illegible] capillaries, there is no appreciable hemolysis, a point of differentiation of tetrachlorethane poisoning from that due to arsine Tetrachlorethane poisoning is distinguished from infectious hepatitis by the absence of high fever; it is slow in onset and the jaundice is severer and more ob-

The jealous insanity of drunkards coincides with the deterioration of ethical standards and loss of self-respect and family respect. As the drunkard g older, he recalls his own amorous affairs away from home in his younger and di ing days. He realizes that he is still absent from home "just for drinking," for c he has become sexually impotent. If he should have a wife at home younger tha is, he suspects that she is having amorous relations with others The idea s becomes transformed into a fixed delusion and is supported by auditory and vi hallucinations The wife is often violently mistreated, and may even be murde The symptoms disappear after a few weeks of total abstinence in an asylum, c

solvent mixtures It causes keratitis, consisting in numerous translucent vacuole the superficial layers of an otherwise normal cornea These lesions may occur w out symptoms When symptoms are present, they consist of pain and epiphora m severe in the early morning *Amyl alcohol* ($C_5H_{11}OH$), commonly known as fu oil, is a poison when taken through the mouth, causing headache, dizziness, naus vomiting, diarrhea, delirium, coma and death

Furfural ($C_4H_3O.CHO$) is one of the essential constituents of Japanese r wine (saké) When fed to animals with rice in amounts varying from 10 to 50 per kilogram of body weight, furfural may produce early death Generally speaki rats fed on these amounts of furfural begin to show evidence of hepatic cirrho in 60 to 90 days; much smaller feedings of furfural may not lead to such a path logic condition until 300 to 500 days later

Oxalic Acid. The adverse effects of administration of oxalic acid are attribut to the formation of a highly insoluble precipitate with calcium. However, many the common articles of the diet contain oxalates and these substances continue be present in the blood and urine. The presence of oxalic acid in the blood and uri may be the result of its being a product of intermediary metabolism, particularly carbohydrate

The oxalate ion reduces the solubility of powdered dental enamel in solutic with an acid reaction There is some evidence that oxalic acid exerts a protecti action against erosion of the teeth by other acids

Poisoning from oxalic acid usually results from swallowing of a solution of in which case there is a marked corrosive effect involving mouth, esophagus, an stomach, with vomiting, intense burning pain, collapse, sometimes convulsions, an death The action of oxalic acid is the result of a chemical affinity for calcium, whic is drawn from the blood, with reduction of alkalinity of the blood and increase i the sugar content The renal tubules become obstructed by the insoluble calciur oxalate, and great disturbances in renal functional activity ensue.

Hexamethylenetetramine. Hexamethylenetetramine (urotropin) causes irri tation of the skin and, in excessive doses, of the urinary tract. In the urinary trac on decomposition it liberates formalin.

Nitroglycerin. Nitroglycerin is a main constituent of dynamite as well as a medicinal preparation. It is a vasodepressant and a common cause of "powde headache," or "dynamite headache." The face is flushed, and there are intense throbbing in the head, palpitation, and sometimes nausea, vomiting and polyuria

Formaldehyde. Formaldehyde (CH_2O) is a powerful irritant to the tissues with which it comes in contact, skin, conjunctivae and mucous membranes. This effect is due to the formation of an irreversible combination of formaldehyde with the protein of the surface cells.

Chlorinated Hydrocarbons. The chlorinated hydrocarbons are of the pe- ... series and are divided into the saturated (paraffin) group, methane, ethane,

the olefins, unsaturated, for example ethylene, propylene; and the naphthalenes. They are strong solvents, used as cleaners of metal and textiles; as solvents for rubber, tar and gums; as thinners of cellulose lacquers; for treatment of garbage, tankage and bones; in the production of high grade lubricating oils from inferior ones; and in the production of vegetable oils They are used in fire extinguishers and refrigerators.

Monochlormethane (methyl chloride) (CH_3Cl) is used in refrigeration It is a weak narcotic and a severe nerve poison Refrigerator repairmen after chronic exposure may have attacks of dizziness and drunkenness, apathy, anorexia, persistent somnolence, loss of power in the legs, uncertain gait and disturbances of vision. There may be anemia, jaundice and impaired or disturbed function of the kidneys.

Trichlormethane (chloroform) is no longer used extensively as a general anesthetic agent and therefore it is not an important cause of disability.

Tetrachlormethane, known as carbon tetrachloride, is a noninflammable fluid used in chemical fire extinguishers and as a dry cleaner. It is a narcotic with an action very like that of chloroform The after-effects of severe narcosis are more serious than are those of delayed chloroform poisoning.

In man, poisoning by carbon tetrachloride produces symptoms of hepatic and renal injury. Persistent headache, nausea, vomiting, diarrhea, pain, and tenderness in the hepatic region and jaundiced scleras characterize the early stages. The renal injury is manifested by oliguria; the urine is heavy with albumin and casts These manifestations follow those from hepatic injury Soon uremia, increasing in severity as the suppression of urine becomes complete, ends in death

The recovery of renal function following acute renal failure due to carbon tetrachloride poisoning is characterized by three clinical phases The first phase starts with the cessation of oliguria and is associated with rising concentrations of creatinine and urea in the blood despite an adequate excretion of urine It lasts 1 to 3 days. The second phase begins with a rapid decline in the concentrations of urea and creatinine After 5 to 6 weeks the renal functional activity begins to improve and slowly regains normal limits.

Chronic poisoning by carbon tetrachloride seems to be well established as an entity. The symptoms are headache, vertigo, loss of appetite, gastric distress, loss of strength and, in some, jaundice

Monochlorethane (ethyl chloride) (C_2H_5Cl) is used as a local anesthetic agent, as a refrigerant, and as a solvent in making perfumes It is less toxic than methyl chloride (monochlormethane) but similar in its action

Dichlorethane (ethylene dichloride) is an excellent solvent and a dangerous poison It is used in dry cleaning, in the production of photographic films and as a thinner of lacquers, especially for coating the interior of beer vats. It is a narcotic poison and causes a severe dermatitis of the hands, leukocytosis and hepatic disturbance, but no evidence of renal involvement Fatal injuries are rare

Trichlorethane ($C_2H_3Cl_3$) when made from grape pips which are crushed and dried and distilled may endanger those near by its rapidly acting anesthetic fumes and by causing acute congestion of the lungs and kidneys and to a less extent of the liver and spleen Lesions of the skin are formed which resemble burns

Tetrachlorethane ($C_2H_2Cl_4$) is a solvent for the fats and gums and best of all for cellulose acetate It is a dangerous narcotic poison. It acts more slowly than chloroform, but the effects are more lasting.

Chronic tetrachlorethane poisoning often causes acute yellow atrophy of the liver. The earliest changes are in the biliary capillaries; there is no appreciable hemolysis, a point of differentiation of tetrachlorethane poisoning from that due to arsine Tetrachlorethane poisoning is distinguished from infectious hepatitis by the absence of high fever, it is slow in onset and the jaundice is severer and more ob-

stinate than in delayed chloroform poisoning. The blood changes in moderate poisoning consist in a mononucleosis with increase of the lymphocytes.

Chloral (CCl_3CHO) is a soporific, intensely irritating vapor. Its action on the lungs is similar to that of phosgene and therefore it can produce fatal pulmonary edema.

Trichloroethylene $CHCl:CCl_2$ (C_2HCl_3) is noninflammable and has a strong narcotic action In acute poisoning there are excitement, drunkenness, or dullness and confusion. Death may ensue from the narcotic effect without the victim regaining consciousness. There is congestion and acute edema of the lungs, liver and kidneys It does not seem that sequelae result from acute poisoning, nor is there a chronic form of poisoning

Tetrachloroethylene ($CCl_2{\cdot}CCl_2$) is a safe substitute for carbon tetrachloride for hookworm therapy It can be used for the same purposes as trichloroethylene, and is a relatively harmless solvent.

Ethylene chlorohydrin (C_2H_4ClOH) may cause death from edema of the lungs and degeneration of kidneys There may be symptoms suggestive of a narcotic poison and the vomiting of bile-stained fluid. The liver and spleen may be swollen, hard, and intensely congested There is evidence that this solvent is a cumulative poison and that men of poor physique and women are more susceptible than healthy men.

Bromine Derivatives of the Hydrocarbons. The bromine compounds, methyl bromide, ethyl bromide and ethylene dibromide, are much more toxic than the chlorine compounds They are used as refrigerants and, in combination with carbon tetrachloride, as fire extinguishers Ethylene dibromide is used in tetraethyl lead gasoline to act as a catalyst.

Methyl bromide (CH_3Br) on the skin may cause painful burns with blistering. It has an apparent action on the basal ganglia and the cerebellum Methyl bromide has been used as a refrigerant, as a fire extinguisher and as a fumigant for cereals and seeds. It is shipped as a liquid in cylinders and either is allowed to evaporate directly into the fumigation area or is conveyed there by pipes

Methyl bromide is more toxic than either chloroform or carbon tetrachloride. When inhaled, it causes congestion of the lungs, edema, and injury to the vascular system as manifested by hemorrhage After a single exposure degenerative changes in the organs are observed, especially in the kidneys

Symptoms referable to the nervous system are manifest as headache, vertigo, paralyses, visual disturbances, delirium, psychic disturbances and even convulsions and coma Acute poisoning usually results in pulmonary irritation leading to bronchial pneumonia Anorexia, nausea and vomiting are seen most frequently, then headache, vertigo, difficulty in focusing the eyes, lethargy, gastrointestinal symptoms, muscular pains, faintness and dimness of vision. A vesicular burn, resembling a second degree burn, occurs when liquid methyl bromide comes in direct contact with the skin, and a late itching dermatitis will result from contact

In patients who recover from acute symptoms there has sometimes been evidence of lasting injury to the central nervous system After a transient narcosis there is a free interval of several hours or days, and then muscular twitchings and cramps begin, increasing to convulsions, coma and death

Ethyl bromide is nontoxic on inhalation

Carbon Disulfide. Carbon disulfide (CS_2) dissolves fats and gums, gutta-percha, and rubber. In the production of viscose rayon, cellulose is treated with an alkali to form alkali cellulose. This is changed to cellulose xanthate by being treated with carbon disulfide. The exposure to fumes of carbon disulfide takes place during this process

The commonest manifestation of carbon disulfide poisoning is a peripheral neuritis Usually the symptoms begin with parasthesias. Pain and tenderness are

soon associated with these symptoms and are distributed along the course of the nerve trunk. The senses of touch, pain, and temperature are heightened.

During the night, pain in the legs may reach an intolerable intensity. The radial, ulnar, sciatic, and external peroneal are the nerves commonly affected. Motor involvement is manifested by early fatigue and gradually increasing loss of strength Weakness in the legs appears earlier and is complained of more frequently than weakness in the arms. Sometimes there is an exaggeration of the deep tendon reflexes. As time passes, wasting appears according to the severity and duration of the poisoning The course of carbon disulfide neuritis is slow.

Turpentine. When turpentine was in general use by painters, they often complained of turpentine intoxication, which consists of periods of drowsiness, headache, nausea, loss of appetite, vomiting, vesical and renal complaints, inflammation of the eyes, irritation of the throat, bronchitis and cutaneous eruptions.

There is little real evidence of lasting injury to the kidneys, despite the belief of painters to the contrary During colonial days turpentine was often taken internally for renal complaints

Tobacco. Work with tobacco has been considered unhealthful but there are no objective data to bear out the accuracy of the belief.

Newcomers in tobacco handling experience the same symptoms as the inexperienced smoker—headache, palpitation of the heart, perhaps rapid, irregular pulse, nausea, and vomiting—but sooner or later an immunity is established It is often asserted that nicotine causes toxic amblyopia, just as do alcohol, lead and carbon disulfide, but examination of tobacco workers does not substantiate this assertion.

Synthetic Rubber. The toxic substances used in the production of rubbers are acrylonitrile or vinyl cyanide (see Cyanides, p. 1430) butadiene and monomeric styrene. Butadiene is mildly narcotic. The vapors cause irritation of eyes, nasal passages, throat, and lungs, sometimes with cough and also a sense of fatigue and drowsiness

Styrene causes irritation of eyes and nose, and the inhalation of styrene fumes causes light narcotic symptoms

Chlorobutadiene causes a loss of hair Men and women in contact with it experience loss of hair which is never patchy and is not long lasting, even if it goes on to total alopecia. Hair on the body is not affected, nor are eyebrows, and there is no accompanying dermatitis

There are numerous rubber solvents and many of them are toxic These solvents are often used in the manufacture and repair of shoes The solvents present in rubber cements are petroleum naphthas, benzol, toluol, xylol, cyclohexane and methycyclohexane, acetone, methyl ethyl ketone, carbon tetrachloride and trichloroethylene

Welding. The use of oxyacetylene torches in small, closed spaces creates a highly irritating dust or gas which may cause respiratory irritation and pneumonia Ferric oxide is contained in the gas, it acts like silicon in the lungs and cannot cause acute disease

Electric arc welding is attended with the production of ultraviolet rays, necessitating protection of eyes and skin, and a greater production of heat The intense odor of arc welding is from ozone. The possible dangers in welding may be summarized by enumeration of the toxic agents present, namely, ultraviolet rays, excessive heat, the volatile products of heated metals, zinc, lead, cadmium, fluorides, manganese, phosphorus, vanadium and chromium The composition of the welding rod is almost pure steel However, some rods are coated with a complicated mixture of organic and inorganic substances in addition to the forementioned metals. There is a greater production of nitrous gases, an accepted cause of lung fever, when bare rods are used, or of metallic fumes when the rods are coated.

Ocular injuries from welding are among the first effects to be noted. A welder

must protect not only himself and his eyes against the torch flame but also the men working near him.

Oil Folliculitis. Oil folliculitis or furunculosis is caused either by the plugging of sebaceous hair ducts or by the production of small abrasions by metal filings. All oils have a penetrative power, and almost all have an irritant action which causes swelling of the mouths of the sebaceous hair ducts, with production of blackheads and then retention cysts The entrance of pyogenic bacteria turns the cyst into an abscess, which discharges and heals, leaving a hole, so that after some time the skin is pock marked Oil boils can be prevented by using sawdust soaked in liquid soap and warm water, followed by gentle drying and covering the boils with lanolin or castor oil.

Riehl's melanosis or pigmented reticular poikiloderma is an occupational cutaneous affection which is connected with the use of mineral oil. There are dark patches of skin, often on the face, neck and folds of the axillae. The process begins with redness followed by patchy browning surrounded by a violet zone When the melanosis fades, the skin is left somewhat atrophic

Cruickshank and Squire called attention to cutaneous contamination of workmen where automatic machines are used which eject much oil The skin of the machine operators becomes grossly contaminated with cutting oils. Eight of every 10 workers observed by the writers were afflicted with oil folliculitis. In addition, workers who had been exposed for long periods had multiple hyperkeratotic lesions on their arms. Scrotal carcinoma was observed in one operator. An investigation of the records of the United Birmingham Hospitals revealed that during the last 10 years 34 instances of scrotal cancer occurred Of these, 6 occurred in machine operators and 6 in other workers exposed to oil in the engineering industry; 13 occurred in workers exposed to tar, pitch and similar products

Drug Addiction. In its broadest sense the term drug addiction applies to any person in whom for either physical or psychologic reasons a compelling need for certain drugs has developed.

Habit-forming drugs may be classified into two categories. the narcotic group, and the various types of sedatives and hypnotics

According to federal statutes, the narcotic drugs are opium and its derivatives, cocaine, marihuana, heroin and demerol, and addiction to these substances is legally narcotic drug addiction.

Himmelsbach stated that addiction to the opiate drugs embraces three related phenomena (1) tolerance or the gradual decrease in the effect produced by the repeated administration of a drug, (2) physical dependence, which is manifested by the appearance of a characteristic illness if the drug is withheld and (3) habituation or psychic dependence, which implies an intense desire for the repetition of pleasurable effects associated with the use of a drug.

In the nonnarcotic group are alcohol, paraldehyde, the various barbiturates, especially veronal, amphetamine or benzedrine, rarely ether by inhalation, and similar drugs These differ in the main from the narcotic group in that they do not produce a physical dependence and their rapid withdrawal is accompanied by very slight abstinence symptoms

There are two types of drug addicts: (1) the emotionally stable person who acquires the addiction accidentally, and whose normal personality make-up will be re-established after he recovers from his physical illness and is relieved from his drug addiction and (2) the psychopathic person who becomes an addict through curiosity or association, or as a sequence to his inadequate personality The prognosis as to relapses and the method of treatment are different in these two groups The first group can be rehabilitated.

Morphine and Morphine Addiction. As with alcohol, certain people have nervous systems unable to resist the tendency to relieve discomfort or depression

by morphine. It is especially common among those to whom morphine is easily accessible (druggists, physicians, veterinarians, registered nurses), though it sometimes develops in psychopathic patients following morphine therapy. Husband and wife not infrequently become simultaneous victims The hypodermic use is the commonest.

Once established, the habit is very hard to break. Many hypodermic injections are taken secretly each day. If the physician suspects it, verification can be made by finding the numerous, small, pigmented spots, corresponding to the sites of injection in the skin Cachexia gradually develops, with sallowness and emaciation, ethical defects, lying, egoism and loss of memory Sudden abstinence produces alarming symptoms such as restlessness, anxiety, despair, vomiting and delirium All of the manifestations are quickly relieved by a hypodermic injection of morphine

The patient's complaint is likely to be one which he has learned will often induce the physician to administer morphine. Seldom will the complaint be of the addiction itself.

Heroin (Diamorphine) and Heroin Addiction. Heroin is formed from morphine by substituting acetyl for hydroxyl groups. Its effects are very much the same as those of morphine but it affects the cerebrum and medulla more profoundly than morphine.

Heroin addiction is easily acquired due to the ease of administration of small quantities of the drugs by snuffing or by hypodermic injections. Addiction causes rapid changes in the personality, utter disregard for moral standards and conventions, and the addict rapidly becomes a mental and moral degenerate The habit is exceedingly difficult to cure, not only in the active withdrawal period but also in the convalescent stage, and relapse is frequent. The manufacture and importation of heroin has been outlawed in the United States.

Cocaine and Cocaine Addiction. In the cocaine habit the deterioration progresses more rapidly than in the morphine habit Very frequently morphinism and cocainism are associated In the cocaine habitude acute hallucinatory confusion often develops Withdrawal symptoms in the cocaine habit are milder and disappear more quickly than in the morphine habit

Here again the complaint is unlikely to be sincere if made by the patient himself

Demerol Hydrochloride and Demerol Addiction. Demerol, ethyl 1-methyl-4-phenylpiperidine-4-carboxylate hydrochloride, is a proprietary analgesic, spasmolytic and sedative drug which is administered orally or intramuscularly in doses of 50 to 150 mg Addiction to this drug is not uncommon.

Hazards from Agricultural Chemicals (Pesticides). In recent years atten-

poisonous Dangerous quantities of these substances may enter the body through the lungs, by absorption through the skin, or by swallowing.

Protection against the hazard of poisoning is effected by the use of personal protective measures, proper design and installation of spraying and dusting equipment and the employment of operational procedures which minimize exposure. The personal protective measures include avoiding contact with the skin by the use of shirts buttoned at the wrist, the wearing of gloves; the prompt washing with soap and water of any part of the skin that comes in contact with the chemical, and the replacement of contaminated clothing with clean clothing, avoidance of inhalation of dust, mist, spray or aerosol containing the chemical and the use of appropriate breathing equipment if there is any suspicion of the pilot's being harmfully affected; the avoidance of contamination of food, refusal to eat, smoke or drink in the dusting or spraying area and the washing of hands and face before eating or using tobacco; protection of the eyes with goggles,

since some of the insecticides, for example, the organic phosphates, can harmfully affect vision. A bath, followed by the use of freshly laundered clothing, should be taken after handling or coming near these chemicals

Organic Phosphorus Insecticides. The toxic manifestations of the organic phosphorus insecticides are similar and are referable to the postganglionic cholinergic nerves (muscarine-like effects), the preganglionic and somatic motor nerves (nicotine-like effects) and the central nervous system The muscarine-like effects are the earliest and commonest signs of poisoning

These chemicals do not produce local inflammatory changes in the skin. When symptoms begin, there may be little warning of impending serious effects

MUSCARINE-LIKE EFFECTS. The first symptoms to appear are usually anorexia and nausea These are soon followed by vomiting, abdominal cramps, excessive sweating, and salivation. If the exposure is extensive, diarrhea, tenesmus, involuntary defecation and urination, pallor, pinpoint nonreactive pupils, blurred vision, excessive bronchial secretion, sometimes respiratory difficulty and pulmonary edema with cyanosis ensue The respiratory manifestations are severest when the respiratory tract is one of the routes of absorption. Elevation of the blood pressure is common during severe intoxication due to parathion

NICOTINE-LIKE EFFECTS Muscular fasciculations in the eyelids and tongue are early signs If the exposure is extensive, these are followed by fasciculations in the muscles of the face and neck and in the extra-ocular muscles (resulting in jerking movements of the eyes) and then by generalized fasciculations and weakness In the severest cases there may be weakness of the muscles of respiration

EFFECTS ON THE CENTRAL NERVOUS SYSTEM. Giddiness, uneasiness, restlessness, anxiety and tremulousness occur early, followed by headache and sometimes by the sensation of "floating," insomnia and excessive dreaming. If the exposure is extensive, ataxia, tremor, drowsiness, difficulty in concentrating, mental confusion and occasionally disorientation develop Paresthesias are common after exposure to TEPP, while changes in speech consisting of slurring, difficulty in forming words and multiple repetition of the last syllable may occur after exposure to parathion. In very severe cases this stage is followed by coma, with the disappearance of all reflexes, and then by generalized convulsions During the coma there may be Cheyne-Stokes respiration

In poisoning due to the organic phosphorus insecticides 2 mg. of atropine is administered intramuscularly at hourly intervals, or more often if necessary, until signs of atropinization appear. The dose of atropine may then be reduced, but its administration should be continued as long as any muscarine-like symptoms are present Atropine should not be administered prophylactically

DDT (*Chlorophenothane U S P*) DDT is the abbreviated name for the various mixtures of para, para prime (p,p') and ortho, para prime (o,p') isomers of dichloro-diphenyl-trichloro-ethane which are used for insecticidal and *medicinal* purposes.

In therapeutics, DDT is used as a pediculicide and in conjunction with benzyl benzoate and ethylaminobenzoate as a pediculicide and scabicide A mixture of these compounds has been accepted for inclusion in *New and Nonofficial Remedies* for the treatment of scabies and pediculosis. DDT is official in the *United States Pharmacopoeia*, 14th Revision, under the name Chlorophenothane.

Acute poisoning from the absorption of crystalline DDT either through the skin or through the respiratory tract is unlikely, and large oral doses of the undissolved chemical must be ingested to produce symptoms of acute intoxication DDT in lipoid solvents has a greater tendency than in other mediums to be absorbed from the skin and the gastrointestinal tract and is therefore dangerous The intrinsic toxicity of DDT is about the same for insects and mammals.

kilogram of body weight or about 1 ounce of the solid material for the average person. Ingestion of massive amounts of powdered formulations of the chemical produces acute poisoning in spite of the fact that much of the material may be removed by vomiting.

Chronic DDT poisoning may result from the ingestion of small amounts of the material over a long time. Since the chemical is irregularly absorbed, the level below which adverse long range effects are absent is unknown

Powdered DDT rarely is toxic or irritating to the *intact skin*. An oily layer of sebum on the skin or the presence of greasy solvents on the integument increases absorption of DDT. Certain solvents and other additives incorporated into DDT formulations are capable of producing irritation of the skin and mucous membranes

DDT is not considered harmful to the *eyes*, since ointments and solutions up to 5 per cent have been used without ill effects. Powdered DDT thrown into the eye is not more irritating than other fine crystalline material.

The *inhalation* of DDT powder offers little hazard because of the large particle size and the relative insolubility of the compound Certain supposedly inert diluents used in the formulation of DDT wettable powders may irritate the bronchi, producing a persistent cough

The symptoms of DDT poisoning commence with twitching of the eyelids which progresses until severe generalized tremors become apparent. The tremors are coarse; they begin in the muscles of the head and neck, then progress caudally to involve the entire musculature with increasing intensity They are particularly severe in the extremities The convulsive seizures are similar to those encountered in strychnine poisoning and are elicited by irritation and mechanical stimuli such as sudden noises and jarring Death usually results from respiratory failure, although heart failure induced by ventricular fibrillation may intervene Pulmonary edema is common to solvent poisoning and is not characteristic of DDT.

Chronic intoxication may be manifested by loss of weight, anorexia, mild anemia, muscular weakness and tremors that terminate in convulsive seizures, coma and death

Diagnosis of DDT poisoning is based on the history of exposure and the presence of the foregoing-enumerated characteristic neurologic manifestations Tests of hepatic function may reveal injury to the liver due to prolonged exposure to DDT.

Solvents used in the formulation of DDT preparations, particularly kerosene, often produce symptoms which simulate those of acute DDT poisoning The signs of solvent intoxication set in promptly, in contrast to the latent period of several hours required for the development of DDT symptoms.

TREATMENT The treatment of acute DDT poisoning is directed toward removing DDT from the alimentary tract and allaying neurologic manifestations.

Benzene Hexachloride and Its Principal Isomers. Benzene hexachloride is an insecticidal agent. Although incorrect chemically, the name benzene hexachloride and its abbreviation, BHC, have been generally accepted as common designations for commercial mixtures of the stereoisomers of 1, 2, 3, 4, 5, 6-hexachlorocyclohexane The gamma isomer is of greatest entomologic and medical interest Lindane is the coined, common name for essentially pure grades of this isomer which are used for agricultural and related purposes The generic name, gamma benzene hexachloride, has been adopted

The gamma isomer is a strong excitant of the central nervous system The delta isomer is a depressant of the
ing effects of the gamma isom
in their action The alpha is
which is followed by depression, and the beta constituent provokes tremors and then depression of the central nervous system on prolonged administration.

The presence of fat or other lipoids facilitates penetration of the intestinal barrier. *Cutaneous absorption* of the material from oil solutions has been firmly established. Absorption of dusts from the skin is known to occur

Benzene hexachloride gives pathologic changes resembling those of DDT, with

hepatic damage the most prominent feature There is a moderate degree of hyaline granular degeneration of the renal convoluted tubular epithelium, and there are as well mild changes in the bone marrow, lymphoid tissues, adrenal cortex, and cerebrum Considered anatomically, these lesions have not always been sufficient to cause death However, all isomers may cause a general emaciation, and atrophy of various tissues

The symptoms of acute poisoning from technical benzene hexachloride are excitation, clonic-tonic convulsions, followed by hyperirritability to external stimuli and, finally, depression. Intoxication from benzene hexachloride of high gamma content or from the gamma isomer alone is manifested by restlessness, micturition, intermittent muscular spasm, loss of equilibrium, convulsions, and then collapse and death

The course of symptoms depends largely on the direct proportion to the amount of gamma isomer which is present. The immediate cause of death is functional disturbances of the central nervous system, and especially of the respiratory center.

Chronic symptoms are predominantly those of nervousness and lack of co-ordination, their severity depending on the frequency and the degree of exposure. Nausea, loss of weight, and general emaciation are manifestations of this type of exposure to the technical mixture.

The diagnosis of benzene hexachloride poisoning should be based mainly on a history of exposure to the product since poisoning by other pesticides, as well as the presence of other neurologic conditions, should be considered.

There is no specific antidote for poisoning from benzene hexachloride or its gamma isomer

Hair Dressings. The technics employed at the beauty parlor which may be of particular medical interest are (1) hair dyeing and (2) hair waving, the permanent wave

Hair Dyeing. Hair dyes have been in use as long as dyes have been employed for any purposes These dyes may be solely of vegetable or of mineral origin or they may be synthetic Some dyes are compounded from one or more of the basic materials.

The *vegetable dyes* are generally less likely to cause dermatitis or systemic effects from their use than are the mineral or the synthetic dyes. The extract from the green hulls of the American walnut turns the hair yellow or brown. The powdered leaves of *Lawsonia inermis*, a tropical shrub, are widely used to dye the hair a henna or a red color In recent years a vegetable dye is used by aging ladies to turn gray hair a blue color. The vegetable dyes are generally devoid of cutaneous or systemic effects.

The *metallic dyes* have been widely used Silver hair dyes too are generally harmless They can be employed to form blond, brown and black hair colors Nickel, cobalt, iron and silver can be used alone or in combination with pyrogallol to form almost any desired color for the hair

Of the numerous *synthetic hair dyes* the following are the compounds employed which may give local or systemic effects amino-anisole, p-aminodimethylaniline, p-aminodimethylamine, chloroaminophenols, chlorodiamines, diaminophenols, nitrodiamino compounds and toluylene diamine

The *compound hair dyes* are numerous and in recent years they are the dyes most commonly used For example, henna is often compounded with diamines or pyrogallol.

Hair dyes are potential skin irritants The compound and synthetic dyes are more likely to cause local or systemic effects. However, only a small proportion of those exposed acquire sensitization A patch test should be carried out before each application of a para dye, whether the dye is used for the whole head or for touching up. All reputable hairdressers recognize that this test should be done, but the client may be impatient. Some clients and beauticians believe that, once the hair has been dyed without ill effect, any dye can be used thenceforward without fear. Allergic sensitization, however, may develop after prolonged periods of use of the same dye or it may be present on the first application of another dye

No hair dyes should be applied during pregnancy or menstruation or in the presence of eczema or dermatitis on any part of the body. It is also best to avoid

them if the general health is poor They should never be used in the presence of hay fever or of asthma. They must never be applied to eyebrows or eyelashes.

The Permanent Wave. The technic of cold waving can produce local irritation of the skin Some persons appear to be more susceptible to this irritation than others. Some factors which may be considered are the differences in the materials employed and the technics of their use. Rarely, eczematous hypersensitivity may be produced in the cold waving process It seems that this eczematous hypersensitivity is more frequently due to materials other than the cold waving solutions themselves and, as Schwartz and Peck mentioned, especially the perfumes, gums and resins Ammonium thioglycolate is potentially a mild irritant for the skin.

When ammonium thioglycolate is used, despite considerable caution dermatitis may occur about the neck from the seepage between towels and the surface of the neck. Similarly, the dermatitis of the scalp may be due to unduly prolonged contact of the ammonium thioglycolate with the scalp, to inadequate removal of the material after its effect has been achieved, or to its incomplete neutralization at the proper time. Ammonium thioglycolate causes more cutaneous injury to beauty parlor operators than to the patrons.

The specific cause of a skin irritation sustained at a beauty parlor can rarely be proved by the diagnostic procedures available at present, since the lesions are nonspecific, being those of primary irritation

INORGANIC COMPOUNDS

Alkalies. The common caustic alkalies which produce injury and are often the concern of the physician are the hydrates of sodium, potassium and ammonium The anhydrous sodium carbonate (soda ash), calcium oxide (quicklime), calcium chloride, barium oxide and hydrate, the sulfides of sodium, calcium, arsenic, and the alums too have caustic properties. Quicklime, the alums and the sulfides will rarely be responsible for anything worse than dermatitis and conjunctivitis Caustic soda or potash may cause fatal burns or blindness, and severe injury may follow the splashing of ammonia into the eye, resulting in inflammation of conjunctiva and cornea, followed by atrophy of the iris and opacity of the lens The fumes of ammonia may cause death from congestion and edema of the lungs. Ammonia gas is very irritating to the upper air passages. If the escape is delayed, the gas may be deeply inhaled and may cause congestion of the lungs followed by edema, bronchial irritation and hemoptysis and, in some instances, death from pulmonary edema.

Inorganic Acids. The inorganic acids are known as mineral or heavy acids. The common ones which are prone to produce injury are sulfuric, hydrochloric, nitric, and hydrofluoric acids Their physiologic actions are the same as those of sulfur dioxide, chlorine, phosgene and the nitrogen oxides, but since the latter are gases, they are far more dangerous than are the acids, which usually cause no severer damage than caustic burns of skin or eyes. Nitric and hydrofluoric acids have a solvent action on metals and clay, and give rise to leaks in containers The burns from handling such weakened containers are more serious than those received otherwise from these acids Hydrofluoric acid is intensely caustic.

Acute poisoning from *hydrochloric acid* occurs usually from leaking chlorine cylinders or from the apparatus used to disinfect water. Chlorine injury produces tracheobronchitis and pulmonary edema Pneumonia may develop as a sequence of the respiratory irritation

Phosgene ($COCl_2$) is a deadly gas used as an intermediate in the production of aniline dyes, and it may also be encountered as a decomposition product of chlorinated hydrocarbons.

Phosgene hydrolyzes in the presence of water, forming hydrochloric acid gas

within the bronchial tubes There is consequently no protective respiratory reflex to prevent the deep inspiration of this gas In the alveoli the newly formed hydrochloric acid gas is liberated, causing congestion and edema which may be quickly fatal. If death does not occur, lobular pneumonia ensues. In the acute stage of the injury, which is in reality asphyxia, there is a high erythrocyte count, and increased hemoglobin

Nitric acid is dangerous because its fumes are composed of a series of anhydrides and various oxides which are liberated on exposure of nitric acid to the air. These fumes do not stimulate violent respiratory reflex. Thus the poisoning may be of an insidious onset.

Poisoning may occur in association with the manufacture of explosives. Explosives are nitrated products formed by the action of nitric acid on cellulose, glycerin, phenol, benzol and toluol. Nitrocellulose is the basis for smokeless powder, lacquers, and photographic films and celluloid. Nitrobenzol and nitrophenols are used in the production of drugs, dyes, and explosives

Nitric acid is used in metal etching and photoengraving and for cleaning ("bright dipping") copper and brass

Nitrogen peroxide, a main component of nitric acid fumes, or having other sources of origin, may cause almost immediate death However, the usual onset of symptoms is from 6 to 48 hours after exposure. First there is dyspnea, which increases rapidly as the acute pulmonary congestion is supplanted by edema If all the bronchial tree has been affected, death follows within 36 hours There are those, however, who recover from the immediate effects of the gas and have pneumonia later on. In addition to the action on the lungs, there may be intense congestion of the meninges and the cerebrum. A continued exposure to diluted nitrous fumes causes headache, sleeplessness, anorexia and gradual loss of strength, dyspepsia, constipation, sometimes ulcers on the lips and on the mucous membrane of the mouth and pharynx These manifestations clear up when exposure to the fumes ceases.

The venous blood is thick, coagulates rapidly, and turns red when diluted with water The nitrites which are formed in the blood produce their characteristic vasodepressant effect in a subject who has a severe or a rapidly fatal poisoning Destruction of erythrocytes, lesions in liver and kidneys, and an increasing jaundice may be present.

Dynamite contains nitroglycerin, and farmers and laborers who are not meticulous in protecting themselves from the postexplosive fumes of dynamite may have a cough, headache, and sensations of fullness in head and chest. These effects pass away on rest.

Hydrogen fluoride and its compounds are caustic, corrosive to the skin, the conjunctivae, and the mucous membranes The acid is used in etching and clouding of glass, cleaning sandstone and marble, in pickling metal, removing enamel from defective porcelain, treating textiles to remove the weighting metals, and it as well as its salts may be added to laundry mixtures. Hydrofluoric acid may be employed as a catalyst in the production of high-octane aviation fluid.

Fluorine compounds (cryolite and barium fluosilicate) are often contained in insecticidal sprays for fruits and vegetables and in phosphate rock which is mined and converted to superphosphate, which is used as fertilizer. The fluorides may be used in bleaching of cane for furniture, in the disinfection of hides (silicofluorides), and in poison for rats and cockroaches

Fluoride in domestic water supplies is a causative factor in dental fluorosis, or mottled enamel. Intensive investigation has been made of the physiologic chemistry of this element with respect to its influence on the skeleton, its metabolic effects and its relation to dental caries In view of the observation that fluorine in the drinking water is correlated with a significant decrease in dental caries, suggestions

have been made that fluoride be added to city water supplies in areas where this element is absent. However, the need for caution has been expressed for fear of the occurrence of less desirable effects of ingested fluoride such as a decrease in breaking strength of bones when fluoride in abundance is present in the diet or in the water.

Older persons subjected to excessive amounts of fluorine may develop an osteopathy of the osteitis fibrosa type. There are successively destruction of bone, osteoclasis, a progressive atrophy, then an osseous regeneration, and osteosclerosis. Roholm recorded that men who work with cryolite excrete large quantities of fluorine in the urine, a condition which persists for years afterward, since the fluorine is constantly mobilized from the bones.

Sodium fluoride may be eaten with food and not discovered by taste. Vomiting and diarrhea caused by ingestion of the chemical are often effective in eliminating much of the poison and thus make it difficult to determine the fatal dosage for man.

Nausea, vomiting, and diarrhea occur immediately and at times simultaneously in sodium fluoride poisoning. In many instances blood is present in the vomitus and stools. Soon after eating, the patients may complain of abdominal burning and cramps In some cases local or generalized urticaria may occur In all there is a thick, mucoid discharge from the nose and mouth General collapse may occur at varying periods of time but some hours after ingestion. Death may follow in from 2 to 4 hours In severe poisoning, when death is delayed for 18 to 20 hours, paralysis of the muscles of deglutition, carpopedal spasm, and spasm of the extremities occur Convulsions, abdominal tenderness, and rigidity are absent

The metal *chromium* is inert. *Chromic acid* and the chromates produce very painful and very obstinate lesions of mucous membranes, skin, and conjunctivae

The term holes applies to the ulcers caused by chromates because these ulcers slowly penetrate, burrow deep under the skin, and rarely suppurate. If the lesions or holes are serious enough to cause disability, it is prolonged, for these chronic ulcers heal slowly. The holes are usually situated around the fingernails, on the knuckles, the forearms, rarely on the toes. Sometimes the eyelids and the nasal mucosa may be affected by ulcers, which may cause disability owing to the severity of the pain

Ulcers of the nose are characteristically painless and chronic, are confined to the cartilaginous portion of the septum, and do not involve the bone or cause deformity. Progression of the lesion results in a perforation of the septum Perforation usually causes but little discomfort. In some, however, there is discomfort such as mouth breathing because of the constant formation of crusts. Rarely, the patient is aware of a whistling sound on nose breathing after the perforation has become established

Hydrobromic Acid. Hydrobromic acid (HBr) is a mineral acid, chemically a halogen acid, closely related to hydrochloric acid Injuries from it are the same as those from mineral acids in general.

Hydrobromic acid and its salts such as sodium, potassium and strontium bromide are used therapeutically as sedatives

Bromic acid ($HBrO_3$) has powerful oxidizing action The sodium salt is used in mixture with bromide for dissolving gold from its ores, and the potassium salt is used as an oxidizing agent in certain preparations for giving cold wave hair permanents The ingestion of salts of bromic acid causes immediate vomiting, and is followed by injury to the liver and the kidneys

Bromide Intoxication. Some proprietary medicines such as bromoseltzer, neurosine, sedormid and B C. headache powder contain bromides.

Bromides, like chlorides, are equally distributed in the extracellular spaces and soon reach a concentration in these regions corresponding to that in the blood stream. They are found in smaller amounts in the brain and in the spinal cord. This

may be one of the reasons, in addition to other factors, why it apparently requires varying quantities of bromides to produce central nervous system symptoms in different persons. Concentrations of plasma bromides in bromide intoxication vary widely. They may reach 150 mg per 100 ml. before there is intoxication.

With such variations in blood bromide levels, it is concluded that a number of factors other than the absolute dose of bromide are concerned in the development of bromide intoxication. A reduction of chloride in the diet is found to be effective in increasing the blood bromide concentration on a constant bromide intake. Wuth expressed the belief that intoxication begins at 25 per cent replacement of the blood chlorides and that 40 per cent replacement is fatal Renal injury, by interfering with bromide excretion, may produce the same effect.

Bromidism may be present in patients who either resort to self-medication or are given the drug by physicians. In either case there is a tendency by certain psychoneurotic patients to use the agent in increasing amounts over long periods of time.

In bromide intoxication there may be slowed mental processes and speech, ataxia and tremors of the hands Hallucinatory tendencies may occur, but definite hallucinosis is rare. Paranoid delusions are frequent. In acute intoxication delirium may be present.

The diagnosis is made on the history, symptoms, and the presence of increased (100 mg or more) concentrations of blood bromides. It is well to know, however, that the concentration of bromides may reach 150 mg per 100 ml. of blood without producing symptoms

A recent method of treatment of bromide intoxication is the judicious intravenous administration of physiologic salt solution

Boric Acid. Boric acid, whether applied in the form of an ointment or a saturated solution to extensive wounds, is to be considered a cumulative poison It may be absorbed in toxic quantities from ointments applied to burned areas or to wounds involving loss or injury to large areas of skin Of a 5 per cent boric acid solution used to irrigate cavities, most of the boric acid is absorbed by the tissues

Boric acid is not toxic when administered in a single large dose; however, repeated doses result in accumulation in the brain, liver and body fat After absorption boron occurs in both the white matter and the gray matter of all parts of the central nervous system and in the peripheral nerves. The spinal cord and the gray matter of the cerebrum contain the highest amounts. The boron found in the brain is not combined with phospholipids or cholesterol

Death is due to a shocklike syndrome which ensues as the result of sufficient amounts of boron quickly absorbed to produce poisoning If moderate doses of boron are given over a period of several days, or if the substance is slowly absorbed from a wound, death may result from inanition Even in the slow poisoning death is preceded by convulsive tremors and meningismus

Lead. Lead is amphoteric and occurs in nature as *galena* or lead sulfide (PbS). The lead sulfide is heated until a part of the sulfide is converted to lead monoxide, or lead oxide (PbO) and lead sulfate ($PbSO_4$). Lead is often combined with other metals for particular purposes, for instance an alloy of lead containing arsenic (0 5 per cent) is used in making shot and shrapnel bullets: type-metal contains from 20 to 25 per cent antimony; and solder contains 50 per cent tin The principal uses of lead are in storage batteries, paints, and as tetraethyl lead in gasoline

There are five oxides of lead Of these oxides the lead monoxide, or lead oxide (PbO), a solid crystalline yellowish red mass, is called *litharge;* the powdery form is called *massicot*

The basic carbonate is white lead, often manufactured by the old Dutch process and used in house paints. The sugar of lead used in medicine is ($Pb[CO_2CH_3]_2{\cdot}3H_2O$), an acetate of lead.

Lead suboxide may be present in the dust wherever solid lead is handled, and in the

fumes from molten lead Exposure to lead suboxide occurs in smelting zinc, in type founding, in founding brass, bronze, bearing metal, and babbitt, for these materials are of high lead content Exposure to lead occurs in soldering, in making molded lead materials and finishing them, and sometimes in the printer's trade

The use of solder as in brass founding may be attended with the production of lead fumes, and thus lead poisoning. Metallic lead particles in the lung act much as do silica particles, originating a fibrotic process.

Litharge (red lead, orange mineral) is employed extensively in many industries and in common work, for example in the manufacture of rubber glaze for pottery and tiles, and lead glass and varnish, in making storage batteries, in glazes, enamels for cast iron and sheet iron, and in paint.

White lead is readily soluble in human gastric juice It is responsible for the lead poisoning of painters, of most pottery workers, and of lithotransfer-makers The dust produced in dry sandpapering of painted surfaces and in handling of dry glazed ware, is a common source of the poisoning. The making of lithotransfer paper is a dangerous occupation in this regard, because of scattering of finely ground lead colors on the lithotransfer paper The chromates of lead, yellow and green, give little trouble, for paints containing these salts are used chiefly as exterior paints. In soluble lead glaze of some non-American pottery, the white lead is added after the fusion of the borates, silicates, and like substances, and is therefore unchanged It thus remains as a poorly soluble silicate, and borosilicate Fritted glaze as manufactured in American potteries is no longer a source of lead poisoning

The degree of risk of lead poisoning in mining lead ores depends on the presence of soluble ores Lead sulfate and carbonate are for practical purposes insoluble.

Tetraethyl lead as it occurs in gasoline is rapidly absorbed and soluble in fats, which leads to its concentration in the central nervous system and in the liver. All who handle and use gasoline containing lead are constantly warned by appropriate signs on gasoline pumps of its injurious effects

The manifestations of plumbism differ according to the degree of exposure, the solubility of the lead, the individual size of the particles of the lead compounds, and the concentration of the fumes or dust in the air Exposure to heavy amounts of soluble lead compounds may occur when heavy doses of lead fumes are obtained, resulting in severe acute plumbism As in almost every other poison or infection there are persons who have an increased susceptibility and therefore may be severely poisoned by relatively small doses of lead In such a susceptible person wristdrop, ankledrop or an encephalopathy may develop after there has been exposure only long enough to make one lead soldering

Swallowed lead is excreted in feces Absorption through the skin, except in the case of tetraethyl lead, is not an important source of plumbism Absorption from the respiratory tract is rapid due to the fact that inspired lead enters directly into the general circulation instead of passing through the liver as in gastrointestinal absorption. In the gastrointestinal tract, absorption is depressed by the presence of soluble phosphates which prevent solubility of particulate lead or force soluble lead out of solution

PATHOLOGY. Changes in the vascular system resulting in multiple small hemorrhages and in thickening of the walls of the blood vessels are commoner than any other pathologic change

Volhard assumed that lead causes spasmodic contraction of the smooth muscle fibers of the *renal blood vessels*, and that this results in ischemia followed by parenchymatous degeneration, a saturnine nephritis which is closely associated with the attacks of colic.

Lead is temporarily stored in the liver before elimination. It damages the liver, as revealed by slight jaundice and by indirect reaction to the van den Bergh test.

The lesion in the peripheral nerves is an atrophic degenerative neuritis, with subsequent fibrosis It is distinguishable from paralysis following actual lesions of the cord The lesion in the nerve is periaxial which explains the reversibility of lead palsy There is a marked atrophy of the affected muscles

Muscles affected by lead palsy are not supplied by the same nerve nor are all the muscles affected which a single nerve supplies Aub is inclined to find the cause of lead palsy in the metabolism of the muscle

may be one of the reasons, in addition to other factors, why it apparently requires varying quantities of bromides to produce central nervous system symptoms in different persons. Concentrations of plasma bromides in bromide intoxication vary widely. They may reach 150 mg. per 100 ml. before there is intoxication.

With such variations in blood bromide levels, it is concluded that a number of factors other than the absolute dose of bromide are concerned in the development of bromide intoxication A reduction of chloride in the diet is found to be effective in increasing the blood bromide concentration on a constant bromide intake. Wuth expressed the belief that intoxication begins at 25 per cent replacement of the blood chlorides and that 40 per cent replacement is fatal Renal injury, by interfering with bromide excretion, may produce the same effect.

Bromidism may be present in patients who either resort to self-medication or are given the drug by physicians. In either case there is a tendency by certain psychoneurotic patients to use the agent in increasing amounts over long periods of time

In bromide intoxication there may be slowed mental processes and speech, ataxia and tremors of the hands Hallucinatory tendencies may occur, but definite hallucinosis is rare. Paranoid delusions are frequent In acute intoxication delirium may be present

The diagnosis is made on the history, symptoms, and the presence of increased (100 mg. or more) concentrations of blood bromides. It is well to know, however, that the concentration of bromides may reach 150 mg per 100 ml. of blood without producing symptoms

A recent method of treatment of bromide intoxication is the judicious intravenous administration of physiologic salt solution

Boric Acid. Boric acid, whether applied in the form of an ointment or a saturated solution to extensive wounds, is to be considered a cumulative poison. It may be absorbed in toxic quantities from ointments applied to burned areas or to wounds involving loss or injury to large areas of skin Of a 5 per cent boric acid solution used to irrigate cavities, most of the boric acid is absorbed by the tissues

Boric acid is not toxic when administered in a single large dose, however, repeated doses result in accumulation in the brain, liver and body fat. After absorption boron occurs in both the white matter and the gray matter of all parts of the central nervous system and in the peripheral nerves The spinal cord and the gray matter of the cerebrum contain the highest amounts. The boron found in the brain is not combined with phospholipids or cholesterol.

Death is due to a shocklike syndrome which ensues as the result of sufficient amounts of boron quickly absorbed to produce poisoning If moderate doses of boron are given over a period of several days, or if the substance is slowly absorbed from a wound, death may result from inanition. Even in the slow poisoning death is preceded by convulsive tremors and meningismus

Lead. Lead is amphoteric and occurs in nature as *galena* or lead sulfide (PbS) The lead sulfide is heated until a part of the sulfide is converted to lead monoxide, or lead oxide (PbO) and lead sulfate ($PbSO_4$) Lead is often combined with other metals for particular purposes, for instance an alloy of lead containing arsenic (0 5 per cent) is used in making shot and shrapnel bullets; type-metal contains from 20 to 25 per cent antimony, and solder contains 50 per cent tin The principal uses of lead are in storage batteries, paints, and as tetraethyl lead in gasoline

There are five oxides of lead Of these oxides the lead monoxide, or lead oxide (PbO), a solid crystalline yellowish red mass, is called *litharge;* the powdery form is called *massicot.*

The basic carbonate is white lead, often manufactured by the old Dutch process and used in house paints The sugar of lead used in medicine is ($Pb[CO_2CH_3]_2, 3H_2O$), an acetate of lead.

Lead suboxide may be present in the dust wherever solid lead is handled, and in the

frequency to be useful diagnostic aids. Stipple cells are present in normal persons. In hepatic cirrhosis, pulmonary disease, and especially in hemolytic crises, stipple cell counts as high as 40,000 to 50,000 per million of erythrocytes may be present without associated exposure to lead. However, usually lead absorption is accompanied by an increased stipple cell count Basophilic stippling becomes significant in lead absorption when the range of stipple cells is known for a particular individual Increases then would indicate exposure to lead and would be evidence in favor of the diagnosis of lead intoxication The degree of reduction in hemoglobin is never great in lead intoxication

The New York Division of Industrial Hygiene has adopted the following standard for practical use in determining *lead absorption in excess of normal*

Urine Lead in urine in excess of 0.1 mg. of lead per liter of urine indicates an excretion of lead above that which one would ordinarily expect

Feces. Lead in the feces in excess of 0 5 mg. of lead per gm of ash may be regarded as higher than normal

Blood. Lead in whole blood in excess of 0 07 mg. per 100 ml of blood may be regarded as higher than normal

The irregularity with which porphyrinuria occurs in lead poisoning has discouraged reliance on its presence as a diagnostic aid in lead poisoning

The presence of lead in urine and blood in excess of the normal does not prove lead intoxication, only absorption. Lead in the feces does not prove even that, for the lead may have passed through the intestinal tract without being absorbed at all.

Diagnosis of Lead Poisoning The diagnosis of lead poisoning may not be difficult if there is a history of exposure to lead The intensity, the duration, whether the exposure was recent or some years previous to the examination, whether the lead compound was one of the readily soluble or one of the poorly soluble compounds are important data for diagnostic purposes However, the diagnosis of lead poisoning in practice depends on obtaining evidence of lead poisoning and then determining a possible source of lead sufficient to cause poisoning Gastrointestinal disturbances with or without colic, pains in the joints and muscles, tremors, rarely with palsy, headache and disturbed sleep are the usual symptoms of plumbism In addition to these symptoms there are the presence in the urine of concentrations of 0 04 mg of lead per liter and the presence of basophilic stippling of the erythrocytes in the absence of a severe anemia.

Mercury. The sources of mercurialism are mining of mercury, the treatment of fur with mercury nitrate and the treatment of seeds and grain It is rare, in recent times, for mercurialism to be caused by the administrations of mercury by mouth or intramuscularly

Cinnabar (HgS) is insoluble in the body fluids Miners often work alternately between mining and metallurgy In the metallurgy of mercury, metallic mercury is collected in condensers made of tile or wood Quicksilver penetrates these substances, working its way through the lining of the furnace, iron pipes, fire bricks, terra cotta and the sides of the condensers so that periodic cleansing of this equipment is necessary It is during this changing process that laborers may contract mercurialism

[illegible]

portable radios and miniature flashlights

The occurrence of chronic mercurialism among dentists is a result of continual handling of amalgam In dentists the mercury is absorbed by breathing the vapor and not through the skin

Mercury fulminate causes a *dermatitis* of the face, neck, hands and forearms, associated with conjunctivitis and inflammation of the nasal and laryngeal mucous membranes The dermatitis is described as moist eczema; the skin is reddened, swollen and tense, later exuding serum, then scaling The eyelids are often much swollen. Hands and forearms are affected first, then face, neck and genitalia A considerable number of

Saita found, in studies of human marrow (sternal puncture) in cases of subacute and chronic plumbism, evidence that the anemia of plumbism has definite characteristics: hyperplasia of the erythroblasts, maturation of erythroblasts and granuloblasts, accelerated in subacute poisoning, delayed in chronic poisoning.

Absorbed lead is deposited in the skeleton as tribasic phosphate which is of low solubility.

Lead ingested in small quantities is excreted in the feces Lead in the urine, *when a person is constantly inhaling lead, reflects the air-lead value in the environ*ment. The deposition and elimination of calcium and hence lead are influenced chiefly by high or low intake of calcium Both acidity and alkalinity of sufficient degree are capable of *dissolving the relatively insoluble tribasic phosphate of lead* deposited in the bone and causing acute exacerbation of symptoms.

SYMPTOMS. Often the first symptom of lead poisoning is pain referable to the joints. *Lead arthralgia* consists of pain in joints or muscles or both of the lower extremities The pain may be severe and accompanied by muscular cramps. There is no swelling of the joints, nor is there tenderness along the course of the nerve trunk.

Lead poisoning may commence with wristdrop The earliest complaint referable to drop wrist is the dropping of the two middle fingers when the hands are stretched out, with fingers separated and extended After drop wrist has been present for two years, it will be permanent Lead is a common cause of peripheral neuritis of many of the peripheral nerves.

The common form of plumbism is manifested by increasing anorexia, disagreeable sweetish taste, dyspepsia, and constipation

Lead colic begins suddenly and is characterized by acute abdominal pain which may be relieved by pressure on the abdomen. Without pressure, however, the pain will subside; *in the interval there is some diffuse abdominal tenderness.* The patient often lies on the face with the fists buried in the midabdomen for relief of the pain There may or may not be vomiting The colic lasts for several days to a week

Lead amblyopia occurs but is a rare manifestation It is the result of an optic neuritis

Lead encephalopathy is preceded by other symptoms of lead poisoning There are headache and disturbed sleep, with increasing irritability and attacks of excitement These symptoms increase until a sudden attack of unconsciousness, with convulsions, or of delirium ensues The attack may begin as a convulsive disorder without warning. Recovery from such an attack is slow, and full recovery is often not attained Permanent mental deterioration, partial or total blindness, and paralysis often ensue

EXAMINATION On examination there is pallor of the skin, out of proportion to the degree of anemia, which is attributed to spasm of the arterioles. There may be a bluish black stippling which appears along the margin of the gums, usually showing most clearly along the lower incisors, but perhaps showing on the buccal surface of the cheeks The stippling lies within the tissues and is composed of the black sulfide of lead produced by contact of the absorbed lead with the hydrogen sulfide produced by the decay of protein matter between the teeth. It therefore is not found in those who take care of their teeth

There is slight extensor weakness of the middle and ring fingers when the hand is held out in pronation If a definite palsy is present, it may involve the extensor muscles of the wrists and fingers, but not the supinator longus or the flexor muscles. At times the deltoid, biceps, brachialis anticus, and the long supinator muscles are weakened. Of the leg muscles the extensors of the toes and foot, the tibialis anticus, may be affected.

There are no specific hematologic changes indicative of lead absorption. Punctate basophilia (or stippling) and reduction in hemoglobin occur *with sufficient*

like that by the trioxide of arsenic, is largely manifested by cutaneous lesions. These lesions vary from a mild inflammation with or without ulceration to scleroderma, melanoderma, warts, and a slowly developing cancer of the skin which usually has a benign course and does not give rise to metastasis

When systemic manifestations occur in the slowly developing arsenical poisoning from solid arsenic, there are neuralgic pains and a mild multiple neuritis with motor palsy. The palsy commonly affects the long extensors of fingers and toes, as does that from lead poisoning.

Lead and calcium arsenate are widely used as spray material for fruits. Thus small quantities of the arsenates of lead and calcium appear in the fruit. Poisoning from eating such fruits does not seem to occur However, poisoning may occur in those who operate the spraying machines if proper caution is not exercised.

Gaseous Compounds of *Arsenic*. When inhaled, arseniuretted hydrogen (hydrogen arsenide, arsine, or AsH_3) causes a rapidly developing, severe form of poisoning.

Arsine is a powerful hemolytic agent. Six to 36 hours or longer, according to the dose, is required after the gas has been inhaled for the destruction of erythrocytes to be manifested. Early symptoms are those of anoxemia, which is followed in 4 to 6 hours by the passage of dark or bloody urine. In 24 to 48 hours jaundice appears As the disease progresses, jaundice deepens and the volume of urine decreases until just before death there is complete suppression Arsenic can always be detected in the urine In those who recover, it may continue to be excreted for many weeks after the acute symptoms have disappeared. The anemia is likely to be chronically persistent.

A cause of poisoning from arsine is the cleansing of tanks and tank cars that have contained either hydrochloric or sulfuric acid There is no danger while the tank is full of the concentrated acid, but when it is emptied and flushed out with water, weak acid is left in the residue The weak impure acid reacts with the iron, and in the reaction arsine forms and accumulates in the tank sludge Anyone entering the tank may succumb to the arsine.

The symptoms of mild arsine poisoning commence some hours after the inhalation of the gas. They consist of headache and nausea More severe poisoning is characterized by exhaustion, dizziness, nausea, pressure in the epigastric region, vomiting, distention of the abdomen, diarrhea, and jaundice, the jaundice appearing in 2 or 3 days after onset of symptoms Paresthesias and neuralgic pains may be present. The urine contains blood and is bile-colored and heavy with albumin.

The diagnosis is suspected from the history of possible exposure.

Hydrogen arsenide poisoning resembles that produced by benzene and its derivatives. It is differentiated from acute poisoning with the nitro and amido derivatives of benzene by the absence of methemoglobin formation and of cyanosis. The presence of jaundice and of blood in the urine favors poisoning with hydrogen arsenide. It has been said that arsine poisoning is the only important industrial poisoning manifested by hemolysis. The hair and the liver of the victim of acute arsenic poisoning contain more arsenic than does the blood or the excreta The arsenic appears late in the hair, five days at the earliest after poisoning, but remains there even longer than in the liver and the bones.

Phosphorus. The inhaled fumes of phosphorus have access to the teeth and thus to the periosteum of the jaw bone. When these fumes are dissolved in the saliva, a solvent action is exerted on the teeth. On continued exposure caries of the teeth result The lower teeth, softened by caries, allow the fumes to penetrate to the periosteum Often fresh sockets from which carious teeth have been extracted admit the fumes to the periosteum

The periosteum and the subperiosteal bone enter into a series of formations of layers of compact tissue and thickening which may persist for several years before necrosis of

cases occur, with nervous symptoms predominating in some, and in others, signs of nephrosis Stomatitis is rare, but salivation and hyperhidrosis may be present.

Mercurialism may arise from the manufacture of tungsten and molybdenum rods and wires for electrical contacts, filaments, electrodes, radio tubes and heaters. Poisoning comes from spillage of quicksilver on wooden benches and floor and from fumes escaping from the apparatus with subsequent contact with the skin while at work.

Organic compounds of mercury used as fungicides affect the *nervous system* and cause tremor, ataxia, dysarthria, and gross constriction of the visual fields but no changes in memory or intelligence.

Mercury compounds are used for treating grain and seed. These compounds volatilize slowly, so that it is not necessary that each seed come in contact with the powder The salts of mercury which are used as fungicides are the acetate, lactate, chloride, nitrate, and borate salts of the phenylmercuric compounds They are used also in the manufacture of some contraceptives and bacteriostatic agents These compounds of mercury give rise to dermatitis

Bichloride of mercury may be accidentally or intentionally ingested. The severe gastrointestinal symptoms caused by the bichloride with nausea, vomiting, pain, purging, and bloody stools and the severe involvement of the kidneys with scanty urine loaded with albumin and casts are unmistakable However, such symptoms are not commonly present in mercurialism unless the exposure is unusually great (see Diseases of the Kidneys, Chapter 11).

On examination of a person who has mercurialism there will be present a fine tremor, worse during volitional movement or under emotional stimulus; irritability, timidity, apprehension, and restlessness; vasomotor disorders, shown by readiness to blush, sweating and dermographia, increased reflexes; gingivitis, and slight abnormalities in speech. Psychic disturbances are detected more often than they are reported by the patients, which is characteristic of this form of intoxication. Instead of dwelling on or exaggerating his trouble, the victim of mercurialism seems anxious to hide it A tendency to underweight, to an increase of systolic blood pressure, and to albuminuria and hematuria are often present.

The diagnosis of mercury poisoning is facilitated by detection of mercury in the organs or body fluids The service of the chemist is required

Arsenic. *Solid Compounds of Arsenic.* Solid white arsenic, the trioxide (As_2O_3), is the compound commonly employed as the killer of pests or of men On ingestion it produces inflammation of the stomach and bowels, violent purging and vomiting, accompanied by a profound nervous collapse, hemolysis with jaundice and scanty bloody urine, and in fatal poisoning, complete suppression of urine As small a dose as 2 grains may be fatal In those who survive, there are sensory nervous disturbance, neuralgic pains, and paresthesias; later there is motor paralysis, together with loss of hair and deformities of the nails.

Other sources of arsenic poisoning may be contact with the white arsenic (arsenic trioxide, As_2O_3) which is added to the glass mixture in the manufacture of glass, contact in stitching window shades that are dyed with arsenic green; and in handling hides and skins treated with white arsenic, as is done by amateur taxidermists.

Poisoning by solid arsenicals when not ingested results from the exposure of the skin to dusts containing arsenic. In this form of poisoning, the skin, mucous membranes and conjunctivae are affected Moist surfaces are affected most, for instance, the lips, nares, eyelids, pharynx and scrotum Hoarseness and perforation of the nasal septum are often present in arsenic workers There is at first a clogging of the nostrils, with consequent mouth breathing, and usually some inflammation in the throat and larynx. There may be salivation much the same as in mercurial poisoning. Sloughing of the mucous membrane and necrosis of the nasal cartilage ensue The bony septum is not involved, and healing occurs without deformity.

Poisoning by copper aceto-arsenite (Paris green), $Cu(C_2H_3O_2)_2\ 3Cu(AsO_2)_2$,

Cadmium food poisoning follows the accidental contamination of acid foods and drinks with soluble cadmium compounds. The source of cadmium in poisoning is from new utensils plated with a plate high in cadmium content. The association of immediate food poisoning of groups with the ingestion of an acid liquid prepared in new metal containers should cause suspicion that cadmium-plated utensils have been used

When a very small amount (67 parts per million) is ingested, symptoms will ensue within 30 minutes, whereas with a larger amount of dissolved cadmium, symptoms appear within 10 to 15 minutes. The symptoms vary from nausea, abdominal cramps, and weakness in persons who have consumed small amounts to vomiting, cramps, and diarrhea in patients who have consumed the large amounts. Thirteen to 15 parts per million of cadmium in popsicles (a fruit beverage frozen in a small mold around a wooden stick, which serves as a handle) will cause violent nausea, but recovery will take place in 5 to 6 hours.

Antimony, Metal Fume Fever, Zinc, and Manganese. *Antimony* resembles arsenic in its action, having an irritating effect on the skin and mucous membranes and causing eczema and other forms of dermatitis and inflammation of the lining of the mouth, nose, and throat It has much less action than arsenic on the nervous system. In other respects, when effects are acute, it resembles lead in causing metallic taste, vomiting, colic and diarrhea, if chronic, indigestion, and loss of appetite and of weight Looseness of the bowels is commoner in antimony poisoning than in lead poisoning Sores in the mouth and sore throat help to distinguish antimony poisoning from that of lead Practically all the antimony of industry contains some arsenic

Printers' type contains more lead than antimony and for this reason it is difficult to differentiate the symptoms of antimonial poisoning among printers from those of lead poisoning because the symptoms of lead poisoning are much the same as those of antimony It is only when a dermatitis is present that the possibility of antimony poisoning is considered.

Antimony food poisoning has resulted from cooking food in gray-enameled cooking utensils of a questionable quality There is a history of the use of new utensils of this kind for cooking of the sickening food The illness is characterized by vomiting within a few minutes to an hour after ingesting the food Recovery is rapid and there is no sequela .

Stibine (antimony hydride, SbH_3) is of the same order of toxicity as arsine Stibine has been shown to be liberated during the "forming" of storage batteries in an acid bath through the action of nascent hydrogen on the antimony present in the plates.

The term *metal fume fever* is used to designate such affections as brass founders' ague, smelter shakes, and brass chills, for the same symptoms occur as those which result from exposure to the hot metallic fumes originating in connection with the use of other metals, especially zinc

The symptoms of metal fume fever come on a few hours after exposure and usually follow chilling of the body The chill is preceded by a feeling of dryness in the throat, with cough and a sense of oppression in the chest The chill is followed by sweating and mild prostration The illness lasts only a few hours. The temperature may reach 101 F (38 3 C) There is leukocytosis which persists for a day or two

Industrial poisoning may be caused by the *zinc oxide* powder which is formed in the smelting of zinc and in brass founding Drinker, Thomason and Finn have shown that a certain degree of resistance may be acquired from repeated exposure. Both zinc chloride and zinc sulfate caustic may cause a troublesome dermatitis. A soluble zinc compound may cause chronic gastritis with vomiting, and the condition does not improve until the exposure to zinc in the air ceases

Manganese is used in the production of steel and the making of dry batteries for flashlights, radios, electric bells and telephones

the bone develops. This process does not go on to necrosis unless there is an injury to the soft parts permitting entrance of pyogenic bacteria. Necrosis follows suppurative inflammation. In rare instances comparable changes occur in the periosteum of other bones, making them brittle and liable to fracture.

In recent years an occasional instance of phosphonecrosis has occurred in phosphorus-producing and converting plants (converting yellow phosphorus into red allotrope) and in the manufacture of phosphor bronze and in making lights for miners' lamps

Acute phosphorus poisoning differs from chronic phosphorus poisoning In acute poisoning there is a vascular collapse from injury of the heart muscle. Fatty degeneration of the liver is common, whereas in chronic poisoning the bone structures, especially the jaw, are affected Salivation, ulcerative stomatitis, and rapid deterioration of the teeth, if there is a possibility of exposure to phosphorus, arouse the suspicion of chronic poisoning

Phosphorus poisoning affecting the jaw is known as phossy jaw because of the swollen, conspicuous prominence of the jaw During the slow, insidious process of development there may not be pain for a long time, but once the tissues are irritated, the pain is intense, prolonged and tiresome, and is accompanied with a foul, fetid discharge and distressing disfigurement.

Radium and radioactive substances cause necrosis of the jaw which resembles that present in phosphorus poisoning.

In acute poisoning of a mild degree there is gastric irritation, nausea, vomiting, and abdominal pain The vomitus smells like phosphorus, is luminous in the dark and may contain blood and mucus Soon a bloody dysentery follows. In severe poisoning the patient may collapse and die in a few hours The patient is lethargic, pale, and ecchymosis of the skin develops The blood pressure decreases rapidly Convulsions may come just before death

In instances of temporary improvement the nausea, vomiting and diarrhea with bloody feces return with renewed violence Evidence and symptoms of hepatic injury are prone to develop, indicated by hemorrhages in the skin or mucous membranes and jaundice. A fully manifested acute yellow atrophy of the liver is common. In some there will be early manifestations of renal injury, oliguria, hematuria and hyperazotemia These manifestations may develop rapidly and end in fatal uremia.

In the diagnosis of acute phosphorus poisoning dependence is placed on the garlicky odor of the vomited material or the feces Luminosity may be present if this material is placed in the dark

Cadmium. Cadmium is used in the manufacture of alloys, bearing metals, and ceramics, in electroplating and process engraving, in cadmium vapor lamps, and for rustproofing tools and other iron and steel articles such as marine hardware. Photoelectric cells, made by coating small steel plates with selenium, are sprayed with metallic cadmium Welding metal or the welding rod may contain cadmium Silver polishes containing cadmium may be the source of poisoning.

Small repeated doses of cadmium cause chronic poisoning, and produce gastroenteritis, emaciation, and infiltration of the liver and heart by fat It is impossible to distinguish these symptoms of cadmium poisoning from those of lead and arsenic In cadmium poisoning there is no colic, but there is pain or tenderness in the epigastrium, associated with nausea and anorexia.

[illegible] when ignited will produce cadmium [illegible] dangerous to those who inhale the [illegible] the eyes, headache, vertigo, dryness of the throat, cough, constriction of the chest and weakness of the legs Ross reported that after 3 hours a set of delayed effects was reported These included complaints of nausea, epigastric pain, dyspnea, precordial constriction, prostration and chills.

is no proof that the ingestion of vegetables or fruits grown on selenious soils adversely affects man.

Selenium poisoning may occur in those engaged in the production of sulfuric acid from iron sulfide carrying selenium sulfide, in the chemical production of hydrogen sulfide, and in copper refineries where selenium is encountered as an impurity. There seem to be, in some men, bronchial irritation, cough, and inflammation of the upper part of the respiratory tract, sometimes pain in the lumbar region, garlic breath, and night sweats It seems, however, that the commonest lesions are dermatitis and paronychia. The teeth may be affected. The hair may become stained red with the precipitation of minute amounts of amorphous selenium in the tissue.

Tellurium. Tellurium compounds are only mildly toxic The possible toxic effects may arise in the recovery of such elements as lead and copper. Tellurium hardens lead and improves its resistance to acids Small amounts of tellurium are used in making chilled car wheels and chilled iron castings, rubber hose and cable coverings. It may be used as a substitute for zinc, nickel, aluminum, magnesium and copper. Alloys of tin, silver, and magnesium are improved by the addition of tellurium.

Steinberg recorded the symptoms of tellurium poisoning as garlic breath, dryness and metallic taste in the mouth, anorexia, nausea, and somnolence. Tellurium was found in the urine in amounts ranging from 0 01 to 0 06 mg per liter of urine. These symptoms were not lasting

Vanadium. The pentoxide of vanadium may cause a suppurating conjunctivitis, inflammation of the upper part of the respiratory tract, cough and profuse expectoration and bronchitis

Aluminum. Aluminum and its compounds are considered harmless in industrial exposures. However, bauxite heated to 3,632 F (2,000 C) gives off fumes which on analysis consist of alumina, silica, iron and magnesium oxides These fumes cause a respiratory disease (Shaver's disease) which is characterized by cough, substernal pain, weakness, and fatigue On roentgenologic examination of the lungs there is bilateral thin shadowing most intense toward the hila of the lungs Distortion of the diaphragm is roentgenographically constant in this disease. The disease may prove to be due to silicosis.

Iron. Ordinary therapeutic doses of soluble iron preparations may produce gastrointestinal symptoms such as an insignificant diarrhea Massive overdosage of iron can produce serious, even fatal, consequences Thus the ingestion by children of 6 0 to 10 0 gm. of ferrous sulfate has produced death with acute hemorrhagic gastritis and hepatic injury Adults can endure large doses of iron.

The parenteral administration of small amounts of iron (colloidal ferric oxide or colloidal ferric hydroxide) may be dangerous It is followed by a febrile reaction, shock and thrombosis of the receiving vein However, there is a preparation of "saccharated iron" which it seems may be administered to patients intravenously in quantities supplying up to 500 mg of elemental iron without development of these toxic reactions

Copper. The green copper sulfate (copperas) is irritating to the skin and the eyes An itching cutaneous eruption may arise from contact with finely divided "cement copper" obtained from the precipitation of the metal from solution by metallic iron On exposure there may be irritation of the nasal passages and the throat, and a sweetish taste in the mouth Copper when imbedded in the skin or in the eye gives a rather violent inflammatory reaction Copper sulfate when ingested produces gastrointestinal irritation, vomiting and severe diarrhea.

Tin. The only use of tin in industry which causes injury seems to result from the use of tetrachloride of tin in weighting silk.

Tin poisoning is practically unknown Most of the reported outbreaks of food poisoning reputedly traced to tin date back many years, and these outbreaks were probably due to other causes.

Manganese poisoning may be manifested as a psychic type of intoxication or as a parkinsonian or extrapyramidal neuron type of nervous manifestation. The psychic symptoms of manganese poisoning are impulsive acts, running, dancing, singing and uncontrolled talking Some patients have attacks of irritability. The nervous symptoms comprise the presence of tremors, a parkinsonian masked expression, muscular pains, and hoarse dysarthric voice The prognosis is generally good but recovery is slow Some may die

Beryllium and Berylliosis. Beryllium and beryllium compounds have many uses in combination with copper, aluminum, nickel, magnesium, silver and iron Beryllium is employed as a phosphor in the manufacture of fluorescent lamps, radio and electronic tubes, neon sign tubing, incandescent lamps, electric heating elements, roentgen ray tube windows, and luminous indicators. *Beryllium oxide* is used as a refractory in certain types of crucibles and in bricks for high temperature ovens.

The toxic effect appears to be due to the vapors of beryllium oxyfluoride in a state of great dispersion. Vapor dispersion also explains the occurrence of poisoning of workers at a distance from the source of vapors

The clinical manifestations of acute berylliosis caused by fumes are characterized by two stages The first stage consists of the symptoms of metal fume fever. The second stage begins 1 to 4 or more days after the metal fume fever and is characterized by an extensive pneumonitis with a tendency for relapses. The relapses are characterized by severe dyspnea, cyanosis, paroxysmal cough, blood-streaked sputum and high fever The pneumonitis clears in from 1 to 4 months.

Hardy and Tabershaw in 1946 called attention to "delayed chemical pneumonitis" in workers exposed to beryllium The entity they described is characterized by a delay between exposure and onset of illness of from 3 months to 3 years A delay of 5 years has been observed

Microscopic studies revealed a granulomatosis Studies of sputa and of sections of lung did not reveal pathologic bacteria.

The manifestations are the same as those present in the second stage of the acute form of poisoning The disease progresses despite change of environment. There is a progressive loss of body weight On roentgenologic examination the roentgenograms reveal a diffuse nodulation throughout the lungs which resembles that occurring in miliary tuberculosis and silicosis These changes are incident to a pulmonary granulomatosis due to the inhalation of the fumes of beryllium.

The term *berylliosis* designates a granulomatosis of the lungs, more rarely of the skin, subcutaneous tissue, lymph nodes, liver, and other structures A berylliosis may be caused by inhaling or by accidentally implanting finely divided beryllium dust in the skin or subcutaneous tissue by laceration or puncture

In berylliosis fine particles of beryllium may be found in cutaneous papules, in cutaneous ulcers, and in granulomas.

Beryllium granuloma is a specific process, as illustrated by Nachtwey's case The patient, a man aged 35 years, was in the electric business and had worked with fluorescent lamps, blowing the glass and coating the tubes. For many years he had a nonproductive cough and more recently he had noticed dyspnea, fatigue, and thoracic pain. Examination revealed persistent fine rales over the lower two thirds of both pulmonary fields. At the base of the nail on the left fourth finger there was a healed scar, which the patient said was the result of a lesion which would occasionally swell, drain and then heal over He thought this lesion had followed a cut by a piece of fluorescent glass. An abnormally enlarged lymph node was found in the left axillary space. This node was removed; microscopic examination revealed that it was a granuloma, and spectrographic analysis disclosed beryllium

Selenium. Cattle that feed on grass grown on certain alkaline soils containing excessive amounts of selenium have what is known as alkali disease. However, there

most effective against arsenical poisoning and has proved of practical value in preventing and counteracting many of the toxic effects of antisyphilitic arsenicals.

The administration of BAL causes lead to appear in the urine in increasing quantity with only a slight exacerbation of symptoms of plumbism The untoward symptoms from the administration of BAL in man are a feeling of constriction and oppression in the chest, burning lips, dry throat, nervousness and restlessness, nausea and vomiting. There may be a transient rise in blood pressure.

Carbon Monoxide. Carbon monoxide gas is odorless, tasteless and nonirritating. Carbon monoxide is formed whenever there is incomplete combustion of carbon. Natural gas does not contain carbon monoxide, but unless it is burned with sufficient supply of oxygen the vapors which form during its combustion may be very rich in this substance. Other gases which are used for illumination and for heat and power contain varying amounts of carbon monoxide, and the gases that result from the explosion of coal dust, from the detonation of blasting charges, and from the partial burning of such charges may contain carbon monoxide in detectable to sizable concentrations

When there is a concentration of about 0 02 per cent of carbon monoxide in the inspired air, discomfort begins

Truck drivers, occupants of cars with faulty exhaust systems, and traffic policemen may complain of malaise and mild headaches If the carbon monoxide is excessive, the occupants of cars after a 3 or 4 hour run have collapsed from carbon monoxide asphyxia

In any place where carbon monoxide gas is used as a source of heat or power, or in the production of illuminating gas and of power gas, or in the repair work on pipes or when the pipes and flues are cleaned, there is some danger of excessive amounts of this gas being present

Carbon monoxide acts more quickly at high temperatures, in humidity, and during muscular exertion than under other conditions Young persons are more susceptible than older ones Those who have chronic bronchitis or asthma, alcoholism, obesity, and chronic disease of the heart are the most susceptible to the effects of carbon monoxide.

The asphyxia of carbon monoxide is due to an increased affinity of hemoglobin for this gas and the more stable compound, carbon monoxide hemoglobin, formed when hemoglobin is combined with it In addition, carbon monoxide hemoglobin in the blood interferes with the dissociation of the oxyhemoglobin For instance, a person who has anemia and who has lost one half of the total blood utilizes the oxygen in the blood well enough to be fairly comfortable, whereas a person who has one half of the blood saturated with carbon monoxide hemoglobin is not comfortable

The lesions in the central nervous system are primarily vascular. A hyperemia of the cerebral tissues seems to be the first effect of the anoxemia There is a rise in intracranial blood pressure attributable to the increased congestion and edema The congestion of the brain is as intense as that observed after strangulation or drowning.

The cell degeneration, necrosis, and subsequent softening vary in intensity according to the adequacy or inadequacy of the blood supply, and are typically most marked in the lenticular nucleus of the corpus striatum, particularly the pallidal region The exaggeration of the process in the globus pallidus of the lenticular nucleus is explained by the poor blood supply This degeneration may proceed in those who recover, apparently, and who have been adequately treated

Hemorrhage may occur in practically every organ or tissue as a result of the high blood pressure and of the dilatation and weakening of the vessel walls. There may be epistaxis and hemorrhage from both nose and lungs, from the uterus with premature expulsion of [illegible]
culature of

The inh

There is a common concept among the laity that food may become poisonous if it is left standing in an open tin can. Poisonous effects or spoilage results from bacteria growing in a food and not from the tin can Contamination is less likely to occur if the food is left in the sterile can than if placed in a clean but not sterile dish.

Nickel. Nickel eczema or "nickel itch" seems to be fairly common in those who work in nickel-plating plants The eczema comes first on the arms and may spread to the neck, the legs, or the body. There are itching, soreness and burning, and sometimes swelling of the parts affected. Nickel seems to be a true allergen.

Nickel carbonyl is a gaseous compound of nickel which volatilizes at room temperature, and when heated to 302 F (150 C), decomposes with a deposit of metallic nickel and the release of carbon monoxide.

Nickel carbonyl is decomposed in the lungs into carbon monoxide and some gaseous compound of nickel The gaseous nickel compound in the lungs produces congestion, edema, and consolidation which may be fatal. Once the gaseous compound is in the blood, the endothelium of the capillary vessels is injured and hemorrhages, especially in the brain and the adrenal glands, ensue.

Magnesium. Wounds, scratches, or cuts that are caused or contaminated by magnesium or its alloys are prone to become inflamed, with accompanying blebs which resist healing. All particulate magnesium should be removed from a wound

Thallium. Thallium poisoning follows the use of the metal as a depilatory, in the treatment of parasitic diseases of the hair follicles, in children especially, or its administration, in the form of a rat exterminator, for murder or for suicide. Thallium is a powerful agent for the removal of hair It will cause complete loss of hair in children on the sixteenth to eighteenth day Poisoning has followed such administrations of thallium Toxic effects are manifested by swelling of feet and legs, with pains in the joints sometimes suggestive of acute articular rheumatism, hyperesthesia and paresthesia of hands and feet, colic and vomiting, and sleeplessness and mental confusion. It is possible to demonstrate thallium in the blood and urine 4 weeks after the administration of a large dose.

Industrial thallium poisoning is characterized by coloration and subsequent falling out of the hair, severe cramplike pains in the knees and calves; and optic neuritis, followed by atrophy

Cobalt. A lack of cobalt in the soil may produce a deficiency disease in sheep and cattle. No such disease is recorded in man The powdered cobalt encountered in the tungsten-carbide industry will cause dermatitis in man Arsenical compounds of cobalt may cause a localized dermatitis Cobalt is eliminated from the tissues slowly.

Platinum. Complex platinum salts are encountered in photography Karasek and Karasek have described a specific clinical syndrome due to platinum poisoning which is characterized by sneezing and respiratory distress.

Osmium. Osmium produces an exceptionally hard alloy, used to tip fountain pens, as a catalyst in preparing synthetic ammonia, in taking fingerprints, and in the laboratory technics of histology. Osmium causes lacrimation and pain and irritation of the eyes.

The inhalation of osmium tetroxide has a marked and immediate effect on the mucous membranes of the nose, throat, and bronchi with a sensation of constriction of the chest and inability to breathe which is of short duration.

Silver. Argyria, a bluish black deposit of metallic silver in the skin, apparently is the only lesion produced by silver It is localized usually in those areas of the skin which have come in contact with silver. The condition appears slowly, taking from 2 to 25 years or even longer to develop There may be pigmentation of the lining of the mouth Argyria, local or generalized from prolonged application or ingestion of silver-containing medicaments, is now very infrequent.

BAL. The use of BAL (British anti-lewisite), 2, 3-dimercapto-1-propanol, as an antidote for metallic poisons has come to be a common remedy. It seems to be the

Asphyxiation with cyanide gas occurs in connection with the fumigation of ships, workshops, and dwellings, in fumigation intended to kill agricultural parasites, in chemical laboratories, in blast-furnace gas, in the manufacture of illuminating gas, and in the gas from burning nitrocellulose, in the preparation and decomposition of cyanides by exposure to the air and by weak acids; in the extraction of phosphoric acid from bones; and in the use of lime from gas works in tanneries as a tanning agent. Hydrogen cyanide is produced in nature by certain plants as a side reaction in their protein metabolism with occasional accidental poisoning to agricultural workers and animals.

Hydrogen cyanide acts rapidly on the respiratory ferments of tissue cells and prevents the uptake of oxygen by the tissues with resulting paralysis and asphyxial death. The blood itself, saturated with oxygen, remains arterial in color after it reaches the venous circulation, producing the characteristic cherry-color appearance of the victim of acute cyanide poisoning In low concentration in the human body the cyanide ion stimulates respiration Part of the cyanide absorbed is exhaled unchanged. The greater part is changed into the relatively nontoxic thiocyanates.

Calcium cyanamide ($CaCN_2$) is severely irritating to the skin. Exposure of the skin to calcium cyanamide causes flushing of the skin, a rapid pulse, fall in blood pressure, sweating, pressure in the head, or headache, dyspnea, and sometimes syncope. In its toxic action calcium cyanamide is found to resemble hydrocyanic acid very closely

Dermatitis is common in those chronically exposed to cyanide. There is a severe itching followed by a scarlet rash Occasionally a blotchy eruption of the face may follow prolonged exposure to hydrogen cyanide vapors in low concentration or to dilute solutions of cyanide salts

Hydrogen Sulfide During the separation and deposition of free sulfur in nature, pockets of hydrogen sulfide may accumulate. For instance, hydrogen sulfide may collect in pools of water in coal mines when iron pyrites decompose, in waters from industrial plants, and where the somatic decay of man and animals occurs. Gassing from hydrogen sulfide occurs in tanneries, glue factories, fur-dressing and felt-making plants, abattoirs, beet-sugar factories and sewers Hydrogen sulfide is formed in certain industrial processes, as in the production of sulfur dyes, brown, black and blue; production of carbon disulfide, in the action of acids on sulfides, in purifying sulfuric acid; in heating rubber containing certain sulfur compounds in the process of vulcanizing.

Hydrogen sulfide is of the same degree of toxicity as hydrogen cyanide. Death results from respiratory failure within a few seconds. The heart continues to beat several minutes longer and the victim may be saved by prompt measures to restore breathing

Mild forms of hydrogen sulfide poisoning are characterized by irritation of the conjunctivae and sometimes by a severe conjunctivitis with keratitis. If aware of the significance of an increased sensitiveness to all kinds of light and the appearance of a colored ring around a light, a person exposed to hydrogen sulfide may escape serious poisoning. In more severe poisoning the eyelids become swollen. So great may be the swelling that both the upper and lower lids are everted

Recovery from acute poisoning by hydrogen sulfide is usually complete, but on rare occasions lasting injury, which is irreversible, in certain cells of the body results in prolonged anoxia and thus permanent injury. Permanent injury from hydrogen sulfide is manifested much the same as that from hydrogen cyanide and carbon monoxide.

Diagnosis of hydrogen sulfide poisoning depends on the history and the presence of hydrogen sulfide detectable in the environment where exposure occurred.

body temperature, and in fatal gassing there is a fall in the oxygen content and the carbon dioxide content of the blood, together with an increase in blood sugar. The hydrogen ion concentration of blood is lowered

Administration of alkalies lessens the injury from carbon monoxide and decreases the concentration of blood sugar

The symptoms of acute carbon monoxide poisoning are described in stages In the *first stage* there may be no awareness of the impending disaster. In some, however, there may be a sense of pressure in the head or bandlike constriction or throbbing, a feeling of weakness in the knees, mental confusion, headache, roaring in the ears, nausea, and perhaps vomiting.

On continued exposure the *second stage* of poisoning commences with headache, dizziness, and inability to think clearly and to decide and act Soon the victim becomes soothed to drowsiness and thus fearless Soon consciousness is lost, which is attended by vomiting and involuntary evacuations, and occasionally general muscular contractions Rarely are there convulsions until just prior to death, convulsions may appear with the return to consciousness if the patient has been rescued and is undergoing treatment

The presence of abnormal amounts of moisture in the lungs is a common manifestation of acute gassing The moisture may increase until edema of the lungs ensues Pneumonia, often deglutitive in origin because the patient may have vomited before recovering consciousness, often develops. A pneumonia may occur weeks after the accident as the result of lowered resistance to infection.

In severe gassing, when consciousness is regained, there is excitement, often delirium, with an ensuing depression, apathy, indifference to the surroundings, shivering, and inability to remember anything about the accident. Convulsive disorders or psychoses may appear for the first time during recovery.

Blindness, complete or incomplete, transient or permanent, is a rare accompaniment or a sequel of carbon monoxide asphyxia.

On examination the appearance of the victim is unforgettable. The cheeks and lips are richly pink in color, and there are red blotches on various parts of the skin. If consciousness is still maintained, there are manifestations comparable to those present in alcoholic intoxication. Later the red blotches over the skin may form blisters, and trophic changes, necrosis and gangrene ensue.

Carbon monoxide in excessive amounts may be demonstrated in the blood by chemical or spectroscopic analysis A profound anemia often develops

The blood cells in carbon monoxide asphyxia are usually normal, although a compensatory polycythemia has been found in both acute and chronic poisoning Usually if polycythemia develops it is transient.

The diagnosis of acute gassing with carbon monoxide depends on the history of exposure, the appearance of the victim, and the detection of carbon monoxide in the blood or in the air of the place in which the victim was overcome.

Carbon Dioxide. Carbon dioxide poisoning is rare When it does occur, it is from gas produced by the fermentation of carbohydrates Green fodder in silos and residue in brewery vats have caused fatal poisoning Carbon dioxide may also be a danger in beet-sugar production, since the juice of the beets is treated with milk of lime and the calcium saccharate is precipitated by carbon dioxide The handling of dry ice, or carbon dioxide snow, solid carbon dioxide, causes injury to the skin.

The therapeutic use of carbon dioxide to stimulate respirations, if prolonged, is not without danger. Toxic concentrations of the gas produce headache, vertigo,

The pulse and respirations are slowed
ons. Administration of the gas is much
or alkalosis.

The Cyanides. *Hydrogen cyanide* is a highly volatile gas The cyanide ion is absorbed by all tissues, including the uninjured skin.

Asphyxiation with cyanide gas occurs in connection with the fumigation of ships, workshops, and dwellings, in fumigation intended to kill agricultural parasites, in chemical laboratories, in blast-furnace gas, in the manufacture of illuminating gas, and in the gas from burning nitrocellulose, in the preparation and decomposition of cyanides by exposure to the air and by weak acids, in the extraction of phosphoric acid from bones, and in the use of lime from gas works in tanneries as a tanning agent. Hydrogen cyanide is produced in nature by certain plants as a side reaction in their protein metabolism with occasional accidental poisoning to agricultural workers and animals.

Hydrogen cyanide acts rapidly on the respiratory ferments of tissue cells and prevents the uptake of oxygen by the tissues with resulting paralysis and asphyxial death. The blood itself, saturated with oxygen, remains arterial in color after it reaches the venous circulation, producing the characteristic cherry-color appearance of the victim of acute cyanide poisoning. In low concentration in the human body the cyanide ion stimulates respiration Part of the cyanide absorbed is exhaled unchanged. The greater part is changed into the relatively nontoxic thiocyanates.

Calcium cyanamide ($CaCN_2$) is severely irritating to the skin Exposure of the skin to calcium cyanamide causes flushing of the skin, a rapid pulse, fall in blood pressure, sweating, pressure in the head, or headache, dyspnea, and sometimes syncope. In its toxic action calcium cyanamide is found to resemble hydrocyanic acid very closely

Dermatitis is common in those chronically exposed to cyanide. There is a severe itching followed by a scarlet rash Occasionally a blotchy eruption of the face may follow prolonged exposure to hydrogen cyanide vapors in low concentration or to dilute solutions of cyanide salts

Hydrogen Sulfide. During the separation and deposition of free sulfur in nature, pockets of hydrogen sulfide may accumulate For instance, hydrogen sulfide may collect in pools of water in coal mines when iron pyrites decompose, in waters from industrial plants, and where the somatic decay of man and animals occurs Gassing from hydrogen sulfide occurs in tanneries, glue factories, fur-dressing and felt-making plants, abattoirs, beet-sugar factories and sewers. Hydrogen sulfide is formed in certain industrial processes, as in the production of sulfur dyes, brown, black and blue, production of carbon disulfide; in the action of acids on sulfides, in purifying sulfuric acid, in heating rubber containing certain sulfur compounds in the process of vulcanizing.

Hydrogen sulfide is of the same degree of toxicity as hydrogen cyanide. Death results from respiratory failure within a few seconds. The heart continues to beat several minutes longer and the victim may be saved by prompt measures to restore breathing

Mild forms of hydrogen sulfide poisoning are characterized by irritation of the conjunctivae and sometimes by a severe conjunctivitis with keratitis. If aware of the significance of an increased sensitiveness to all kinds of light and the appearance of a colored ring around a light, a person exposed to hydrogen sulfide may escape serious poisoning In more severe poisoning the eyelids become swollen So great may be the swelling that both the upper and lower lids are everted.

Recovery from acute poisoning by hydrogen sulfide is usually complete, but on rare occasions lasting injury, which is irreversible, in certain cells of the body results in prolonged anoxia and thus permanent injury. Permanent injury from hydrogen sulfide is manifested much the same as that from hydrogen cyanide and carbon monoxide

Diagnosis of hydrogen sulfide poisoning depends on the history and the presence of hydrogen sulfide detectable in the environment where exposure occurred.

body temperature, and in fatal gassing there is a fall in the oxygen content and the carbon dioxide content of the blood, together with an increase in blood sugar. The hydrogen ion concentration of blood is lowered.

Administration of alkalies lessens the injury from carbon monoxide and decreases the concentration of blood sugar.

The symptoms of acute carbon monoxide poisoning are described in stages In the *first stage* there may be no awareness of the impending disaster. In some, however, there may be a sense of pressure in the head or bandlike constriction or throbbing, a feeling of weakness in the knees, mental confusion, headache, roaring in the ears, nausea, and perhaps vomiting

On continued exposure the *second stage* of poisoning commences with headache, dizziness, and inability to think clearly and to decide and act. Soon the victim becomes soothed to drowsiness and thus fearless Soon consciousness is lost, which is attended by vomiting and involuntary evacuations, and occasionally general muscular contractions Rarely are there convulsions until just prior to death, convulsions may appear with the return to consciousness if the patient has been rescued and is undergoing treatment.

The presence of abnormal amounts of moisture in the lungs is a common manifestation of acute gassing The moisture may increase until edema of the lungs ensues. Pneumonia, often deglutitive in origin because the patient may have vomited before recovering consciousness, often develops A pneumonia may occur weeks after the accident as the result of lowered resistance to infection.

In severe gassing, when consciousness is regained, there is excitement, often delirium, with an ensuing depression, apathy, indifference to the surroundings, shivering, and inability to remember anything about the accident Convulsive disorders or psychoses may appear for the first time during recovery

Blindness, complete or incomplete, transient or permanent, is a rare accompaniment or a sequel of carbon monoxide asphyxia.

On examination the appearance of the victim is unforgettable. The cheeks and lips are richly pink in color, and there are red blotches on various parts of the skin. If consciousness is still maintained, there are manifestations comparable to those present in alcoholic intoxication Later the red blotches over the skin may form blisters, and trophic changes, necrosis and gangrene ensue.

Carbon monoxide in excessive amounts may be demonstrated in the blood by chemical or spectroscopic analysis. A profound anemia often develops.

The blood cells in carbon monoxide asphyxia are usually normal, although a compensatory polycythemia has been found in both acute and chronic poisoning. Usually if polycythemia develops it is transient.

The diagnosis of acute gassing with carbon monoxide depends on the history of exposure, the appearance of the victim, and the detection of carbon monoxide in the blood or in the air of the place in which the victim was overcome.

Carbon Dioxide. Carbon dioxide poisoning is rare. When it does occur, it is from gas produced by the fermentation of carbohydrates. Green fodder in silos and residue in brewery vats have caused fatal poisoning. Carbon dioxide may also be a danger in beet-sugar production, since the juice of the beets is treated with milk of lime and the calcium saccharate is precipitated by carbon dioxide The handling of dry ice, or carbon dioxide snow, solid carbon dioxide, causes injury to the skin

The therapeutic use of carbon dioxide to stimulate respirations, if prolonged, is not without danger. Toxic concentrations of the gas produce headache, vertigo, oppression in the chest and unconsciousness The pulse and respirations are slowed and death may ensue after asphyxial convulsions. Administration of the gas is much more dangerous in those who have acidosis or alkalosis.

The Cyanides. *Hydrogen cyanide* is a highly volatile gas. The cyanide ion absorbed by all tissues, including the uninjured skin.

Asphyxiation with cyanide gas occurs in connection with the fumigation of ships, workshops, and dwellings, in fumigation intended to kill agricultural parasites, in chemical laboratories, in blast-furnace gas, in the manufacture of illuminating gas, and in the gas from burning nitrocellulose, in the preparation and decomposition of cyanides by exposure to the air and by weak acids; in the extraction of phosphoric acid from bones; and in the use of lime from gas works in tanneries as a tanning agent. Hydrogen cyanide is produced in nature by certain plants as a side reaction in their protein metabolism with occasional accidental poisoning to agricultural workers and animals.

Hydrogen cyanide acts rapidly on the respiratory ferments of tissue cells and prevents the uptake of oxygen by the tissues with resulting paralysis and asphyxial death The blood itself, saturated with oxygen, remains arterial in color after it reaches the venous circulation, producing the characteristic cherry-color appearance of the victim of acute cyanide poisoning In low concentration in the human body the cyanide ion stimulates respiration Part of the cyanide absorbed is exhaled unchanged. The greater part is changed into the relatively nontoxic thiocyanates

Calcium cyanamide ($CaCN_2$) is severely irritating to the skin Exposure of the skin to calcium cyanamide causes flushing of the skin, a rapid pulse, fall in blood pressure, sweating, pressure in the head, or headache, dyspnea, and sometimes syncope In its toxic action calcium cyanamide is found to resemble hydrocyanic acid very closely.

Dermatitis is common in those chronically exposed to cyanide. There is a severe itching followed by a scarlet rash Occasionally a blotchy eruption of the face may follow prolonged exposure to hydrogen cyanide vapors in low concentration or to dilute solutions of cyanide salts

Hydrogen Sulfide. During the separation and deposition of free sulfur in nature, pockets of hydrogen sulfide may accumulate For instance, hydrogen sulfide may collect in pools of water in coal mines when iron pyrites decompose, in waters from industrial plants, and where the somatic decay of man and animals occurs. Gassing from hydrogen sulfide occurs in tanneries, glue factories, fur-dressing and felt-making plants, abattoirs, beet-sugar factories and sewers Hydrogen sulfide is formed in certain industrial processes, as in the production of sulfur dyes, brown, black and blue, production of carbon disulfide; in the action of acids on sulfides, in purifying sulfuric acid, in heating rubber containing certain sulfur compounds in the process of vulcanizing.

Hydrogen sulfide is of the same degree of toxicity as hydrogen cyanide. Death results from respiratory failure within a few seconds. The heart continues to beat several minutes longer and the victim may be saved by prompt measures to restore breathing

Mild forms of hydrogen sulfide poisoning are characterized by irritation of the conjunctivae and sometimes by a severe conjunctivitis with keratitis. If aware of the significance of an increased sensitiveness to all kinds of light and the appearance of a colored ring around a light, a person exposed to hydrogen sulfide may escape serious poisoning In more severe poisoning the eyelids become swollen. So great may be the swelling that both the upper and lower lids are everted

Recovery from acute poisoning by hydrogen sulfide is usually complete, but on rare occasions lasting injury, which is irreversible, in certain cells of the body results in prolonged anoxia and thus permanent injury Permanent injury from hydrogen sulfide is manifested much the same as that from hydrogen cyanide and carbon monoxide.

Diagnosis of hydrogen sulfide poisoning depends on the history and the presence of hydrogen sulfide detectable in the environment where exposure occurred.

ALLERGIC REACTIONS TO DRUGS AND CHEMICALS

Drugs and *chemicals* are common sources for hypersensitiveness. These agents are sources of drug idiosyncrasy as well as the ill effects from unknown and unpredictable physiologic action Often it is impossible to determine whether symptoms are of allergic origin or whether they are due to the physiologic action of the drug Likewise it may be impossible to learn whether the hypersensitiveness was produced by contact or by ingestion.

Generally, when there is hypersensitiveness to a drug or chemical, the compound is of low molecular weight, for instance the frequency of response to formaldehyde, *2, 4-dinitro-1-chlorobenzene*, paraphenylenediamine, mustard gas, quinine, aminopyrine, sulfadiazine, and metals such as nickel

When due account is taken of all the tangible factors, such as age and weight, which might alter the susceptibility of persons to drugs, there still remains a wide normal variability in the quantitative response Pharmacologists take cognizance of this by the use of such terms as ED_{50}, ED_{99} and ED_1, signifying by the first the average dose of a drug which is effective in 50 per cent of the population and using the latter two terms to give expression to the range of variability by indicating the doses which are correspondingly effective in 99 per cent and 1 per cent of the population Persons showing susceptibilities at or beyond these extremes are said to be tolerant in the former and hypersensitive in the latter case The quantitative variability in the response to drugs is not particularly disturbing in clinical practice and seldom precludes the use of any drug Largely because of this fact, the term idiosyncrasy has come to have the narrower meaning of a qualitative abnormality in the response to drugs, signifying such effects as urticaria, neuritis, jaundice, anemia, leukopenia and the like, which some drugs produce in some persons but do not produce in the majority, irrespective of the dose employed Whether idiosyncrasy is due to a constitutional defect, unchangeable and incurable, or to a transitory state brought about by disease or nutritional deficiency is not known The statement is commonly made that some 10 per cent of the population have an inherited predisposition to the allergic diseases caused by foods, inhalants and similar environmental agents Whether this is the same fraction of the population that shows idiosyncrasy to drugs is not known.

The causative agents in drug allergies and contact dermatitis are not antigens, but it appears that by combining the offending agent with the tissues of the host, the tissues acquire antigenic capacity and function which arise when hapten structures become attached to indifferent foreign protein

The cutaneous lesions from a drug depend on the method of exposure to the drug. These eruptions may arise as a consequence of contact of the drug with the skin or as a consequence of ingestion of the drug.

The manifestations of allergy to drugs may be anaphylactic, immediate-type [illegible] example, *like those of serum sickness*, arthralgia, [illegible] asthma, flare-and-wheal reactions, urticaria, [illegible] by far the most commonly encountered is the delayed type Aside from an inherited predisposition in a given person, the chief determining elements appear to be the frequency and mode of contact through which sensitization has arisen and especially the chemical properties of the sensitizing material.

Common offenders among drugs are aspirin, salicylates, phenacetin (acetophenetidin), *iodides, bromides, sulfonamides, penicillin,* phenolphthalein and ovarian extracts. The heavy metals, among them arsenic (inorganic and organic compounds), gold, silver, lead and bismuth produce erythema, papules, vesicles and ulcerations Gold, silver and bismuth are all dangerous to the skin Silver may

stain the skin a dark bluish color which is permanent (argyria). Bismuth and mercury cause stomatitis (salivation).

In any instance of a sudden appearance of a cutaneous rash all medications being used at the time are suspected as the cause of the eruption, irrespective of the length of time the drug or drugs have been administered One or two doses of a drug may be sufficient to produce an eruption. The eruption occurring from ingestion of the drug seems to arise most commonly in persons who have a decreased renal functional activity or in those who have a congenital or acquired sensitiveness to the drug in use

Dermatosis and Dermatitis Due to Chemical Agents. Many and varied forms of dermatosis arise from drugs, toilet articles (soaps, perfumes, talcum powders, cold creams, nail polishes, hair dressings, hair waving preparations) and contact with plants. Most of these are described in appropriate places in this text.

DIAGNOSIS OF POISONING BY CHEMICALS

The diagnosis of a disease due to a chemical agent requires a history of a contact or a suspicion of its nature, or manifestations specifically indicating a particular poison. In the absence of such information the special technics of qualitative and quantitative chemical analysis are so limited that the number of procedures necessary to identify an unknown agent would occupy the lifetime of the chemist. It is for these reasons that the emphasis in the descriptions of the chemical agents of disease is placed on contacts and the possible sources of contacts with these agents, organic or inorganic

ACUTE POISONING BY CHEMICALS WHICH REQUIRES IMMEDIATE TREATMENT

Acute emergencies arise from the accidental or intentional ingestion, inhalation, or absorption of certain chemicals In such instances the diagnosis of the offending substance may be obvious or totally obscure, depending on the circumstances When suicide is the intent, the patient usually lives long enough to repent. However, when homicide is the intent, there is no immediate information at hand in regard to the chemical or its method of administration. In any case, immediate treatment is urgent

In instances of poisoning when there is no evidence available as to the nature of the offending agent, and even if such information is at hand, there are three approved therapeutic procedures, one or more of which may be employed, depending on the situations which prevail These procedures are (1) gastric lavage, (2) emetics and (3) antidotes Antidotes are of two kinds (a) those which seem to be safe and which usually are beneficial and (b) specific antidotes. The specific antidotes themselves are poisons and their administration is limited by their own range of safe dosage

Gastric Lavage. In infants the gastric tube is introduced through the mouth. However, a small tube (No 8 to No 10 French catheter) may be introduced through the nose Solutions generally used in lavage are water, saline, weak sodium bicarbonate, potassium permanganate 1.10,000 solution, specific or general antidotes, and cathartics It is well to remember that compounds formed by antidotes may be only slightly less toxic than the poison itself. All chemical antidotes, stimulants, or sedatives are employed cautiously and if there is doubt, they are not used at all Avoid saline cathartics in phosphorus poisoning, and the passage of stomach tubes when caustics have been the offending agents.

The contraindications to lavage are (1) strychnine poisoning in which the characteristic muscular spasms may be changed, by the stimulating effect of gastric

lavage, to fatal convulsions; (2) erosion of the esophagus due to corrosive agents such as phenol (the tube may cause perforation of the esophagus); and (3) shock, if shock supervenes. If shock should be present, its treatment takes precedence over lavage. The therapy is by inhalation of oxygen with 5 per cent carbon dioxide. Artificial respiration is instituted in instances of depressed respirations.

The general precautions during lavage are as follows: (1) restrain the patient, (2) turn the head to the side and keep it low in order to prevent aspiration into lungs, (3) use amounts of liquid just sufficient to be aspirated by suction with a large glass syringe and (4) close the tube by pinching it before withdrawing from the stomach.

Emetics. In general, emetics are not used to avoid the employment of gastric lavage However, many lives are saved by the voluntary or involuntary induction of vomiting, which is often an efficient way of emptying the stomach It is only in rare instances that emetic drugs are of value. Emetics are avoided if strong acids or alkalies have been ingested If the situation demands the psychologic effects of an emetic, harmless ones consist of (1) 2 tablespoonfuls of salt in 1 glass of warm water or milk, (2) ¼ glassful of a mild soapy water solution, (3) 1 teaspoonful of dry mustard in 1 glass of warm water Any one of these emetics may be administered at 15-minute intervals until vomiting ensues.

Antidotes. ***Unknown Poisons.*** If after gastric lavage the poison is unknown, an antidote consisting of powdered charcoal, 2 parts; magnesium oxide, 1 part; and tannic acid, 1 part, is given The dose is 1 teaspoonful in a small glass of lukewarm water Simple home remedies may be useful. (1) flour and starches for their colloidal action on iodine, (2) weak tannic acid, strong tea or dilute tincture of iodine (10 drops in ½ glass of water) is effective against alkaloids such as atropine or morphine, (3) milk and eggs are useful in heavy-metal poisoning for they provide protein to precipitate these metals, (4) strong coffee or tea is valuable as a stimulant when the central nervous system is depressed, as occurs when excessive doses of opiates, barbiturates or alcohol have been consumed.

Known Poisons. In the next few pages are discussed antidotes for use when the poisons are known.

Acetic Acid, Chromic Acid, Hydrochloric Acid, Nitric Acid, and Sulfuric Acid The lethal dose of acetic acid is up to 20 ml; of nitric acid, 6 to 8 ml., of sulfuric acid, 4 to 6 ml

The patient should drink freely of lukewarm water until vomiting ensues Magnesium oxide, chalk or soapy water or other protective substances such as eggs are administered after vomiting but never in excessive doses (1 glassful each half hour) For acid vapor inhalation the nose should be sprayed and the mouth washed with a solution of sodium bicarbonate

Alcohol. The lethal dose is undetermined. The stomach is washed with water. Heat is applied to the body, cold applications are applied to the head, and black coffee is given freely (see Alcohols, p. 1402) If delirium is present, barbital is administered intravenously as pentobarbital sodium, 0 25 to 0 40 gm

Alkalies, Caustic Soda, Liquor Potassae The lethal dose is about 150 to 300 grains. Injuries due to ingested alkali are treated by the use of weak acids such as vinegar water, sour wine, tartaric acid, citric acid, lemon juice or apple juice and milk. Washing of the stomach with acidulated water (a teaspoonful of vinegar to 500 ml water) may be used, but with caution. For alkali in the eye, water is used to wash the eye and is sprayed under the lids with a medicine dropper, if available If a dropper is not available, hold the upper lid up and wash For lime in the eye 0 10 per cent sulfuric acid solution (1 teaspoonful to 1,000 ml) may be used as a wash, but with great caution.

Ammonia. The lethal dose of caustic ammonia solution is *1 ounce. When the* esophagus and stomach are eroded, the treatment is the same as for injury from

ı the air passages have been injured, the inhalation of the vapor
/inegar or lemon juice may be helpful.
ıvatives. Acetanilid, nitrobenzol, antipyrine, phenacetin, dichlori-
nol are aniline derivatives. The lethal dose of aniline is less than
id and of nitrobenzol, 64 to 160 grains.

lavage, to fatal convulsions; (2) erosion of the esophagus due to corrosive agents such as phenol (the tube may cause perforation of the esophagus); and (3) shock, if shock supervenes. If shock should be present, its treatment takes precedence over lavage. The therapy is by inhalation of oxygen with 5 per cent carbon dioxide. Artificial respiration is instituted in instances of depressed respirations

The general precautions during lavage are as follows: (1) restrain the patient, (2) turn the head to the side and keep it low in order to prevent aspiration into lungs, (3) use amounts of liquid just sufficient to be aspirated by suction with a large glass syringe and (4) close the tube by pinching it before withdrawing from the stomach.

Emetics. In general, emetics are not used to avoid the employment of gastric lavage However, many lives are saved by the voluntary or involuntary induction of vomiting, which is often an efficient way of emptying the stomach. It is only in rare instances that emetic drugs are of value. Emetics are avoided if strong acids or alkalies have been ingested. If the situation demands the psychologic effects of an emetic, harmless ones consist of (1) 2 tablespoonfuls of salt in 1 glass of warm water or milk, (2) ¼ glassful of a mild soapy water solution, (3) 1 teaspoonful of dry mustard in 1 glass of warm water Any one of these emetics may be administered at 15-minute intervals until vomiting ensues.

Antidotes. *Unknown Poisons.* If after gastric lavage the poison is unknown, an antidote consisting of powdered charcoal, 2 parts; magnesium oxide, 1 part; and tannic acid, 1 part, is given. The dose is 1 teaspoonful in a small glass of lukewarm water. Simple home remedies may be useful: (1) flour and starches for their colloidal action on iodine, (2) weak tannic acid, strong tea or dilute tincture of iodine (10 drops in ½ glass of water) is effective against alkaloids such as atropine or morphine, (3) milk and eggs are useful in heavy-metal poisoning for they provide protein to precipitate these metals, (4) strong coffee or tea is valuable as a stimulant when the central nervous system is depressed, as occurs when excessive doses of opiates, barbiturates or alcohol have been consumed.

Known Poisons. In the next few pages are discussed antidotes for use when the poisons are known.

Acetic Acid, Chromic Acid, Hydrochloric Acid, Nitric Acid, and Sulfuric Acid. The lethal dose of acetic acid is up to 20 ml ; of nitric acid, 6 to 8 ml.; of sulfuric acid, 4 to 6 ml

The patient should drink freely of lukewarm water until vomiting ensues Magnesium oxide, chalk or soapy water or other protective substances such as eggs are administered after vomiting but never in excessive doses (1 glassful each half hour) For acid vapor inhalation the nose should be sprayed and the mouth washed with a solution of sodium bicarbonate

Alcohol. The lethal dose is undetermined. The stomach is washed with water Heat is applied to the body, cold applications are applied to the head, and black coffee is given freely (see Alcohols, p 1402). If delirium is present, barbital is administered intravenously as pentobarbital sodium, 0 25 to 0.40 gm.

Alkalies, Caustic Soda, Liquor Potassae. The lethal dose is about 150 to 300 grains Injuries due to ingested alkali are treated by the use of weak acids such as vinegar water, sour wine, tartaric acid, citric acid, lemon juice or apple juice and milk. Washing of the stomach with acidulated water (a teaspoonful of vinegar to 500 ml. water) may be used, but with caution For alkali in the eye, water is used [illegible] with a medicine dropper, if available. [illegible] lid up and wash. For lime in the eye [illegible] onful to 1,000 ml.) may be used as a wash, but with great caution.

Ammonia The lethal dose of caustic ammonia solution is 1 ounce. When the esophagus and stomach are eroded, the treatment is the same as for injury from

Colchicine. The lethal dose is 1/3 grain The stomach is emptied, and milk or 2
[illegible] may be necessary
[illegible] 'thal dose is 150 to 300 grains. Gastric lavage
[illegible] tash (1:1,000 solution) is performed After the lavage, albumin of 1 egg is instilled into the stomach and a comparable dosage of egg albumin is given each 4 hours The oral administration of magnesium oxide, potassium iodide and charcoal is a valuable treatment

Croton Oil. Administer mucilaginous and oily substances. Opiates may be necessary to allay tenesmus from frequent bowel movements.

Crude Petroleum. See Benzene Poisoning, page 1396.

Cyanide. The lethal dose of hydrocyanic acid is 1 grain, the lethal dose of potassium cyanide is 3½ grains If cyanide is swallowed, apomorphine (5 mg) is administered subcutaneously unless muscular cramps are present. After the patient has vomited, gastric lavage with 1 2,000 solution of potassium permanganate or 2 per cent solution of hydrogen peroxide and charcoal is performed Methylene blue, 50 ml., administered intravenously, followed by intravenous injection of 50 ml. of a 2 per cent solution of sodium hyposulfite, given slowly, may be used in all instances of poisoning with this chemical The administration of 20 units of insulin may be helpful. Artificial respiration (with oxygen) is used if necessary and if time permits.

If cyanide is inhaled, emetics and washing out the stomach are not helpful.

DDT. The stomach is lavaged with warm water. Five to 10 ml of a 10 per cent solution of calcium gluconate may be given intravenously. If convulsions occur, atropine and barbiturates may counteract them Glucose may be administered orally or parenterally if sufficient fluids cannot be taken by mouth. (See DDT Poisoning, p 1412.)

Digitalis The lethal dose of digitalis varies through wide limits. Forty to 50 grains of the leaves or 1 ounce of the tincture are considered lethal. The stomach is lavaged, and atropine, alcohol, tea, and coffee may be administered Often death can be prevented if physical effort is avoided. If necessary to procure absolute rest, the patient, including the arms and legs, may be wrapped tightly in a blanket or a bed sheet

Ephedrine Immediate gastric lavage is performed and sedatives are administered.

Ergot (Secale cornutum, Aconite) The lethal dose is 16 to 64 grains of ergotamine. Gastric lavage is performed immediately Opiates, amyl nitrite or nitroglycerin may be administered in adequate doses

Formaldehyde (Formalin) The lethal dose is 1 ounce of the 4 to 40 per cent solution Immediate gastric lavage, followed by the administration of 6 raw eggs, should be performed Administration of urea in doses of 20 grains may be repeated. Cutaneous injuries may be washed with dilute ammonia or ammonium carbonate When the poison is in the eye, treatment with weak ammonia vapors is safe.

Insulin Insulin shock is treated by the immediate administration of fruit juices of any kind by mouth If the patient is unable to take liquids by mouth, 20 ml. of a 10 per cent solution of dextrose is given intravenously. If shock is severe, 0.5 ml of 1.1,000 epinephrine solution subcutaneously may precede the administration of the dextrose.

Iodine, Iodoform, Tincture of Iodine The lethal dose of iodine is 48 to 64 grains; of iodoform, 128 grains; of tincture of iodine, ⅔ to 1 ounce. Immediate gastric lavage is performed and is followed by the instillation into the stomach of a solution of starch or of a solution of sodium bicarbonate.

Iron Large amounts of iron are required to kill The stomach should be lavaged with generous amounts of warm water followed by the administration of milk and egg albumin

every 30 minutes may be given until reflexes return. Thereafter small doses intramuscularly should be used until full consciousness is restored.

Picrotoxin is used in doses of 1 to 3 mg. dissolved in physiologic saline solution and administered slowly intravenously. Picrotoxin should not be given if there is a weak heart or pulmonary edema.

Caffeine is not nearly so effective a respiratory stimulant as metrazol but may be used if necessary, as caffeine-sodium benzoate administered subcutaneously.

Barium Chloride and Barium Nitrate. The lethal dose of barium chloride is 48 grains; of barium nitrate, 48 to 64 grains Gastric lavage with a solution of sodium sulfate (500 grains to a quart of water) is employed. Milk, albumin or tannin may be left in the stomach after lavage.

Benzine, Benzol and Kerosene Benzine is a distillate from petroleum, whereas benzene is a distillate of coal tar The lethal dose of benzine is about the same as of benzene, ⅓ to 1 ounce (see Benzene Poisoning, p 1396), of benzol, 1 ounce. In acute poisoning with benzine or benzol the stomach is lavaged with tea, and cardiac stimulants are administered if necessary. For kerosene poisoning, see Petroleum, page 1399

Bismuth The symptoms and treatment are the same as those of mercury poisoning

Boric Acid The stomach may be lavaged with a solution of sodium bicarbonate if the boric acid has been taken orally Sodium lactate may be administered to correct acidosis. Parenteral administration of chlorides to counteract displacement of boron in body fluids is valuable treatment. (See also Boric Acid Poisoning, p 1418.)

Bromides. Gastric lavage is done if the patient is seen immediately after ingestion of the drug If not, caffeine is given subcutaneously and sodium chloride, a 1 per cent solution, is administered intravenously (see Bromide Intoxication, p 1417).

Calabar Bean Gastric lavage is used if the patient is seen early after ingestion of the beans Atropine is an antagonist to the action of calabar beans and should be given hypodermically until the pupils dilate. Strychnine hypodermically, strong coffee and brandy orally, and artificial respiration are appropriate measures as the occasions arise for their use

Cantharides. After the stomach is emptied, mucilage of acacia is given to soothe; anything fatty or oily is avoided until gastric irritation has subsided

Carbolic Acid The lethal doses by mouth of phenol, lysol, and compound cresol solutions are ¼ to ½ ounce Emetics, lime water, magnesium sulfate, magnesium oxide and milk, are administered. Stimulants may be necessary immediately. Later in the illness opiates may be necessary for the pain

Carbon Monoxide Illuminating gas, trench gas and carbonic acid gas contain carbon monoxide. The patient must have fresh air or oxygen inhalations In severe injury, venesection (letting of 300-500 ml. of blood) followed by injection of physiologic saline solution, 600 to 1,000 ml., is beneficial Muscular infusion of physiologic salt solution may be helpful during succeeding hours

Chloral Hydrate. If the victim is seen immediately, the stomach is lavaged. After sleep has become established, stimulants are administered.

Chlorine Gas and Similar Gases From Fluorine and Bromine. The inhalation of the hot vapor of weak ammonia, or vapor from a solution of 48 grains of sodium hyposulfite containing 12 grains of sodium carbonate or a teaspoonful of sodium bicarbonate in 5 ounces of water is comforting treatment

Cocaine and Eucaine. The lethal dose is 16 grains. If the patient is seen immediately, gastric lavage is performed and 200 to 300 ml of tea or coffee is instilled into the stomach Atropine (1/100 grain) may be given subcutaneously, or amyl nitrite inhalations may be tried Artificial respiration may be necessary.

Picric Acid. Poisoning with picric acid is treated by gastric lavage and the free administration of water by mouth.

Picrotoxin In treatment for barbiturate poisoning, picrotoxin may be given in excessive doses or accidentally administered There is no known antidote. Convulsions may be partially controlled by administration of chloroform (chloroform administered in the manner of chloroform *à la reine*).

Potassium Chlorate. The lethal dose is 80 to 240 grains. The stomach is washed and if necessary oxygen inhalations and venesection (500 ml.) are administered. The administration of acids, lemonade or acetates is avoided.

Pyrethrum. This poison is present in rotenone, a pesticide. The stomach is thoroughly washed with warm water, and 300 ml. of black coffee is instilled into the stomach. Artificial respiration and oxygen therapy may be necessary

Quinine. Thorough gastric lavage is followed by the instillation of 300 ml. of black coffee into the stomach Large doses of charcoal may be given.

Salicylic Acid (Sodium Salicylate and Aspirin). The stomach is cleansed with water or with a 1:1,000 solution of permanganate of potassium. One hundred milliliters of 1 per cent solution of sodium chloride is given intravenously Alkalies are not given unless the carbon dioxide-combining power and the blood pH are known. Dire results may ensue if an alkali is administered during the early phase of the respiratory alkalosis Alkalies may be necessary during the later phase of acidosis. Sedatives are administered for the hyperpnea and excitability.

Santonin. Santonin is lethal in doses from 1½ to 5 grains. Poisoning is treated by gastric lavage followed by chloral hydrate, 5 grains, repeated for the colicky pains If collapse has taken place, artificial respiration is given

Silver and Silver Nitrate. The stomach is washed out thoroughly with a solution (10 to 20 gm to 1,000 ml) of salt, and 30 ml of castor oil is given.

Sodium Hypochlorite and Sodium Hyposulfite Gastric lavage is performed with generous amounts of warm water or a weak solution of vinegar.

Strychnine. The lethal dose varies but is less than 20 grains. Apomorphine (5 mg.) is administered subcutaneously Rectal instillation of 15 grains of chloral hydrate and chloroform inhalations are useful Morphine is not used if artificial respiration seems necessary Venesection with letting of 500 ml. of blood has seemed to be helpful if followed by saline infusions

Sulfonal. The lethal dose is 160 to 480 grains. If the patient is seen immediately, the drug is removed by gastric lavage Artificial respiration, stimulants, epinephrine, picrotoxin or metrazol may be needed as in barbituric acid poisoning.

Sulfur and Sulfides Often artificial respiration and oxygen therapy are necessary. Venesection of 500 ml of blood followed by muscular infusion of physiologic saline solution is a recognized procedure Some good may be obtained from the administration of a solution of colloidal iron intravenously.

Thallium Gastric lavage with sodium thiosulfite is performed and 30 ml. of 3 per cent solution of sodium thiosulfite is administered intravenously BAL may be used as it is used for poisoning with arsenic (see Arsenic, p. 1422).

Turpentine. Gastric lavage with generous amounts of warm water or weak sodium bicarbonate solution is performed. Saline cathartics are recommended.

Veratrum Viride Lugol's solution in 15 minim doses is administered, and the patient is kept lying down and comfortably warm Artificial respiration and oxygen therapy may be necessary

Zinc (Zinc Chloride, Zinc Sulfate). The lethal dose is 80 to 160 grains. Gastric lavage with solution of sodium carbonate or of sodium bicarbonate, if the carbonate is not immediately available, is followed by the instillation of 300 ml of strong tea into the stomach Milk is given by mouth.

Lead Salts. These are lead acetate, white lead, lead oxide and red lead. The acute poisoning is treated by gastric lavage followed by the instillation of weak solution of sodium sulfate (1 per cent solution) into the stomach. Eggs, milk (eggnog), and charcoal may be given Lead colics are treated by opiates, atropine, belladonna and warm enemas

Lye The stomach is lavaged with dilute vinegar or lemon juice. Cream may be given by mouth. If more than an hour has elapsed since ingestion of lye, lavage is avoided and only aspiration of secretions from pharynx performed. Oral administration of olive oil in small amounts is made frequently Opiates may be required to allay the pain.

Mecholyl Atropine sulfate should be administered in doses of 0.25 to 0.6 mg. intravenously ($\frac{1}{250}$ to $\frac{1}{100}$ grain). If asthmatic attack is precipitated, epinephrine in the usual doses as indicated is employed. If the patient is in shock, administration of plasma or whole blood may be beneficial

Mercury (Corrosive Sublimate, Bichloride of Mercury). The lethal dose of corrosive sublimate is 8 grains. The mouth and stomach are washed with a solution of sodium perborate An eggnog is instilled into the stomach Infusions of dextrose and sodium bicarbonate are helpful

Methyl Alcohol (Methanol, Wood Alcohol) The lethal dose is 3½ ounces. Immediate gastric lavage is effected Venesection, letting from 500 to 750 ml. of blood, may be helpful. The patient is kept warm. Oxygen inhalations and stimulants such as caffeine and strychnine may be helpful in the presence of profound intoxications

Morphine (Opium, Codeine and Dionin) The lethal dose for adults is about 7 grains by mouth, about 4 grains subcutaneously; for children, $\frac{1}{15}$ grain The stomach is washed with 1 1,000 solution of potassium permanganate followed by the instillation of 300 ml of black coffee. Stimulation is applied to arms and legs to keep the patient awake if possible Artificial respiration may be required. The administration of atropine sulfate ($\frac{1}{100}$ grain subcutaneously, repeated) may be beneficial Strychnine sulfate, $\frac{1}{40}$ grain, may be given

Naphthalene (Moth Balls) A generous gastric lavage with water is the immediate treatment Oils are to be avoided, since moth balls are soluble in oil

Nicotine In pure form nicotine is lethal in doses of ½ grain Thirty to 50 grains of snuff or 75 to 200 grains of tobacco are considered to be lethal doses The effects of nicotine may be somewhat combated by the administration of morphine, ¼ grain, and atropine, $\frac{1}{150}$ grain, subcutaneously.

Nitrates Gastric lavage and external stimulation are the preferable treatment.

Oxalic Acid (Acid Potassium Oxalate). The lethal dose is 40 to 112 grains The stomach is washed with a solution of calcium, chalk lime or magnesium oxide. Subcutaneously or intravenously, 30 to 60 grains of calcium chloride in a quart of physiologic saline solution is administered.

Phenolphthalein To confirm diagnosis, a pink color should develop in the lavaged material on the addition of alkali. Phenolphthalein is present in cathartics such as analaz, ex-lax, phenolax and in some chewing gums.

Phosgene. Treatment for phosgene poisoning is given intravenously with injections of 10 ml. of 5 per cent solution of calcium chloride. The inhalations of the vapor from sodium bicarbonate solution (0.25 per cent solution) are comforting Venesection and the administration of 100 ml. of a 5 per cent solution of dextrose may be helpful.

Phosphorus. The lethal dose is about $\frac{1}{16}$ to 1 grain. The stomach is cleansed with a 1:1,000 solution of potassium permanganate. A solution containing 15 grains of copper sulfate is instilled into the stomach. The administration of sodium bicarbonate and lime water by mouth is helpful Milk, egg yolk, a [illegible] are avoided. Phosphorus burns are painted with a 10 per cent solution of silve

repeated dental trauma over a long period, but only one, finger biting and toe biting, can be called a bite.

Dog Bites and Cat Bites. Owing to the configuration of the teeth of carnivorous animals which are designed to puncture and tear flesh, the bite of the dog, cat or any other carnivorous animal will be characterized by puncture wounds where the tusks enter the flesh and by tears. Such wounds are always heavily infected.

These wounds when made prior to death show evidences of trauma and hemorrhage. If made after death, they show no evidence of hemorrhage. There is a clean removal of tissues with jagged, chewed edges Sometimes the skin of the dead may be torn away over a wider area than that where the flesh has been eaten. The gnawing of the body of the dead, either man or animals, by rats produces the characteristic excavations made by these animals on cheese, wood, or any other solid material. There is a clean rough-edged removal of tissue which contrasts sharply with the jagged-edge wounds inflicted by the carnivora.

Cat Scratches and Cat-Scratch Disease (Nonbacterial Regional Lymphadenitis). The disease apparently is widespread. It has been reported as having occurred in many cities of the United States and France According to Daniels and MacMurray the first reported cases were associated with cats. The disease may be due to cat bite, injury to the skin by beef bone, thorns, wood splinter, mosquito bite, and laceration while butchering pork. The disease is probably due to a virus of the psittacosis-lymphopathia venereum group of viruses.

The patient is not severely ill, although in the early stages the temperature may be elevated and occasionally may reach 104 F (40 C) Headache is common but chills are rare A rash, either macular or vesicular, appears early in the disease, lasting 2 days The leukocyte count is usually normal but may be slightly elevated Erythema nodosum has been described

On examination a cutaneous lesion is present in one half of those incapacitated by this disease. The lesion develops at the site of a scratch or other injury to the skin. It may consist of a slightly raised erythematous nodule or plaque surmounted by a vesicle, pustule, or scab which may simulate a furuncle. The cutaneous lesion usually appears within a few days of inoculation However, it may not develop until after the regional adenopathy appears

Regional adenopathy may appear in 4 days after the cutaneous lesion, or its appearance may be delayed for as long as a month One or more regional lymph nodes may become so enlarged as to be evident on simple inspection.

In the limbs adenopathy is unilateral, involving the epitrochlear and axillary regions or the femoral or the inguinal regions More than half of the patients have involvement of lymph nodes of the head and neck, and of the anterior cervical, the posterior cervical, the submaxillary, the submental, or, occasionally, the occipital lymph nodes The nodes may remain movable and nontender or may become tender and progress to suppuration

The diagnostic skin test originated by Hanger and Rose according to Daniels and MacMurray utilizes the principle of the original Frei test. Pus is diluted 1 part to 5 parts with isotonic sodium chloride solution and heated at 56 C for 1 hour on 2 successive days. The test is performed by injecting 0.1 ml of the material intradermally and the result is read in 48 hours, when the reaction is maximal. A positive reaction is comparable with the tuberculin reaction and consists of a raised indurated papule measuring 0 5 to 1 0 cm. in diameter, surrounded by an erythematous areola measuring 3 to 5 cm or more in diameter. Rarely, the injection of antigen activates the primary lesion and may be associated with a rise in temperature

Rats and Rat Bites. Rats harbor and transmit the infectious organisms responsible for some 20 diseases of man. Some are serious and some are not. The

20

INJURIES AND DISEASES DUE TO ANIMALS AND PLANTS

INJURIES AND DISEASES DUE TO BITES AND STINGS OF ANIMALS OR TO INGESTION OF FISH OR MUSSELS

The natural method of injury to an opponent varies somewhat in different animals In the lower forms of life the methods of inflicting injury often are analogous to those employed in obtaining food, as exemplified in parasitism. The free-living animals of the lower orders inflict injury by employment of the sucking or biting apparatus, again as in obtaining food Many species of animals, right on up to and including man, use their bite for inflicting wounds for their protection.

Certain insects are provided with stingers equipped with adjacent apparatus for the injection of venom The sting and the venom too are apparatus employed for the getting of food

Certain reptiles such as serpents are equipped with fangs which are employed in the injection of venom These animals inflict wounds by their teeth and inject venom in order to kill their opponents for food or for protection to themselves

It is thus evident that the wounds inflicted by an animal for protection are usually analogous to wounds inflicted in obtaining food.

Human Bites. There are two considerations pertaining to human bites. (1) infection and (2) the presence of crushed tissues The lesions include necrosis of soft tissue and, as is often the case if the bite has been placed on the hand, tenosynovitis, and infections of the thenar and palmar spaces and the dorsal subcutaneous subaponeurotic space are common. Osseous and articular involvement may be obvious or it may be revealed on roentgenologic examination. The constitutional reaction to the infection is manifested by chills, elevated temperature, headache, malaise and leukocytosis The possibility of a bite should be borne in mind in any injury to the hand, particularly in one in which there is a foul discharge, and endeavor should be made to elicit the true history. The treatment, in early stages, for injury from a human bite is the conversion of the anaerobic state to an aerobic state and the excision of devitalized tissue in which the fusiform bacillus and spirochete might readily grow in symbiosis

A human bite is infected but it rarely is the means of transferring infections, that is, syphilis or rabies

Dental Injury. A distinction is made between a bite and a dental injury, either a self-inflicted bite or a bite by another person Hitting any part of the body against another person's teeth and sustaining an injury should not be called a bite For instance, a wound of a knuckle incurred by striking an opponent is correctly called a human tooth wound. Likewise a dental injury may be incurred from pressure in the process of finger sucking, or in lip biting, a nervous habit in which the lips may be accidentally injured. The affected person cannot resist these habits. In the case of finger sucking, a child will not fall asleep unless with his index finger all the way in the mouth. The lesion thus produced is similar in appearance and consistency to the lesions due to the actual chewing of the skin. Both are calluses from

tortrix). This snake inhabits high dry ground in the vicinity of swamps or marshy glades in parts of the eastern and all of the southern United States. The copperhead attains a large size, is vicious, and very dangerous.

Coral Snakes. The coloration and the body conformation of coral snakes are similar to those of a variety of harmless snakes For the purpose of quick identification it should be remembered that in the coral snakes the black rings over the back are broad and are bordered by narrower yellow rings, whereas in the nonpoisonous snakes of similar appearance the yellow rings are the wider and are bordered by black. Thus the rule. poisonous, narrow yellow-broad black-narrow yellow; nonpoisonous, narrow black-broad yellow-narrow black, in relation to the borders of the wide body stripes The coral snake is gentle and sluggish when handled; hence it too often is considered harmless Even after this snake has bitten a human being the wound, or series of wounds, because the coral snake does not strike like the vipers but rather tends to chew, are insignificant in appearance and may be ignored until serious symptoms develop.

After bites of a very small coral snake there may be only mild symptoms which appear in 15 minutes to an hour after the injury, with only slight pain at the site of the bite or bites There are dullness, apathy and weakness. When the bite is by a larger snake, there is pain at the site of the bite, and soon there are vomiting, profuse salivation, paralysis of the tongue and larynx, and in fatal instances death results from respiratory paralysis In all, the pulse is rapid and weak The pupils are often widely dilated and insensitive to light

Rattlesnakes, Moccasins and Copperheads The vipers bite by striking A strike will be made when the snake is provoked in any quarters, but when a person is bitten while handling the snake, the consequences may not be so serious as when the bite is given under more favorable conditions for the snake.

The maximal effective strike is made when the viper is coiled. Thus poised, the snake can make a strike at a distance equal to two thirds of the length of its body The strike, under these conditions, is delivered with a great deal of force, that is, a small dog will be knocked off balance by the strike. Stoic human beings describe the impact as stunning, at the moment they do not realize that they have been bitten by a snake The impact is so strong it is thought to be a quick violent blow of some sort As soon as the patient realizes what has happened, intense anxiety ensues

Symptoms Immediately after the bite, there is an intense burning pain at the site of the wound, swelling and darkening discoloration of the skin quickly spread and within a few hours may involve the entire bitten limb. There are immediate nausea, vomiting, giddiness and faintness, and within a very short period after the bite it may be difficult or impossible for the victim to walk In from 1 to 3 hours prostration and coma may be present The body is covered with cold and clammy perspiration The temperature falls below normal, the pulse becomes imperceptible, and death may result from paralysis of the upper nerve centers, usually a respiratory failure, for, as stated, all venoms contain varying amounts of the neurotoxin. If the patient survives, there is fever, and the course of the fever depends on the supervening infection which is always present.

Usually the severe constitutional symptoms pass off slowly, and by the second day the sensorium has cleared, the pulse is stronger, and the sweating has ceased

By the end of the first day the hemotoxic properties of the venom are becoming fully manifested The injured extremity is ecchymotic in appearance and the ecchymosis extends proximally in the bitten limb and often is manifested over other parts of the body The bitten limb is greatly swollen and there may be a generalized edema, with the face more profoundly affected than other parts of the body Vesicles containing hemorrhagic material form in the skin near the bite The site of the bite with surrounding parts may slough away and gangrene may supervene.

Owing to the hemotoxic qualities of the venom, jaundice is an almost constant

serious diseases transmitted by rats are bubonic plague, typhus and rat-bite fever Richter reported that he had observed that over a four-year period almost 25 per cent of the people in a rather large area in an American city had been bitten by rats Most of the bites were unimportant clinically, but hospital treatment was sought by nearly 100 persons from this area. In about a tenth of those who received hospital treatment for rat bites, rat-bite fever developed Uncaptured rats bite man, alive or dead, because they are hungry and they will continue to chew on him unless frightened away The situation cited is presumably not any worse than that in most other cities, and on farms Rats need no longer be endured since the advent of rat poisons which cause internal hemorrhages

Venom, Snakes and Snake Bites. Venom. Venom, composed of modified proteins, is the poisonous substance of the bites of some animals In the snakes it is secreted by glands connected by ducts to the poison fangs. The glands are analogous to the parotid glands in mammals The venom is squeezed out into the hollow fangs by contraction of the temporal muscles.

Venoms obtained from snakes, spiders, scorpions and other sources have proved to be highly antigenic substances. Protection against the action of venom has been obtained by the injection of antitoxins prepared in animals. Professional snake charmers, apparently immune, may have been immunized by injection of a particular preparation of venom These performers, however, before their act often cause their serpents to strike some object a sufficient number of times to exhaust the supply of venom

All snake venom contains mixtures of neurotoxins and hemotoxins, and the venom of all poisonous snakes contains some of the neurotoxic element which affects the higher nerve centers Immediate death (within a day) from snake bite is caused by respiratory paralysis The venom of the coral snake (like that of the cobra) is nearly all neurotoxins It acts on the nervous system, causing respiratory paralysis if injected in sufficient amount The venom of the vipers acts mainly on the vascular system, destroying erythrocytes and weakening the walls of the smaller blood vessels

Venom is not poisonous if it gets in the mouth (of a person who is sucking the bite of a snake or a spider on himself or other victim), for it is immediately destroyed by digestive ferments

Snakes. In the United States of America there are two groups of poisonous snakes, namely, the coral snakes and the pit vipers.

The coral snakes (family Elapidae, species *Micrurus fulvius,* and the subspecies *Micrurus* of Florida, Tennessee, Mississippi to Mexico) inhabit an area along the seaboard from the North Carolina coast southward, and westward along the Gulf coast to the Rio Grande River. The subspecies *Micruroides euryxanthus* is found in southern Arkansas, and in New Mexico and Arizona The northern limit of distribution is about latitude 35 degrees N

Of the pit vipers (group Viperidae, family Crotalidae) the rattlesnakes (species *Crotalus horridus,* the timber rattler, *Crotalus adamanteus,* the diamondback rattler, and the genus *Sistrurus* or pigmy rattler, and their variations, totaling some 15 to 18 subspecies) are the most widely distributed

A second pit viper in the United States is the water moccasin (*Agkistrodon piscivorus*), which lives along streams in the South It is the largest of the vipers, attaining up to 6 feet in length, and the most poisonous because of its correspondingly large dose of venom Many persons, believing that the water moccasin will not bite while in the water, have received bites from this snake. While in the water it not only can and will bite, but it is ready to bite. When the snake is under the water, it cannot strike hard enough to embed the fangs, but strike it will even while submerged Often it will slide from the limb of a tree, an habitual resting place, into the stream, swim to the water's edge, and rest on the bottom with its head above the surface, and body resting on the bottom, in which position it is ready for the strike.

A third pit viper is the copperhead (species *Agkistrodon mokasen,* synonym *con-*

has been discovered, its head and much of its body have been beaten into a pulp, so that it is not recognizable, even if available for identification.

If there is a good full pulse 2 hours after the bite, treatment should be instituted for wound infection as well as for the bite of the viper. If the patient is suffering no ill effects 2 hours after the bite no antivenin should be given.

One of every 5 persons bitten by poisonous vipers dies. The prognosis depends largely on the size of the snake and thus on the dose of venom injected. The period of disability is often of months' duration, owing to anemia and infection.

Antivenin is often available. It should be given up to ten hours after the bite if symptoms of poisoning have followed the bite.

Treatment for Snake Bites. *Local measures* are instituted to delay passage of the venom from the fang wound to the vital organs. Since much of the poison may be held for several hours in the edematous region surrounding the bite and absorbed gradually through the lymphatics, it may be removed in part by suction before it can permeate the body.

1 Apply tourniquet continuously to the limb about 2 inches above the bite, tightening it until the pulse can be felt faintly Do not pull it tightly enough to arrest the arterial circulation but only enough to restrict the venous and lymphatic return When a tourniquet is tightly applied and then loosened at intervals (15 to 20 minutes) the patient may go into shock. Shock may occur under these circumstances from sudden release of dammed blood if the tourniquet has not been loosened at the time interval specified, or it may result from the sudden release of venom into the circulation. (It should be possible to force a finger between the skin and the tourniquet.) If the limb becomes numb and cold, the constricting band is too tight. As swelling advances, move the tourniquet farther up the bitten limb

2. Cleanse with iodine the site of the bite and also the sharp instrument to be used for the incisions. Make incisions (preferably puncture wounds) ¼ inch deep, at the point where the fangs entered the skin and as swelling advances along the limb, make additional incisions at the edges of the swollen areas. For the bite of timber rattlers or other large snakes, deeper cuts may be necessary In cutting, be careful not to sever a large blood vessel, or a tendon, and avoid injuring the covering of bone. Apply suction by mouth, cupping glass or breast pump to produce free bleeding from these cuts. Viper venom does not readily penetrate the intact mucous membranes The mouth and throat may be further protected from infection by rinsing and gargling with dilute solution of potassium permanganate Swallowed venom is destroyed by the digestive juices in the stomach

3. Continue suction at the original bite and at each incision for periods of 15 or 20 minutes during each hour In the intervals between suction periods at each site, cover the individual wounds with cloths saturated with a strong solution of table salt or epsom salt in water

ANTIVENIN. As soon as possible (best within 2 hours) after the bite, antivenin should be administered and the tourniquet removed Antivenin may be given by the layman if a physician cannot soon be reached Prompt injection of sufficient antivenin prevents death in most patients, relieves pain and other local and general symptoms, aborts the serious effects, and shortens convalescence It is never too late to administer antisnakebite serum, and lives have been saved by injection of large doses even when the victims were apparently dying The danger is in undertreatment. Directions for administration of the antivenin are contained in the package

Refrigeration in the Treatment of Venomous Bites. Local refrigeration obtained by means of packing in ice the part injured by the bite of a snake or a spider is an efficacious method of treating such an injury It will control the pain, reduce swelling, retard absorption and promote the serous flow after incision and during suction

The treatment of snake bites by local refrigeration need not prevent treatment by the conventional methods such as incision, suction and the venous tourniquet. However, in all instances, it would be well to employ local refrigeration as soon as

feature following the bite of a viper. The jaundice may be clinically detectable at the end of 24 hours, and in the days immediately following may become intense

DIAGNOSIS The vipers theoretically have distinctive and characteristic bite patterns (Fig. 20-1A), owing to the arrangement of teeth and fangs This bite pattern, if well sustained, may be distinguished from that of the nonpoisonous snakes (of the United States) by the points of entry of the two fangs accompanied by the injury inflicted by a single row of jaw teeth, whereas in the nonpoisonous snake there are no double-pointed fang punctures of the skin. There is only a series of injuries corresponding to the double row of jaw teeth (Fig. 20-1B).

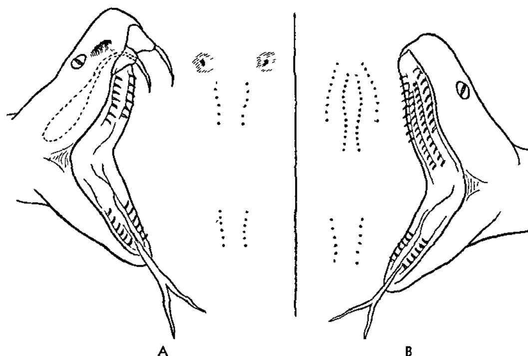

Fig 20-1. Mouth parts and types of wounds inflicted by them A, viper, poisonous snakes. B, nonpoisonous snakes

In practice these theoretic distinguishing features are often modified. The viper is rarely afforded a free range of movement in order that it may inflict a distinguishing wound. The strike is made obliquely on a moving object, for example a human limb, often one covered by clothing of uneven texture The cutaneous wound is a series of superficial scratches with one or two linear tears where the fang or fangs have entered Often one or both of the fangs are torn from the snake's mouth and left in the skin or the clothing

It is thus evident that immediately after the accident the differential diagnosis between the wound inflicted by a poisonous snake and that of a nonpoisonous snake is often difficult. In addition to these technical difficulties in differential diagnosis, man, and in fact all mammals, are inherently afraid of snakes The patient, if of nervous temperament, has abandoned all hope of survival and lies motionless, or may be difficult to keep quiet on account of fear. Commonly, as soon as the snake inflicts the bite, irrespective of whether the snake is poisonous, the skin and tissues about the wound are cut with a knife by the patient or by well-meaning friends Then the bites and the lacerations are sucked and often chewed by someone A tourniquet is applied, almost always too tight; as a result there are circulatory disturbances. In addition, the offending snake has usually crawled away, or if it

has been discovered, its head and much of its body have been beaten into a pulp, so that it is not recognizable, even if available for identification.

If there is a good full pulse 2 hours after the bite, treatment should be instituted for wound infection as well as for the bite of the viper. If the patient is suffering no ill effects 2 hours after the bite no antivenin should be given

One of every 5 persons bitten by poisonous vipers dies. The prognosis depends largely on the size of the snake and thus on the dose of venom injected. The period of disability is often of months' duration, owing to anemia and infection.

Antivenin is often available. It should be given up to ten hours after the bite if symptoms of poisoning have followed the bite.

Treatment for Snake Bites. *Local measures* are instituted to delay passage of the venom from the fang wound to the vital organs. It will control the pain, reduce swelling, retard absorption and promote the serous flow after incision and during suction

The treatment of snake bites by local refrigeration need not prevent treatment by the conventional methods such as incision, suction and the venous tourniquet. However, in all instances, it would be well to employ local refrigeration as soon as

possible, even though incision, suction and venous tourniquet has been employed before it was possible to use local refrigeration.

Ice packs have long been recognized as being helpful in the treatment of the bites of the black widow spider Frequently these bites are so situated that a venous tourniquet cannot be efficaciously applied

Gila Monsters. Gila monsters (species *Heloderma suspectum* and *Heloderma horridum*) are orange-and-black venomous lizards (beaded lizards) 10 or 12 inches in length or longer, which live in the deserts of Arizona and Mexico. Their poison-producing apparatus is situated in the lower mandible. The venom is secreted by the submaxillary glands, which are connected with grooved teeth. This animal bites while lying on its back.

The venom seems to contain considerable neurotoxin. Immediately there is sharp pain at the site of the bite, and there at once ensue weakness, nausea and vomiting There is weakness of the muscles and perhaps flaccid paralysis Dyspnea, venous congestion and cardiac dilatation with fast pulse are common symptoms In fatal bites death is from a respiratory paralysis

The diagnosis is usually obvious, for these sluggish animals are easily identifiable

Fish. Fish have frequently been implicated in *food poisoning*, particularly in tropical or subtropical areas However, it is evident from the following brief remarks that there seems to be much in common between this fish poisoning and staphylococcal food poisoning

In from 1 to 6 hours after eating the poisonous fish, the patient complains of a distinct metallic taste in the mouth and appears critically ill with severe gastrointestinal symptoms of nausea, vomiting, and diarrhea The skin becomes flushed and there are tingling and itching that may last for days Cramps in the extremities may occur Subsequently there may be weakness in the legs with possible temporary paralyses with reduced or absent knee jerks Hyperesthesias and paresthesias are commonly associated For instance, the patient interprets a cold object as feeling warm, or cold food as being hot, this effect in association with the metallic taste in the mouth is characteristic of fish poisoning There may also be associated nervousness, restlessness, or insomnia, albumin and casts in the urine and frequency of urination are prominent symptoms The illness may last from 1 to 3 weeks with gradual but certain recovery.

The symptoms differ from those reported following ingestion of certain Tetrodon fish found in Hawaiian and Japanese waters in which the active toxin, a leukomaine, has been isolated. In these instances the onset often appears within 15 minutes, and while gastrointestinal symptoms predominate there is a marked burning sensation The mortality rate is high. In lethal instances death occurs soon

Treatment for these poisonings is accomplished by immediate gastric lavage followed by the administration of castor oil (2 ounces).

There are a number of *salt-water fishes* which may injure sea bathers and novice fishermen by their *bites, stings*, or *body secretions* The eels of the genus *Muraena*, family Muraenidae, have specialized teeth associated with venom-secreting glands The venom is delivered onto the wound The various ray fish or sting rays, the Trygonidae, can inflict wounds The sting ray has a tail armed on the dorsal side with a barbed spine which in some species is capable of inflicting a poisonous wound Some ray fish, if stepped on in the water, may inflict a wound and contaminate it with tetanus The electric sting ray, family Torpedinidae, has a positively charged dorsal surface and a negatively charged ventral surface, and if an arm or a leg of a human swimmer makes contact with these two surfaces, it is temporarily paralyzed *Trachinus draco*, which resembles a trout, has a grooved spine passing through each gill which is equipped with a poison-secreting gland

Scorpaena scropha, a red fish with a large head and prominent fins, has a poison-producing gland connected with the first three rays of the dorsal fin. A person striking one of these fins experiences sharp pains at the point of contact. Soon a sensation of suffocation follows, delirium develops quickly, and death may ensue. First the area of skin about the wound is reddened, then it turns black and becomes gangrenous. These injuries should be treated with the same measures employed for snake bites except for the use of antivenin

In the United States the *fresh-water catfish* such as *Ameiurus* has a lancelike spine near the gills which may penetrate the hand while the fisherman is removing the fish from the crevices in rocks in which it has sought refuge from the noise and the muddying of the water resulting from the hunt. The small penetrating wounds from the lancelike spine are exceedingly painful and may be followed by severe systemic reactions and bad local infection.

Shellfish. Outbreaks of *mussel* or *clam poisoning* have occurred from Juneau, Alaska, to Southern California and the Gulf of California, Mexico

Shellfish poisoning, mytilotoxism, has been reported in certain shellfish in Nova Scotia. In a survey of commercially important shellfish areas of this region it has been found that paralytic shellfish poisoning is due to the shellfish from the Bay of Fundy only, off the coast of New Brunswick (Sommer and Meyer).

The poisoning is obtained from consuming shellfish or mussels which feed on the dinoflagellate *Gonyaulax catenella* The poison has not been identified, but it has been isolated and proved to belong to the class of alkaloids resembling strychnine, muscarine and aconite The poison has been isolated by chromatographic fractionation. It has been crystallized as rufinanate, helianthate and reineckate The purest preparation of mussel poison has a toxicity of 4 mouse units per microgram The concentration of mussel poison is expressed in mouse units of the poison contained in 100 gm of clam or mussel meat

This poison is one of the strongest known It is an alkaloid and is contained in plankton (*Gonyaulax*), comprising animal and plant life, a food for mussels In many parts of the southern United States it is traditional that fresh water mussels are poisonous, and consequently they are not eaten No specific treatment has been found for this disease.

About 15 minutes after poisonous mussels are eaten, there is nausea but not vomiting, and a feeling of drowsiness may ensue From 1 to 24 hours after ingestion of the mussels a general numbness around the lips, chin and cheeks and in the extremities is felt There is often a complete loss of power of the muscles of the extremities and neck A respiratory paralysis may ensue. Usually the numbness gradually disappears after 24 hours

Jelly Fish. Jelly fish (Medusae, genus *Obelia*) poison by ejecting barbs which cause a numbing effect and swelling and redness of the skin Occasionally there are urticaria and shock from this poison

Corals. Corals are formed by Coelenterata and Zoantharia (genus *Actiniaria*). When contact is made on abrasions, immediately there occur small blisters which itch, and irritation around the blisters is evident The whole area of skin affected becomes edematous

THE BITES AND STINGS OF INSECTS

Centipedes. The small centipedes (class Myriapoda) of temperate climates are often incapable of penetrating the skin, and their bites seldom produce more than mild, local symptoms In the southern United States two species, *Scolopendra heros* and *Scolopendra morsitans*, 10 to 15 cm in length, inflict painful bites. The larger tropical species, such as *Scolopendra gigantea*, 25 to 30 cm. in length, in addition to causing necrotic local lesions, may produce general symptoms of lymphangitis, fever, vomiting and headache.

Beetles. Beetles are facultative or incidental parasites of man. Canthariasis of the digestive tract, urinary system, nasal passages and sinuses, and skin occasionally occurs. This relatively rare condition results from the accidental ingestion of eggs, larvae, or adult beetles, or from their entrance into wounds or orifices of the body.

Blister or Vesicant Beetles. Blister beetles (order Coleoptera, family Meloidae) produce cantharidin, a toxic, volatile, vesicating substance. The commercial preparation, obtained from the Spanish fly, *Lytta vesicatoria* (*Cantharis* (*Meloe*) *vesicatoria*), and species of the genus *Mylarbris*, is used as a rubefacient, diuretic and aphrodisiac (U S Pharmacopoeia), although its internal administration is somewhat dangerous The *Lytta vesicatoria* is a southern European beetle which is abundant, particularly in Spain, in early summer

Vesicating lesions of the skin are produced by a toxic substance, perhaps different from cantharidin, which comes from rove beetles of the family Staphylinidae and from the commonly known blister beetles also Blister beetles are of medium or large size. The body is comparatively soft, the head is broad, vertical, and sharply narrowed into a neck, the prothorax is narrower than the wing covers, which are soft and flexible, the legs are long and slender, the hind tarsi are four-jointed, and the fore and middle tarsi are five-jointed Herms stated that they are named blister beetles because of their vesicating properties, that is, the application of the pulverized bodies or even the simple contact of many species produces a blistering of the skin.

More than 200 species of blister beetles have been found in the southern and western parts of the United States A common species in the East, of the genus *Epicauta*, colored a glossy deep purple, feeds principally on potato leaves and goldenrod pollen. Another common species is of the genus *Macrabasis* This is a black beetle, densely clothed with grayish hairs The Pennsylvania blister beetle, *Epicauta pennsylvanica*, also is a common species in the East.

The bites are received while the victim is visiting the woods or fields. Twelve to 24 hours afterward huge bullae occur, usually on the legs and neck, which heal in about 10 days. Rarely does the stranger to the community remember having been molested by the bug The bullae produced by vesicant beetles tend to be at the same stage of development about a day after contact with the insect. Characteristically, erythema is not present around the fully developed bullous lesion.

Differential diagnosis includes the cutaneous eruptions ordinarily characterized by bullae, that is, pemphigus, dermatitis herpetiformis, erythema multiforme bullosum, dermatitis venenata and bullae produced by thermal and chemical agents.

Honeybees, Wasps, Hornets, Yellow Jackets and Ants. Bees, wasps, hornets, yellow jackets, sawflies and some of the ants (order Hymenoptera) have ovipositors which are adapted for chewing, licking, and sucking plants. In some of these the mouth parts may be used to inflict injury to the human skin

Those possessing ovipositors adapted for stinging inflict injury to the skin by piercing it with the stinger and secondarily injuring it by the injection of venom. The stinger has a barbed sheath, a pair of serrated lancets, and a pair of lateral palps. The venom, secreted by glands, is forced down the canal formed by the sheath and lancets of the stinger. The exact nature of the active principle of this venom is unknown. It is a nonspecific poison of moderate toxicity During the act of stinging, the ovipositor is cast off by the honeybee and some wasps, but is retained by other species

All of these stings cause pain, edema and local inflammation Ordinarily the symptoms disappear after a few hours As in the poisonous snakes, the degree of severity of symptoms from the sting depends on the size of the dose of venom. The larger the insect, the larger will be the possible dose of venom. Likewise the amount of the inflammation depends on the location and number of the stings

In human beings the reaction to bee and wasp stings varies with the idiosyncrasy of the victims. The hardened bee keeper may be stung by 20 bees and have nothing to show for it but a few small, painless and transient pimples, while another person may be stung but once and die in a minute or two if he chances to be hyper-

sensitive to the venom. Hypersensitivity in human beings may take two forms: allergy and anaphylaxis. In the postmortem examination of persons killed by bee stings there are voluminous, overfilled, downy and emphysematous lungs, possibly exuding frothy fluid, overdistention of the right side of the heart and splanchnic dilatation and hepatic engorgement. The poison or antigen of bee venom is believed to reside in its protein.

The stinging ants of the temperate zones cause little injury, but the large, tropical species give rise to considerable pain and local inflammation and, if stings are numerous, may even endanger life.

Bee stings and ant bites are treated by the same therapeutic measures. Oral administration in usual therapeutic doses of an antihistaminic agent is indicated. Immediate application of an ointment with some massage alleviates pain and local swelling

Butterflies, Moths and Caterpillars. Butterflies, moths and caterpillars (order Lepidoptera) undergo complete metamorphosis The caterpillars are usually the voracious destroyers of plants and are the ones that injure the human skin

The severity of the dermatitis varies with the species of caterpillar, the site and extent of the exposure, and the sensitiveness of the victim. The lesions may be local or diffuse, according to the type of exposure Within a few minutes to several hours the exposed skin shows a vesicular erythema accompanied by an early burning or prickling sensation with numbness and pronounced itching. There are necrosis of the epidermal cells around the nettling hairs, the formation of vesicles, and inflammatory changes about the vessels of the corium In sensitive persons edema, urticaria and systemic symptoms may occur Windblown hairs may produce a severe irritative ophthalmia or serious inflammation of the respiratory tract

Grasshoppers, Locusts, Crickets and Cockroaches. The grasshoppers, locusts, and crickets (order Orthoptera) are seldom associated with diseases of man. The cockroaches, of the same order, have long been suspected of being mechanical carriers of certain human diseases.

The cockroaches (genus *Blatta*) are flattened, brownish, swift-running, omnivorous insects with legs of approximately equal length Of the five species which have become domesticated and generally distributed as common household pests, three species are most commonly encountered the oriental cockroach, *Blatta orientalis*, the German cockroach, *Blatta germanica*, and the American cockroach, *Periplaneta americana* The species are distinguished by variations in size and coloration. All cockroaches are of filthy habits, feeding on human excreta as well as on nearly all food consumed by man, and they invade kitchens and rooms where food is stored

Recently evidence of the cockroach as the agency in transmission of disease has been obtained Syverton and Fischer fed cockroaches with poliencephalomyelitis virus and collected fecal specimens daily. They found that for each of the first 6 consecutive days after the experimental feeding, the fecal suspensions contained sufficient virus, when injected into normal mice, to paralyze and kill mice in 2 to 4 days

Flies. Flies (order Diptera) from a medical standpoint are the most important of the orders of arthropods There are many species of bloodsucking and nonbloodsucking flies, some of which are intermediate hosts of animal parasites, and others, mechanical vectors of bacterial, viral and parasitic diseases

Bloodsucking Flies of the Families Muscidae and Hippoboscidae The bloodsucking stable fly (*Stomoxys calcitrans*), also known as the storm fly or stinging fly, is vicious in its attack just before storms or in late afternoon These flies cease attacking just before the sun goes down In the southern United States they are present the year round and are extremely abundant in some years. In the northern United States they appear only during the late summer and fall.

These flies bite by driving the distal half of the proboscis vertically into the skin. The proboscis is driven through the skin by three forceful depressions of the head,

as evidenced by the three sharp successive pains. After the extraction of blood there is discomfort for several minutes. A small roseola with a scarlet center persists for a long time. Almost always a few drops of blood trickle from the wound after the insect has fed.

Their habit of leaving one animal to resume feeding upon another makes stable flies ideal mechanical carriers of disease-producing agents, but so far the case is not proved against them

Tsetse Flies. The tsetse flies (species *Glossina palpalis* and *Glossina morsitans*) are almost entirely confined to equatorial Africa.

Glossina palpalis and allied species frequent the neighborhood of water and dense undergrowth. Their favorite localities are hot, damp areas on the borders of rivers or lakes Species of the *Glossina morsitans* group are less dependent on water than are the *Glossina palpalis* and are found in wooded and brush country that provides moderate shade. Tsetse flies bite more frequently toward evening after the heat of the day is passed than earlier

The bite of the tsetse fly is of minor consequence save as it serves to transmit African sleeping sickness to man and to animals.

Nonbloodsucking Flies. The nonbloodsucking flies affect the health of man by the mechanical transmission of disease-producing organisms and by the parasitic activities of their larvae.

The domestic species, usually of the families Calliphoridae, Muscidae and Anthomydidae, are the most important mechanical vectors Pathogenic bacteria, protozoa and helminthic ova are carried on the external structures (hairs, feet, legs and mouth parts) and in the intestinal tract of flies.

Maggots (Myiasis). Myiasis is the term applied to the invasion of living tissues of man by the larvae of flies, usually of the families Oestridae, Calliphoridae and Sarcophagidae.

Myiasis-producing flies may deposit eggs or larvae in or near living tissues, where the larvae inevitably become parasites This group may be subdivided into (1) flies that deposit their larvae in the habitat of the host, (2) those that lay their eggs or larvae on the hairs or body of the host, whence the larvae invade the local tissues and external atria or migrate to selective tissues, and (3) those that deposit their eggs or larvae in wounds and diseased tissue, where the larvae cause cutaneous atrial and wound myiasis without penetrating unbroken skin

Other myiasis-producing flies deposit their eggs or larvae in decaying flesh about wounds and thus may cause extensive destruction of tissue

Intestinal myiasis in man has been described, but this condition is largely accidental although some 30 species of dipterous larvae have been found in the digestive tract The intestine, however, is the normal environment of the parasitic gasterophilus larvae The accidental invaders, all flies that breed on decaying organic matter, are *Fannia canicularis,* the lesser house fly, *Eristalis tenax,* the rat-tailed maggot; *Aphiochaeta ferruginea* and *Aphiochaeta scalaris* of the family Phoridae; *Hermitia illucens,* the soldier fly, and *Piophila casei,* the cheese skipper. In infants the larvae of the flesh flies of the genus *Sarcophaga* may gain entrance through the anus when the eggs are deposited at the anal orifice. Many larvae are destroyed by the digestive juices, but others may be able to live in the intestinal tract and may produce intestinal distress.

The identity of the parasite causing a particular myiasis may be determined by rearing the adult fly from the larva, except in obligatory parasites that cannot be separated from the host.

Gnats (Eye Flies). The eye flies (family Oscinidae) are small acalyptrate flies about 2 mm. in length Those species that attack man and other mammals use the tips of the pseudotracheal rings of the labella as incising instruments for cutting the skin and conjunctival epithelium. Besides the initial injury a pathway for secondary infection is thus prepared.

The eye gnat (*Hippelates pusio*) spreads an acute seasonal conjunctivitis prevalent among children during the summer in California, and in Georgia and other southern states. Also the eye fly of India (*Siphunculina funicola*) and other species that feed on sores, wounds and conjunctival exudates are believed to be responsible for transmitting certain forms of ophthalmia

Botflies. The nonbloodsucking flies of the family Oestridae are known as botflies, warble flies or breeze flies.

In southern United States the larvae of botflies (genus *Gasterophilus*) affect man by getting into the cutaneous and subcutaneous tissues, causing slight pain, and their migrations produce creeping eruptions.

The larvae of botflies (genus *Oestrus*) may cause painful ocular and nasal myiasis in man.

Botflies (genus *Hypoderma*) affect the subcutaneous tissues and eyes of workers in animal husbandry. The lesion is furunculous in type. The larva may be removed by incising the furunculous lesion.

Blowflies Some of the species of these oviparous flies (family Calliphoridae), attracted by blood or offensive discharges, lay their eggs in cutaneous sores and abrasions, thus causing a myiasis with bloody irritating discharges from the wound

Tabanid Flies The Tabanidae have many common names horseflies, deer flies, mangrove flies, breeze flies, greenheaded flies, clegs and seroots. The family, most numerous of the Diptera, comprises some 60 genera and nearly 2,500 species. The important species are cosmopolitan but many have a local distribution The only species associated with the transmission of disease in man belongs to the genus *Chrysops*

The adult flies frequent stagnant water, hovering near the surface during the day Chrysops attacks man most actively from sunrise to 10:00 A.M. and from 4:00 P.M to dusk.

The bite of *Chrysops* is not immediately painful, although the act of withdrawing the mouth parts is usually noticeable, but within a few hours there is considerable local irritation and often extensive swelling, which may persist for days The flies usually attack the ankle, back of leg and outer side of hand. Tabanid flies are of medical importance, not only because they are biting pests, but also because certain species transmit diseases to man and animals. As mechanical vectors they may carry pathogenic organisms on their mouth parts and bodies *Chrysops discalis*, the western deer fly, as shown by Francis and Mayne is a mechanical vector of *Pasteurella tularensis* in man. Members of the other three common genera serve as mechanical vectors of anthrax and trypanosomal infections of animals

Screw Worm Flies Screw worm flies (genus *Chrysomyia*) similar in appearance and habits to *Cochliomyia*, are confined to Africa, islands of the Pacific, Australia and parts of Asia. These flies deposit eggs in or near wounds or external atria of mammals, and the larvae hatch within 10 hours The larvae produce foul-smelling, secondarily infected, mucopurulent lesions that may erode bone

The screw worm flies (genus *Cochliomyia, Cochliomyia americana, Cochliomyia hominovorax*, less common than *Cochliomyia macellaria*) are found in southern and southwestern United States and in greater numbers in tropical America. The eggs are deposited in small batches on the intact skin when the flies are attracted by purulent discharges and suppurating wounds. The larvae hatch in a few hours, penetrate the skin, and produce deep festering wounds. They can penetrate healthy tissues, even cartilage The turbinates and nasal septum may be destroyed, the sinuses infested and even the brain invaded through the middle ear. The fatality rate in man is about 8 per cent.

Flesh Flies The larvae of flesh flies (Sarcophagidae, genus *Wohlfahrtia*) cause extensive superficial furunculous lesions of the cheeks, neck, arms and chest of infants. These infections usually occur in June in infants sleeping unscreened out of doors.

as evidenced by the three sharp successive pains After the extraction of blood there is discomfort for several minutes. A small roseola with a scarlet center persists for a long time Almost always a few drops of blood trickle from the wound after the insect has fed.

Their habit of leaving one animal to resume feeding upon another makes stable flies ideal mechanical carriers of disease-producing agents, but so far the case is not proved against them.

Tsetse Flies The tsetse flies (species *Glossina palpalis* and *Glossina morsitans*) are almost entirely confined to equatorial Africa

Glossina palpalis and allied species frequent the neighborhood of water and dense undergrowth. Their favorite localities are hot, damp areas on the borders of rivers or lakes. Species of the *Glossina morsitans* group are less dependent on water than are the *Glossina palpalis* and are found in wooded and brush country that provides moderate shade Tsetse flies bite more frequently toward evening after the heat of the day is passed than earlier

The bite of the tsetse fly is of minor consequence save as it serves to transmit African sleeping sickness to man and to animals

Nonbloodsucking Flies The nonbloodsucking flies affect the health of man by the mechanical transmission of disease-producing organisms and by the parasitic activities of their larvae.

The domestic species, usually of the families Calliphoridae, Muscidae and Anthomydidae, are the most important mechanical vectors Pathogenic bacteria, protozoa and heminthic ova are carried on the external structures (hairs, feet, legs and mouth parts) and in the intestinal tract of flies

Maggots (Myiasis). Myiasis is the term applied to the invasion of living tissues of man by the larvae of flies, usually of the families Oestridae, *Calliphoridae and* Sarcophagidae

Myiasis-producing flies may deposit eggs or larvae in or near living tissues, where the larvae inevitably become parasites This group may be subdivided into (1) flies that deposit their larvae in the habitat of the host, (2) those that lay their eggs or larvae on the hairs or body of the host, whence the larvae invade the local tissues and external atria or migrate to selective tissues, and (3) those that deposit their eggs or larvae in wounds and diseased tissue, where the larvae cause cutaneous atrial and wound myiasis without penetrating unbroken skin

Other myiasis-producing flies deposit their eggs or larvae in decaying flesh about wounds and thus may cause extensive destruction of tissue

Intestinal myiasis in man has been described, but this condition is largely accidental although some 30 species of dipterous larvae have been found in the digestive tract The intestine, however, is the normal environment of the parasitic gasterophilus larvae The accidental invaders, all flies that breed on decaying organic matter, are *Fannia canicularis,* the lesser house fly, *Eristalis tenax*, the rat-tailed maggot; *Aphiochaeta ferruginea* and *Aphiochaeta scalaris* of the family Phoridae; *Hermitia illucens,* the soldier fly, and *Piophila casei*, the cheese skipper In infants the larvae of the flesh flies of the genus *Sarcophaga* may gain entrance through the anus when the eggs are deposited at the anal orifice. Many larvae are destroyed by the digestive juices, but others may be able to live in the intestinal tract and may produce intestinal distress

The identity of the parasite causing a particular myiasis may be determined by rearing the adult fly from the larva, except in obligatory parasites that cannot be separated from the host.

Gnats (Eye Flies). The eye flies (family Oscinidae) are small acalyptrate flies about 2 mm. in length Those species that attack man and other mammals use *the tips of the* pseudotracheal rings of the labella as incising instruments for cutting the skin and conjunctival epithelium. Besides the initial injury a pathway for secondary infection is thus prepared.

Several species of *Culicoides* are intermediate hosts of filarial parasites.

The bite of the midge produces an itching, rose-colored papule surrounded by an erythematous area 1 to 2 cm. in diameter. In sensitive persons the local lesions are pronounced and may be accompanied by nausea, fever and malaise.

Pappataci fever, sometimes known as sand-fly or three-day fever, is transmitted by members of the genus *Phlebotomus: Phlebotomus papatasii* and probably by *Phlebotomus perniciosus* and *Phlebotomus minutus*, all of the family Psychodidae and similar to the midges of genus *Culicoides*. This viral disease, most prevalent in the Mediterranean countries and southern Asia, resembles dengue

The exact role of *Phlebotomus* in the transmission of oriental sore and kala-azar is uncertain There is some evidence that Oroya fever, in South America, may be transmitted by *Phlebotomus verrucarum* and *Phlebotomus noguchi*.

The Simuliidae are called blackflies, buffalo gnats, turkey gnats and Kolumbatz flies. Like members of the families Culicoides and Psychodidae, they are important in the transmission of many diseases.

These small flies abound in the vicinity of clear, wooded streams. They shun bright sunlight and do not readily venture into the open Although they do not enter houses, they attack man on shady porches or in the vicinity of dwellings. They are a pest to fishermen and woodsmen and may incapacitate both men and animals

The bite, at first painless, except for a slight prickling sensation, later produces an ulcer-like sore due to the salivary toxin In susceptible persons there may be marked inflammation, local swelling and general incapacity. The flies most frequently attack exposed portions of the body, but they have the habit also of crawling beneath the clothing to inflict bites

Simulium damnosum and possibly *Simulium neavei* are the intermediate hosts of the filarial worm, *Onchocerca volvulus*, in Africa, and *Simulium metallicum*, *Simulium ochraceum* and *Simulium callidum* are involved in the transmission of Central American onchocerciasis *Simulium decorum katmai* is reported to be a vector of tularemia.

Lice. The order Anoplura (lice) includes two suborders: (1) Mallophaga (biting lice) and (2) Siphunculata (sucking lice). The suborder Siphunculata comprises four families, of which the family Pediculidae are important parasites of man.

The parasitic lice of man are (1) *Pediculus capitis* (head louse), (2) *Pediculus corporis* (body louse) and (3) *Phthirus pubis* (crab louse). The term Pediculus humanus includes both the head and the body lice. *Phthirus pubis*, the crab louse, is morphologically a distinct species. The head lice and body lice are apparently varieties of a single species. The body louse is believed to have been derived from the head louse, the result of a process of adaptation after man acquired the habit of wearing clothing Some authorities distinguish separate types of lice for the primary races of mankind, white, black, red and yellow. A distinctive species peculiar to African Negroes, *Pediculus maculatus*, has been reported

The body lice and head lice can move fairly rapidly and pass from host to host during contact The crab louse changes its position infrequently and moves only for a short distance It maintains a temporary position on the body of the host by clasping the hairs with its claws The favorite site for the head louse is the hairs of the back of the head, that of the crab louse the pubic hairs, and that of the body louse the fibers of clothing and the hairs of the chest and axillae

Lice suck blood for long periods but apparently never become engorged. During feeding the feces are dark red

During oviposition the female clasps a hair between the gonopods and the body so that the shaft is in contact with the genital opening. The eggs, called nits, are firmly attached to the hairs or, in the case of the body louse, to fibers of the clothing by a durable chitin-like cement. Eggs remain viable on clothing and blankets for a month

Characteristic cutaneous lesions are produced by the bites of both young and adult lice, the location varying with the three types.

House Flies. These flies (family Muscidae) include both bloodsucking and non bloodsucking species. Their geographic distribution is cosmopolitan.

The common house fly (*Musca domestica*) is the most abundant species of th Muscidae. House flies may cause an occasional intestinal myiasis; otherwise th common fly does no direct damage. It menaces health, however, as a mechanica carrier of pathogenic bacteria, protozoa and helminthic ova or larvae, chiefly thos of enteric diseases

Stable Flies. The nonbiting stable fly (*Muscina stabulans*) resembles *Musca domestica.* It is most persistent in its habit of trying to light about the mouth and nose of man, horse or cow Its larvae have been found in the human intestinal tract

Mosquitoes. The mosquitoes belong to the suborder Orthorrhapha, the family Culicidae The subfamily Culicinae is divided into three tribes: (1) Anophelini, (2) Culicini and (3) Megarhinini, of which the first two are of medical importance.

The identification of a species of mosquito requires training and experience.

The effect of the bite varies with the species of mosquito and with the susceptibility of the victim, some bites causing mild itching discomfort of short duration while others cause extreme irritation. Occasional persons manifest severe local symptoms of an allergic nature. The ordinary bite is followed by the appearance of wheals with erythema, swelling and itching lasting from a few hours to several days Vesicular bullae may appear and secondary infection may supervene.

The irritation is commonly but probably incorrectly believed to result from the salivary secretions injected into the wound. Numerous mosquito bites and poor personal hygiene may result in a severe dermatitis with fever and increased leukocyte counts

Mosquitoes as Vectors of Disease. Mosquitoes are the intermediate hosts in the transmission of four diseases of man: malaria, yellow fever, dengue and filariasis. Malaria and yellow fever have decimated and invalided large parts of total populations by becoming rampant because of the lack of protection from mosquitoes and a proper knowledge of their habits

Malaria Anopheline mosquitoes are the intermediate hosts of the plasmodia of human and simian malaria Of the 150 or more recognized species of anopheline mosquitoes some 70 have been incriminated as potential carriers, of which 19 are of major and 24 of minor importance. The remaining species are not natural carriers of malaria

Yellow Fever *Aedes aegypti* is the mosquito that transmits the virus of yellow fever. The mosquito can be infected only by biting the patient during the first 3 days of the disease; the virus requires an incubation period of 12 days before the mosquito becomes infective; and the mosquito remains infective all its life The rural and jungle types of yellow fever occur in Brazil, Colombia and Bolivia without the presence of *Aedes aegypti.* The existence of these types, with a possible animal reservoir, renders the complete elimination of yellow fever improbable.

Dengue. Dengue fever virus is transmitted chiefly by *Aedes aegypti*, but *Anopheles albopictus* and *Armigeres perturbans* have also been found to be vectors Infection is acquired by the mosquito during the first 3 days of the patient's illness

Filariasis. Mosquitoes are the vectors of two filarial parasites of man: *Wuchereria bancrofti* and *Wuchereria malayi*

Culex fatigans, a night-biting mosquito, transmits *Wuchereria bancrofti. Aedes variegatus,* a day-biting mosquito, also is an important host in the Pacific islands. Complete development has been recorded in 22 species of *Anopheles.*

The principal carriers of *Wuchereria malayi* belong to the genus *Mansonia*

Midges, Sand Flies and Gnats. The midges (genus *Culicoides*) live and swarm [illegible] they bite most actively at dusk or [illegible] ammals. The midges of [illegible] a are nocturnal feeders. [illegible] ht of midges. Their small

size enables them to pass through 16-mesh screening.

Ctenopsyllus segnis, the mouse flea, is a common parasite of the house mouse, rat and other small rodents.

Tunga penetrans, the chigoe, chigo, nigua, jigger or sand flea (sometimes erroneously called chigger), is a parasite of man, hogs and dogs in tropical America and Africa Man is infected by contact with soil infested with immature fleas The site of infection is usually the feet and sometimes the hands

The female jigger, *Tunga penetrans*, after fertilization burrows into the skin, usually about the toes, soles of the feet, fingernails or interdigital spaces, and after engorging herself with blood becomes distended with eggs

The lesion, at first characterized by a central black spot in a tense pale area, becomes a festering sore Secondary bacterial infection may produce an extensive dermatosis and a painful ulcer

Diagnosis is suggested by the bites and confirmed by finding the fleas and identifying them

Fleas as Vectors of Disease Fleas transmit plague, endemic typhus and cestode infections.

Plague. The bubonic and septicemic types of plague, due to *Pasteurella pestis*, are transmitted from rat to rat and thence to man by fleas Epidemics of plague among these wild rodents give rise to infection in rats The spread of the disease in man is chiefly due to the rats associated with human habitations, such as the brown rat (*Mus* (*Rattus*) *norvegicus*) and the black rat (*Mus* (*Rattus*) *rattus*) On the death of the rat the infected fleas seek new hosts, either man or other rats

The most dangerous fleas are those susceptible to infection and to bacterial obstruction of the proventriculus, but the feces of all diseased fleas are infectious.

Typhus Fever Endemic typhus fever, a mild form of *Rickettsia prowazeki* infection occurring sporadically in the United States of America, is transmitted by fleas from rat to rat and from rat to man The common insect vectors are *Ceratophyllus fasciatus* and *Xenopsylla cheopis*. The organism of murine typhus may remain viable for at least 651 days in the infected feces of the flea. Infection occurs by contamination rather than by the bite of the flea

Cestode Infections The rat fleas, *Ceratophyllus fasciatus*, *Ceratophyllus wickhami* and *Xenopsylla cheopis*, the mouse flea, *Ctenopsyllus segnis*, the dog flea, *Ctenocephalides canis*, and the flea of humans, *Pulex irritans*, are hosts of *Hymenolepis diminuta*.

True Bugs (Order Hemiptera) *Bedbugs* The common bedbug, *Cimex lectularius*, and the oriental bedbug, *Cimex hemipterus*, family Cimicidae, are parasites of man. They flourish in warm climates and are more abundant in plains and valleys than in mountainous regions

Bedbugs are nocturnal in their habits, concealing themselves during the day in the crevices of bedsteads, in closets and cabinets, in wainscoting or under loose wallpaper. Both nymphs and adults feed at night on man and small mammals They survive starvation for more than a year, a fact which accounts for their presence in houses long unoccupied

The bite of the bedbug ordinarily produces red itching wheals and causes loss of sleep Some persons show no reaction, others have urticaria, and still others manifest allergic symptoms Asthma has been caused by *Cimex lectularius*.

The bedbug is not a proved vector of human diseases

Reduviid Bugs Species of *Triatoma* and *Rhodnius* (family Reduviidae) are called cone-nosed bugs because of the pointed head, barbers because these insects bite the face, assassin bugs, and flying bedbugs They are dark brown with red or yellow markings on the thorax, wings and sides of abdomen

Several species of reduviid bugs frequent houses They hide during the day in dark recesses and feed at night They move rapidly both in flight and on foot Only occasionally do they bite man and other mammals

The two genera most concerned with the transmission of human disease are *Triatoma* and *Rhodnius* *Reduvius personatus*, the widely distributed and notorious "kissing bug," attacks the face, particularly the lips, often causing intense pain Other species also inflict painful bites. *Triatoma sanguisuga*, the Texas or Mexican

The irritating saliva, injected during feeding, produces a roseate elevated papule accompanied by severe itching Persons with pale delicate skin react more violently than those who have dark skin Scratching increases the inflammation and leads to bacterial infection with the sequelae of pustules, crusts, suppurative processes and matted hair. Severe infestations may lead to scarring, induration and pigmentation of the skin and even ulceration. Infestation of the eyelashes through secondary infection leads to phlyctenular conjunctivitis and keratitis.

Itching is the earliest and most prominent symptom and with the crab louse is especially severe at night. The sequelae of scratching are the most characteristic signs. Old and debilitated persons are most severely affected. In these patients bacterial dermatosis is common; occasionally death may result from ensuing septicemia.

Peck, Wright and Gant have determined the component cutaneous injuries due to the bite of the louse. They have expressed the belief that repeated exposures of the skin to ravages of the body louse result in the development of a dermal hypersensitivity This dermal sensitivity is the result of the action of the feces on the skin. It seems that there are two components to the louse-bite reaction. (1) the purpuric element due to the act of feeding and (2) the development of an inflammatory reaction following skin sensitization The pruritus accompanying infestation with lice seems to be mainly a part of the syndrome of hypersensitivity.

The diagnosis of pediculosis depends on finding the adults or the nits

Lice as Vectors of Disease The body louse is the vector of typhus fever, trench fever, and European relapsing fever The head louse is a less important vector than the body louse, the crab louse has never been incriminated. Temperatures greater or less than the normal body heat of man are unfavorable for lice Lice will leave a febrile patient and seek other hosts, thus increasing the chance of spreading infection Lice crawl away from their dead host.

Typhus Fever Typhus fever, caused by *Rickettsia prowazeki*, is spread by infected lice. Lice become infected by ingesting the blood of a diseased person. Man acquires the infection through contamination from the feces or the crushed body of the infected louse, or when bitten by a contaminated proboscis. The louse remains infective throughout its life

Trench Fever Trench fever is caused by *Rickettsia quintana* The louse becomes infected by the ingestion of the blood of a person sick with trench fever. Infection of a new host occurs as in typhus fever.

Relapsing Fever The European form of relapsing fever is caused by the spirochete *Borrelia recurrentis* The organisms are ingested with blood by the louse Man is infected by the contaminative method, the crushed body of the louse coming in contact with the bite or broken skin

Fleas. Fleas (Siphonaptera) are ectoparasites. Man is the principal host of *Pulex irritans*, an important host of *Tunga penetrans* and an incidental host of several species parasitic to other mammals.

The cutaneous irritation caused by the salivary secretions of fleas varies with different persons Some show no reaction while others have a raised, roseate, slightly edematous lesion at the site of the bite. There are still others who are susceptible who will have extensive inflammation manifested by papular rashes.

Pulex irritans, the flea of humans, is the flea most commonly found on man in houses in Europe and western United States

Echidnophaga gallinacea, the sticktight flea, or southern chicken flea, occasionally infects man. Its burrowing habits are similar to those of *Tunga penetrans*. It ranges in the southern United States of America as far north as Kansas.

Xenopsylla cheopis, the Indian rat flea, is the most important flea associated with the transmission of bubonic plague. It attacks man and other mammals as well as its natural host, the rat

Ctenocephalides canis is the commonest species found in house infections in eastern and southern United States.

The symptoms from the bite vary with the site of the injury and the amount of injected venom. The symptoms are both local and general The lesion is a minute, nonelevated bluish red spot with a white areola that speedily disappears, or it may become red and swollen Urticaria and vesiculation may appear about the site. The bite produces a sensation of lancing which is followed by a latent period of 10 or 15 minutes, at the end of which the generalized symptoms supervene. These symptoms follow a uniformly progressive course, corresponding to the stages of (1) lymphatic absorption, (2) vascular dissemination and (3) elimination of the toxin. Lymphatic absorption is evidenced by the proximal progress of throbbing, lanceolating pains and numbness in the affected part In from 15 minutes to several hours the evidences of the vascular dissemination ensue Agonizing muscular pains increasing in intensity spread over the abdomen. The local pain recurs and rapidly increases to involve the entire body. Clonic contractions, tremors, spasmodic movements and convulsions follow The symptoms and pains are intermittent and reach their maximal intensity in the waist, arms and legs. The muscular contractions and the excruciating pain bring about rigidity of the abdomen and of the chest. The patient experiences precordial and abdominal oppression and has the feeling of approaching death. There may be disorientation, hallucinations, delirium, debilitating sweats, profuse salivation and lacrimation. The sensitivity of the skin and the reflexes are exaggerated The respirations are rapid and shallow Temporary tachycardia is followed by bradycardia The arterial pressure increases and later falls. Albuminuria is always present and uremia may develop. Intestinal and vesical paralysis develop There may be priapism, ejaculations and enuresis After a few hours, the period of elimination of the toxin begins The symptoms abate somewhat, only to return in paroxysms. The disorder persists for a week.

The convalescence is characterized by physical and mental fatigue The bite confers a temporary immunity In animals the immunization persists for about 3 months. Persons have been bitten by *Latrodectus mactans* several times and each time have had all the symptoms of poisoning.

DIAGNOSIS It is often alleged that arachnidism is to be differentiated from acute, surgical conditions in the abdomen, particularly ruptured gastric or duodenal ulcers. It does not seem likely that such a state of diagnostic confusion should exist The history of the spider bite and the spreading course of the cramping muscular pains are not likely to be confused with anything else.

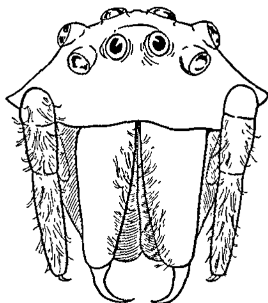
The mortality rate is 4 to 5 per cent Children are more susceptible than adults.

TREATMENT. Ten milliliters of calcium gluconate may be given intravenously. Hot tub baths give some relief *Latrodectus mactans* antivenin may be given intramuscularly, dose 2 5 ml, and may be repeated in 1 to 2 hours if symptoms are not relieved The site of bite is cleansed to prevent secondary infection.

Scorpions. Of the numerous species of scorpions (order Scorpionida) throughout the world, some 20 or more are found in the southern United States and many more in Mexico Some of the larger scorpions injurious to man are *Buthus quinquestriatus* of northern Africa and southern Europe, *Centruroides suffusus* and *Centruroides noxius* of Mexico, and *Centruroides sculturatus* of Arizona.

Scorpion venom is a clear, colorless toxalbumin containing a variety of toxic substances In mice it produces paralysis, nervous disturbances, convulsions and pulmonary disorders

[illegible] contact with [illegible] cause only [illegible] roduce serious and even fatal systemic reactions.



In man the local symptoms of scorpion poisoning are mild. A small, red spot at the site of the sting is followed by slight swelling and excruciating pain that last several hours and subside the following day. Nervous reactions are often severe,

bedbug, has a taste for human blood. It remains hidden during the day and is a nocturnal feeder. Its bite is severe and causes swelling accompanied by itching

Chagas' Disease. Probably all species of *Triatoma* and *Rhodnius*, and even those of *Eratyrus* and the several other related genera, are capable of transmitting *Trypanosoma cruzi*. The trypanosome, introduced into the intestinal tract of the bug during feeding, undergoes a cyclic development in the midgut and hindgut during a period of about 20 days. Infection is usually transmitted by the bug through fecal contamination of the bite, though occasionally directly through regurgitated blood The reduviid bug remains infective for years.

Spiders. The large hairy tarantulas of the family Aviculariidae inflict only slight or, at most, painful injury on man. The small black spiders (black widow), of the genus *Latrodectus*, family Theridiidae, however, possess a potent venom that produces serious symptoms in man. Spiders of this genus range from southern Canada to Chile In the United States of America these spiders are most abundant in the far western and southern parts. The female black widow spider is considered to be the only spider residing within the continental United States capable of inflicting serious injury to man

Black Widow Spider (*Latrodectus mactans*). Only the female is harmful, the male is too feeble to inflict injury. The black widow, so named because of her shining black body and her habit of devouring her mate after copulation, is known also as the hourglass, shoe-button or pokomoo spider.

Modified from Thorp and Woodson, Black Widow America's Most Poisonous Spider, Univ North Carolina Press, 1945

Fig 20-2. Mouth parts of the black widow spider (stripped of most of the hairy coverings)

The over-all length (legs extended) of the female is about 1½ inches (38 mm.), the length of the body about ½ inch (13 mm.), and the width of the abdomen about ¼ inch (6 mm.) The male is much smaller, from one third to one half the size of the female The thorax is brown or black, the long slender legs are dark brown or black, and the abdomen jet black. The legs and body are covered with short black hairs. The female has a variable, median, orange or red spot in the form of an hourglass or Maltese cross on the ventral surface of the glossy, globose abdomen, and almost always there are red markings on the dorsal surface of the abdomen The head and mouth parts are vicious in appearance when viewed clearly without most of their hairy coat (Fig 20-2).

The black widow bites only when disturbed; unfortunately she is easily disturbed. The spider infests piles of wood, wooden fence posts, stumps, undersides of privy seats, outbuildings, cracks in basements, and houses. A favored dwelling is at the junction of an out-of-doors clothesline and its post, from which vantage point the spider often bites women about the face and neck while they are hanging out the washed clothes This spider may get into beds and here may bite any part of the body, but seemingly the bites inflicted in bed are usually about the face and eyes The most frequent situation of bites, however, are the buttocks and the penis, which are bitten while the victim is using the privy.

Symptoms The black widow's nonhemolytic venom, probably a toxalbumin, affects the nerve endings. However, she may and can bite without injecting venom

morphic stages in the tick, and may be transmitted through the eggs to succeeding generations

Diseases transmitted by ticks to man comprise some such listing as the following (from Belding):

BACTERIAL AND SPIROCHETAL DISEASES

Tularemia. *Dermacentor andersoni*, *Dermacentor variabilis*, *Ixodes ricinus*, and *Ornithodorus turicata* and *Ornithodorus parkeri* (experimentally), the United States of America; species of *Ixodes*, Russia, *Hyalomma aegyptium* (experimentally) Greece.

Relapsing fever (for example, *Borrelia duttoni*). *Ornithodorus moubata*, southeastern Africa; *Ornithodorus erraticus*, northern Africa; *Ornithodorus marocanus*, Spain and Morocco; *Ornithodorus papillipes*, central and eastern Asia; *Ornithodorus savignyi*, eastern Asia; *Ornithodorus venezuelensis* and *Ornithodorus talaje*, South and Central America and Mexico, *Ornithodorus turicata*, Mexico and the United States of America, *Ornithodorus hermsi* and *Ornithodorus parkeri*, the United States of America, and *Rhipicephalus sanguineus*, Africa.

VIRAL DISEASES

Equine encephalitis (western strain). *Dermacentor andersoni* (experimentally), the United States of America.

Yellow fever· Experimentally *Ornithodorus moubata*, Africa, and *Ornithodorus rostratus* and *Amblyomma cajennense*, Brazil.

Spring and summer encephalitis *Ixodes persulcatus*, *Dermacentor silvarum* and *Haemaphysalis concinna*, Russia

Lymphocytic choriomeningitis *Dermacentor andersoni* (experimentally), the United States of America

Colorado tick fever *Dermacentor andersoni* (suspected), the United States of America.

RICKETTSIAL DISEASES

Rocky Mountain spotted fever (*Rickettsia rickettsi*) *Dermacentor andersoni*, *Dermacentor occidentalis*, *Dermacentor variabilis* (eastern type), and experimentally *Dermacentor marginatus* and *Amblyomma americanum*, the United States of America.

Boutonneuse fever *Rhipicephalus sanguineus*, Mediterranean countries.

African tick typhus *Rhipicephalus sanguineus*, *Rhipicephalus appendiculatus*, *Amblyomma hebraeum*, *Boophilus annulatus* var *decoloratus*, and *Hyalomma aegyptium* (experimentally).

Russian tropical typhus *Dermacentor nuttalli*

São Paulo fever (*Rickettsia braziliensis*) *Amblyomma cajennense*, *Amblyomma striatum* and *Rhipicephalus sanguineus*, Brazil

Montana "Q" fever (*Rickettsia diaporica*) *Dermacentor andersoni*, the United States of America

PROTOZOAL DISEASES

American trypanosomiasis (*Trypanosoma cruzi*) Experimentally *Amblyomma cajennense*, *Rhipicephalus sanguineus*, and *Ornithodorus moubata* and other species of *Ornithodorus*

This listing is regularly being added to as more care is taken in the identification of a tick found to be a vector of disease.

To remove the embedded head of a tick, apply a few drops of whisky, alcohol, ether, kerosene or white gasoline

Mites. Some mites (order Acarina other than the Ixodoidea or ticks) cause direct injury to man and others transmit human diseases

Red Bug. Red bugs (family Trombidiidae) are usually bright red but may be ornamented with red, orange or black spots The six-legged larvae are the bloodsucking parasites of animals

with throbbing and muscular twitching of the fingers, toes, ears, nose and chin accompanied by itching and paresthesia Other symptoms are headache, giddiness, nausea and vomiting, profuse perspiration, cold extremities, subnormal or slightly elevated temperature and feeble pulse. When the poison is fatal, respiration is accelerated and death results from pulmonary edema

In the south central part of the United States persons observed immediately after having been stung by large scorpions appear pale. They are nauseated and vomit. They complain of being too weak to walk. Examination of a person who has been effectively bitten or stung by a large scorpion below the knee reveals that the weakness complained of is actually a flaccid paralysis of the extremity This paralysis may involve the opposite leg to a slight degree. After 2 to 3 hours the paralysis passes and leaves no residua

Ticks. Ticks are divided into two large families, the Argasidae or soft ticks with two genera, and the Ixodidae or hard ticks with several genera. The argasid ticks are more primitive than the ixodid ticks, are less constantly parasitic, produce fewer progeny and infest the habitat of the host. The ixodid ticks are the more specialized and more highly parasitic, produce more progeny and infest the migratory host itself

Ticks injure man and lower animals in three ways: (1) by the irritation of their bites, (2) by producing tick paralysis through their poisonous secretions and (3) by serving as vectors of bacterial, rickettsial, viral and protozoan diseases.

The insertion of the capitulum into the skin produces an inflammatory reaction of the perivascular tissues of the corium with local hyperemia, edema, hemorrhage, and thickening of the stratum corneum. Occasionally ticks (*Ixodes ricinus*) burrow beneath the skin

A severe localized dermatosis often follows if a part or all of the tick's head is broken off and left in the skin

Tick Paralysis. Tick paralysis occurs in northwestern United States, southwestern Canada, South Africa, Australia and Crete. Sheep are commonly affected, cattle and dogs less frequently, and man and cats occasionally. The disease is usually associated with *Dermacentor andersoni* in North America, *Ixodes holocyclus* in Australia and *Ixodes pilosus* in South Africa, though other species, including *Ixodes ricinus, Rhipicephalus simus* and *Dermacentor variabilis,* have been implicated.

The probable cause of the paralysis is a toxic substance secreted by the salivary glands of the tick rather than a neurotropic virus, since the onset of symptoms, 9 to 16 days after attachment, corresponds to the time of engorgement, and the removal of the ticks permits recovery after paralysis has started The toxic substance is possibly elaborated by the ovaries.

SYMPTOMS. Children are usually affected, adults rarely except, occasionally, aged individuals. Age immunity apparently depends on the size of the host in relation to the amount of toxic secretion; children less than 2 years of age succumb rapidly. The intoxication is the most pronounced when the ticks are attached to the neck or along the spinal column

The disease is a progressive, ascending, flaccid motor paralysis The early symptoms are malaise, lack of appetite, irritability, in-co-ordination, and paralysis of the lower extremities, at times with loss of reflexes. There may be diarrhea, convulsions, and a slight fever or a subnormal temperature. The paralysis ascends to the muscles of the thorax, deglutition and speech, and also involves the involuntary muscles of the anal and vesical sphincters Most affected persons recover. When death results, it is due to respiratory paralysis.

Treatment of man involves the complete removal of ticks and their capitula by hand. As soon as the tick is removed, recovery ensues.

Ticks as Vectors of Disease. Ticks are recognized as vectors of disease in man. In many species of ticks the organisms of disease are carried through the meta-

other mammals. The *Sarcoptes scabiei* is cosmopolitan in distribution and lives solely in the skin of man.

The preferential sites of habitation are between the fingers and toes, the flexor surfaces of the forearm, shoulder blades, small of back, the inguinal region and the genitalia The lesions, minute, translucent, vesicular swellings, appear as slightly reddish elevated tracts on the surface of the skin The intense itching, aggravated by warmth and perspiration, causes scratching, which spreads the parasite, irritates the lesions, and induces secondary bacterial infection. As a result multiple papular, vesicular and pustular lesions may be produced. Unless treated, a chronic condition may ensue, and severe infestations may prove a serious health hazard.

The type and distribution of the lesions are characteristic Conclusive evidence of the infestation is obtained by removing the mite from its burrow with a needle.

Mites of Blackheads. Blackheads result from an obstruction to hair follicles. In some blackheads there is a mite (family, Demodicidae, and one genus, *Demodex*) which does not seem to cause any discomfort. Occasionally, however, when there are many mites present, a dry chronic erythema with burning irritation and scaling of the epidermis occurs.

DISEASES AND INJURIES DUE TO CONTACT WITH PLANTS AND INGESTION OF PLANTS AND PRODUCTS OF PLANTS

Plants Causing Cutaneous Injuries. The following list compiled by Muenscher in *Poisonous Plants of the United States* (1951), includes plants that have caused dermatitis The part of the plant that most frequently causes dermatitis on contact is indicated for each species. Many of the plants produce dermatitis only occasionally or in persons who are especially sensitive. Some species cause poisoning of many but not all persons who come in contact with them. In addition to these cases of dermatitis, many instances of occupational dermatitis result from the handling of certain plants or plant products in certain industries.

Ailanthus altissima—Tree-of-heaven	flowers, leaves
Anacardium occidentale—Cashew-nut	"husks" of nut
Anagallis arvensis—Scarlet pimpernel	leaves
Anthemis arvensis—Corn chamomile	leaves and flowers
Anthemis cotula—Dog fennel	leaves and flowers
Aralia spinosa—Hercules club	bark
Arctium lappa—Great burdock	leaves
Arisaema triphyllum—Jack-in-the-pulpit	leaves, corms
Asarum canadense—Wild ginger	leaves
Asimina triloba—Papaw	fruits
Asparagus officinalis—Asparagus	young stems
Borago officinalis—Borage	leaves
Buxus sempervirens—Box	leaves
Cannabis sativa—Hemp, marijuana	leaves, flowers
Catalpa speciosa—Catalpa	flowers
Caulophyllum thalictroides—Blue cohosh	rootstocks
Chelidonium majus—Celandine	juice
Chimaphila umbellata—Princes-pine	leaves and stem
Clematis virginiana—Virgins-bower	leaves
Colchicum autumnale—Autumn crocus	leaves
Conium maculatum—Poison-hemlock	leaves
Convallaria majalis—Lily-of-the-valley	leaves
Cypripedium reginae—Showy lady-slipper	hairy leaves and stems *
Cypripedium parviflorum—Yellow lady-slipper	hairy leaves and stems *
Daphne mezereum—Daphne	bark
Datura stramonium—Jimson-weed	leaves, flowers, fruits
Daucus carota—Wild carrot	leaves

* The most troublesome species.

Chiggers, the larvae of the North American red bug *Eutrombicula* (*Trombicula irritans*), commonly infest grasses and bushes, particularly wild vines, whence they attack animals and man. The adult red bug is a scaveng the feces of insects and decaying woody substances It is an orange-red m meters in size though 5 times larger than the larva, and lives for about 10 mo

The larvae attach themselves to the skin by the capitulum and after meal drop off in 3 to 5 days. They select the thin, tender, wrinkled surfaces, such as the popliteal region and waist, passing actively up th seldom going above the waist if a belt is worn. If there is no belt, the n the anterior part of the abdomen and chest and the axillae. Women ar are more susceptible than men Attachment takes place within a few mi exposure Itching begins within an hour or two and reaches a maximum part of the first 24 hours During the second day the swelling subsides a pinkish color, which gradually turns to a deep red by the third day, sur puncture point Vesicles frequently occur. The discoloration disappears seventh day. Severe infestations may produce fever. The patient suffe discomfort and torture with attendant loss of sleep. The mites may be re rubbed off or scratched off with the fingernail

The Japanese species (*Trombicula akamushi*) is a proved vector o mushi disease or Japanese river fever

Chicken Mite The chicken mite (*Dermanyssus gallinae*) attacks hum if they are around the infested habitations of chickens Its bite causes dermatitis, usually on the backs of the hands and forearms.

Rat Mite The rat mite (*Liponyssus bacoti*) is prevalent in the United States around stores, factories, warehouses and stockyards. Its bite a vesicular dermatitis with urticaria. Subsequent scratching may cause infection This mite serves as a vector for the transmission of endemic ty rat to rat The rickettsial organisms are passed from one generation to through the eggs of rat mites.

Grain Itch Mite. The grain itch mite (family Pediculoididae, a spec genus *Pediculoides*) produces dermatitis among workers in grain The m *culoides ventricosus*) feeds on the larvae of insects that infest wheat, b other grains and straw

Large numbers of these mites may spread over the entire surface of t of threshers, grain-handlers and persons sleeping on straw mattresses. burrow superficially in the skin, producing local petechiae and erythema fo wheals, vesicles and pustules They cause an annoying pruritus sometim panied by high fever, temperature of 103 or 104 F (39.4 or 40 C)

Itch and Mange Mites. Some of these mites (superfamily Tyrogly infest foods. Grocers' itch is caused by several different mites (genus *Gl domesticus*, of sugar; genus *Tyroglyphus Tyroglyphus siro* of cheese, *Ty longior*, of cheese and cereals, *Tyroglyphus farinae* of flour, grain and Coolie itch is caused by a mite (*Rhizoglyphus parasiticus*). Both the egg mites of the cheese mite are found in human feces, without any injury in t tive tract attributable to their presence

The itch and mange mites, except for the genus *Sarcoptes* and the g *toedres* (family Sarcoptidae of superfamily Sarcoptoidea), are nonburrowi they produce irritation resulting in many-layered scabs on the skin.

Scabies (Seven-Year Itch). The mites of scabies belong to the genus *Sar* the superfamily Sarcoptoidea. This superfamily contains five families par animals. (1) Listrophoridae, the half-clasping mites of small mammals, (gesidae, the feather mites of birds, (3) Cytoleichidae, parasites of the tissue (4) Canestriniidae, parasites of insects and (5) Sarcoptidae, the itch and mar

Rumex crispus—Curly dock	leaves
Ruta graveolens—Rue	leaves
Sanguinaria canadensis—Bloodroot	juice from stem and rootstock
Sedum acre—Mossy stonecrop	juice
Trifolium hybridum—Alsike clover	leaves
Urtica spp—Stinging nettles	hairy leaves and stems
Veratrum viride—Green hellefore	leaves

Most poisonous plants are harmful only when they are eaten. Relatively few plants produce poisoning by contact. The poisoning may consist of minor or temporary irritation of the skin or a painful irritation and inflammation with vesicles or blisters. Such a cutaneous disease or dermatitis may last only a few days or it may persist for weeks, depending on the severity of the infection and the susceptibility of the affected person By far the commonest cause of plant dermatitis in the United States is poison ivy, *Rhus toxicodendron*, and its closely related forms known as poison oak. The poison sumac, *Rhus vernix*, in the North, and poisonwood, *Metopium toxiferum*, in the extreme South, produce similar and even more severe dermatitis The parsnip, *Pastinaca sativa*, lady-slippers, *Cypripedium spp*, spurges, *Euphorbia spp.*, and the cultivated primrose, *Primula obconica*, are other common or widely distributed plants producing a number of cases of dermatitis

The dermatitis due to these plants is exemplified by the fact that the face, hands, forearms and genitals in men are the parts most commonly affected In men and in children there usually is a history of having handled the poisonous plant. In women the disease may occur on almost any part of the body and there may not be a history of direct contact, although there may be a history of handling pets that have come in contact with the poisonous plant The lesions, which vary greatly in size, are extremely numerous, thin-walled, closely aggregated, unruptured vesicles on inflamed bases When they affect the eyelids, the eyes become swollen closed. There are intense itching and burning

Some persons possess natural immunity In those who are susceptible the attacks will be repeated with each contact with the poisonous plant The disease is not contagious The prognosis in the individual attack is good

Plants Causing Photosensitization (Photodynamic Plants). Recently it has been shown that the toxic action of St.-Johns-wort, buckwheat, and several other plants is influenced by light These plants appear to contain substances which, when eaten by domestic animals, sensitize the animals to light so that serious symptoms may develop when the animals are exposed to strong sunlight Plants that sensitize animals to light by substances not normally present in the animal system have been designated as having a photodynamic action

Before photosensitization of an animal can take place as a result of eating a plant, certain conditions must be fulfilled (1) The animal must be white or have an unpigmented skin; otherwise the pigmented skin or dark fur or hair may screen out certain light rays (2) The animal must ingest the plant in question in sufficient quantity to supply the photodynamic substance (3) The animal must be exposed to bright sunlight subsequent to feeding on the plant.

If any one of these conditions is not met, symptoms may fail to develop.

The intricate relationships between sunlight and these cutaneous diseases in animals and man produced by certain plants, for example, fagopyrism by buckwheat and hypericism by St -Johns-wort, are complex and not well known

Food Poisoning From Plants. *Favism,* occurring mainly among Italians, is attributed to eating the fava bean or smelling the blossoms of the bean plant

Many cases of this disease in the United States are probably not recognized. Although there appears to be a hereditary basis for sensitization to this plant, the symptoms follow a definite pattern peculiar to this specific type of poisoning Indi-

Delphinium ajacis—Larkspur	leaves, seeds
Dictamnus albus—Gas-plant	seed pods, leaves
Dirca palustris—Leatherwood	bark
Echium vulgare—Vipers bugloss	leaves and stems
Encelia californica	leaves
Erigeron canadensis—Fleabane	leaves
Euphorbia marginata—*Snow-on-the-mountain*	*milky juice* *
Euphorbia corallata—Flowering spurge	milky juice
Euphorbia cyparissias—Cypress spurge	milky juice
Euphorbia esula—Leafy spurge	milky juice
Euphorbia helioscopia—Sun spurge	milky juice
Euphorbia peplus—Petty spurge	milky juice
Euphorbia lathyrus—Mole-plant	milky juice
Euphorbia ipecacuanhae—Spurge	milky juice
Fagopyrum esculentum—Buckwheat	leaves
Gelsemium sempervirens—Yellow jessamine	leaves and stems
Ginkgo biloba—Maidenhair-tree	fruits
Hedera helix—English ivy	leaves
Helleborus niger—Christmas-rose	leaves
Heracleum lanatum—Cow-parsnip	leaves
Hippomane mancinella—Manchineel	juice
Humulus lupulus—Hop	leaves
Hypericum perforatum—St.-Johns-wort	leaves
Iris versicolor—Iris	rhizomes
Iris spp.—Iris	rhizomes
Iva xanthifolia—Marsh-elder	leaves
Jatropha stimulosa—Spurge nettle	leaves and stems
Juniperus virginiana—Juniper	leaves
Laportea canadensis—Wood nettle	hairy leaves and stems
Leonurus cardiaca—Motherwort	leaves
Lobelia inflata—Lobelia	leaves
Maclura pomifera—Osage-orange	milky juice
Mentzelia oligosperma—Prickly herb	hairy leaves
Mentzelia ornata—Prickly herb	hairy leaves
Metopium toxiferum—Poison-wood	leaves, bark, etc.*
Nerium oleander—Oleander	leaves
	hairs on leaves and stems *
	leaves
	leaves
	leaves

(3) The animal must be exposed to bright sunlight subsequent to feeding on the plant.

If any one of these conditions is not met, symptoms may fail to develop.

The intricate relationships between sunlight and these cutaneous diseases in animals and man produced by certain plants, for example, fagopyrism by buckwheat and hypericism by St.-Johns-wort, are complex and not well known

Food Poisoning From Plants. *Favism*, occurring mainly among Italians, is attributed to eating the fava bean or smelling the blossoms of the bean plant.

Many cases of this disease in the United States are probably not recognized Although there appears to be a hereditary basis for sensitization to this plant, the symptoms follow a definite pattern peculiar to this specific type of poisoning. Indi-

vidual susceptibility varies, and certain persons, after years of eating the beans with immunity, suffer a single severe attack and none subsequently. Ingestion of the beans by immune mothers may affect nursing infants There is no sex predilection

When fields of fava beans are in blossom, the inhalation type of the disease is most prevalent. The pollen is said to be sticky and is not widely disseminated. The first symptom appearing after inhalation of substances originating from the flowers or plant of the fava bean is dizziness, sometimes reaching the stage of collapse. This may occur within a few minutes or some hours after exposure and is usually followed by the gradual appearance of headache, malaise, and nausea. Repeated yawning, vomiting, chill, pallor, and pain in the lumbar region are followed by high fever. The most specific symptom is hemoglobinuria, which occurs within 5 to 40 hours, and is followed by icterus

Mushroom poisoning follows the eating of poisonous mushrooms which have been gathered in the woods and fields and mistaken for edible varieties. The poison is muscarine, a syrupy, alkaloid-like substance, which has been obtained in a crystallizable form as a hydrochloride from the mushroom *Agaricus muscarius* In its action it resembles pilocarpine, which stimulates the myoneural junctions.

There are some 70 to 80 species of mushrooms that are poisonous to man Emigrants from southern Europe to this country often confuse the poisonous ones with the European edible varieties The differentiation of the various types of mushrooms is a matter for a trained mycologist and not for the layman. The layman should not depend on the knowledge that he has gained from reading a book as being an accurate guide for him to select edible mushrooms in the woods

Symptoms often appear within 15 minutes after the mushrooms are eaten, but sometimes are delayed from 1 to 6 hours. This poisoning is characterized by salivation, excessive perspiration, a flow of tears, nausea, retching and vomiting, pain in the abdomen, and violent movements of the intestines which cause profuse watery evacuations The pupils are contracted Respiration is often quickened and dyspneic. Dizziness and confusion of ideas, coma and death may follow within 48 hours. In fatal instances there are fatty infiltration of the liver with central necroses, epithelial necrosis of the kidneys, acute enteritis, and colitis. The uremic condition resulting from the renal damage may be responsible for the symptoms.

Acute mushroom poisoning is treated by immediate gastric lavage followed by the instillation of a solution of starch into the stomach. The immediate intravenous administration of 5 per cent dextrose solution (1,000 ml.) is necessary Opiates may alleviate the distress Sometimes atropine or strychnine is employed.

The *water hemlock, Cicuta maculata,* is often erroneously called parsnip, wild parsnip, or wild carrot Its habitat is in swamps and meadows. The poisonous component of *Cicuta* is a resin.

In from 1 to 3 hours after ingestion of the leaves, flowers or roots there ensue nausea, vomiting and, in some, convulsions. Recovery occurs within a day or two

Country folk know that *rhubarb leaves* are poisonous and refrain from using them as a food, but since these leaves are occasionally so used by the uninformed, the United States Department of Agriculture has issued a warning to housewives against using this portion of the plant for food. Within a short time after ingestion there are cramplike pains in the abdomen which continue intermittently for a period of 36 hours or longer Death may follow.

Milk Sickness. Milk sickness is an intoxication caused by ingestion of milk and milk products of cows that have eaten white snakeroot (*Eupatorium urticaefolium*) or rayless goldenrod (*Aplopappus heterophyllus*) which are found in the central states of the United States, and jimmy weed (*Aplopappus heterophyllus*), found in certain sections of western Texas, New Mexico, and Arizona. Cattle apparently will eat these weeds when grazing is scarce The poison in snakeroot is due to a secondary alcohol, trematol ($C_{16}H_{22}O_3$). The primary intoxication in the animals is known

as "trembles" or "split tail" If the milk is drunk or if milk products are consumed by man from an affected cow, milk sickness ensues Pasteurization does not destroy the poisonous properties of the contaminated milk, butter or cheese.

In the acute form, the symptoms are anorexia, weakness, fatigability, constipation, nausea and retching; in the relapsing and probably in the chronic forms, the symptoms are nausea and vomiting There is a great thirst. The cheeks are flushed, and there may be a marked redness of the lips and tongue. The breath has a distinct odor of acetone The temperature is normal or subnormal despite the flushed appearance of the lips and cheeks. There are widespread muscular soreness and pain on palpation There is no increase in leukocytes The urine is scanty and contains acetone In fatal instances coma and convulsions precede death

Treatment should be directed toward the correction of the dehydration and acidosis. Empirically, as often predicated by folk medicine, the use of intoxicating doses of alcohol apparently improves the prognosis. Convalescence is prolonged, and relapse may follow premature physical exertion In patients who recover, weakness persists for days, weeks, or even months, depending on the initial severity of the illness

Honey Poisoning. A poison may rarely appear in the honey derived from certain nectar-bearing plants such as varieties of azalea, rhododendron, oleander, mountain laurel (*Kalmia latifolia*), palmetto, black locust, yellow jasmine (*Gelsemium sempervirens*) and species of *Andromeda, Leucothoe*, and *Pieris* belonging to the family Ericaceae

In the lay mind bitter honey may be considered as poisonous This is not true. For instance, the slightly bitter honey from dog fennel (*Anthemis cotula*) is delicious and not poisonous

The symptoms of honey poisoning begin immediately after the honey is eaten. There are tingling of the hands and feet, nausea and uncertainty of gait. If attempts are made to walk, the patient falls Headache may be severe. For several hours there is inability to rise Vomiting and severe diarrhea ensue The patient may become irrational and lose the senses for several hours All symptoms except weakness pass away in 24 hours

The diagnosis is made from a history of eating comb honey The comb honey, according to folklore, may be tested by feeding some of it to a dog. If the honey is poisonous, symptoms appear in the dog within one-half hour.

THE PHYSICAL EFFECTS OF HEAT AND COLD ON THE BODY AS A WHOLE

BODY TEMPERATURE

Thermal control of the body depends on balanced autonomic nerve centers situated in the diencephalon The center of control of body cooling is in the posterior hypothalamus. The center for control of overheating seems to be located near the supraoptic and paraventricular nuclei Owing to the thickness of the scalp and calvarium the cranium and its contents are effectively insulated and the heat regulatory centers are rarely affected by the temperature of the environment of the head These regulatory centers are sensitive to changes in temperature and chemical composition of the arterial blood Additional factors in thermal controls are endocrine and autonomic-sympathetic reflex vasomotor responses

Physiologic regulation of body temperature consists of balancing heat production and heat loss Heat production is subject to pituitary, adrenal and thyroid control and the availability of nutritional substances. The rate of heat production can increase by 10 times during heavy work It can rise from 4 to 8 times, without exercise, merely by the onset of shivering Heat loss is achieved through the skin and the lungs The amount lost through expired air depends on the temperature, density and humidity of the air, as well as on the respiratory rate and depth. The amount of heat lost from the cutaneous surface (radiation, conduction, convection and evaporation of water) depends on the relative degree of vascular dilatation of surface and near-surface blood vessels, and on other factors such as pilomotor response and function of sweat glands The amount of heat lost from skin and lungs by evaporation of water is relatively greater at low environmental temperatures than at high environmental temperatures

Normal Limits. The normal temperature of the body varies within narrow limits. The average is 98 6 F (37 C) Any temperature from 97.2 to 99 0 F may be considered to be within proper boundaries, although these may be normally exceeded for short periods of time. The temperature is modified somewhat by age, the temperature of the newborn infant ranging from 99 to 99 7 F; while between 60 and 70 years of age it may vary from 99 7 down to 97 F. Violent exercise, especially in warm weather, will raise the temperature to a slight extent. Mental exertion or excitement may raise it to a moderate degree (100 4 F).

The most nearly constant normal variation is that which occurs diurnally. Under ordinary circumstances the temperature is highest between 5 P.M. and 8 P.M., and lowest between 2 A M and 6 A.M The influence of this rhythmical change of temperature is seen in many fevers In those who work by night and sleep by day this type is reversed. The temperature may rise 0 4 F after a meal, the so-called fever of digestion The readings of the thermometer differ somewhat according to the cavities in which it is placed It is to be remembered that the mean temperature of the

air, (2) its moisture content, (3) air movement and (4) radiation transfer between the body and its immediate environment. The *temperature* of the body and the air is expressed as the dry bulb temperature.

Through the efforts of the United States Public Health Service, the United States Bureau of Mines, and the Research Laboratory of the American Society of Heating and Ventilating Engineers, as recorded by Ferderber and Houghten, not only have the effects of these four environmental factors in controlling heat exchange between the body and the atmosphere been evaluated but these factors have been combined into a single comfort index known as the effective temperature. This scale takes into account the temperature of air, its moisture content and its movement. It has been shown that this effective temperature index, particularly in hot atmospheres, is a true measure not only of a person's feeling of warmth but of many of the physiologic reactions, including changes in body temperature, increase in pulse rate and change in leukocyte count of the blood

The average person at rest is ideally comfortable at about 66 F effective temperature during the winter season, but in a summer-cooled space ideal comfort is attained at about 72 F effective temperature This may be observed with 75 F dry bulb at 70 per cent relative humidity, or 80 5 F dry bulb at 30 per cent relative humidity. Most persons would be uncomfortably warm and perspiring at an 85 F effective temperature irrespective of the moisture content Most persons seated at rest will maintain temperature equilibrium with profuse perspiration in an effective temperature as high as 89 F. At higher effective temperatures equilibrium of body heat will not be maintained, body temperature will rise and pulse rate will increase as the effective temperature increases, so that in a condition of 92 5 F effective temperature the average person will have a rise of 1 7 F in body temperature and an increase in pulse rate of 48 per minute in 3 hours. The same physiologic changes will occur at an effective temperature of 96.5 F and 20 per cent relative humidity when the dry bulb is 131 F, or 32 F above body temperature, as would occur in 96 5 F effective temperature with a high relative humidity of about 90 per cent when the dry bulb temperature is only 99 F, or approximately the same as the body temperature

Physiologic reactions follow the effective temperature index rather than the dry bulb temperature As an example, Simpson has shown that induced fever therapy will give a rise in body temperature to 105 F in from 40 minutes to an hour with a dry bulb temperature ranging from 130 to 150 F and a relative humidity from 35 to 50 per cent However, Houghten, Ferderber and Gutberlet have shown that in a saturated atmosphere the same rise in body temperature will occur in about the same time with a dry bulb temperature of approximately 113 F

Air-Conditioning Shock. The discomfort on emerging during the summer season from a cooled, air-conditioned space into natural atmosphere and the reverse has been made the basis of many complaints against air conditioning. There has come into use the term air-conditioning shock, and unfavorable comment has been made that such swift changes promote respiratory diseases

Mudd, Goldman and Grant demonstrated that chilling of the body surface of human beings causes reflex vasoconstriction and ischemia in the mucous membranes of the nasal cavity and the postnasal space They expressed the belief that this ischemia might cause a lowering of the local resistance, which would allow infection to occur. During the course of their experiments, 10 of the subjects developed acute colds and sore throats, and a change in the bacterial flora was demonstrated.

Workers in mines in which the temperature constantly is at 56 F, on leaving such a mine to enter a natural atmospheric temperature, at times of 96 F, may immediately suffer from dizziness, quick fatigue, profuse sweating, flushing of the skin, syncope and other manifestations suggesting cardiovascular weakness evidenced by a quick lowering of the blood pressure

It is difficult to correlate the foregoing experiences with the number of degrees of change in the environmental temperature, for during the winter season it is not extraordinary to pass from an outside temperature at 0 F into a warm room of 80 F.

Fahrenheit and divide by 1 8 *Conversely, to convert from Centigrade to Fahrenheit* multiply by 1 8 and add 32.

The temperature is recorded by either Fahrenheit or Centigrade thermometer placed in the mouth, axilla, rectum, vagina, or *the fold of the groin* The *temperature* of the urine is sometimes tested in a male suspected of malingering.

If the mouth is employed, neither a very hot nor a very cold drink should have been taken for half an hour before.

It is more accurate to use the rectum or the vagina than the mouth. The thermometer is oiled and introduced to the depth of 2 inches. The rectum must be empty of feces *The temperature may also be taken by the rectum in those who are* being tubbed, and when there is doubt as to a recorded reading or a suspicion of malingering

The *surface temperature is taken by a self-registering thermometer, the base of* which has been flattened or coiled so as to present a relatively large surface for contact with the skin.

In ordinary cases the temperature should be taken if possible morning and night, preferably at the same hour each day If in a private home a professional nurse is not on duty, it is possible to instruct a member of the family in the procedure *or to furnish extra thermometers on which the temperatures are recorded* at specified times and which are then laid aside for reading on the next call

In a report of the Council on Physical Medicine and Rehabilitation on oral and *rectal temperatures of man, Horvath, Menduke and Piersol commented that the* so-called normal body temperature of a healthy person has been stated categorically to be 98 6 F (37 0 C), and repeated the clinically accepted truism that the *rectal temperature is 1 F higher than the oral, or approximately* 99 6 F (37.6 C). These values have as their basis the present-day standard of 98.6 F which originated from the work presented long ago by Becquerel and Breschet, and by Wunderlich *who, working separately, found the mean oral temperature* to be 98 6 F The range of the means reported is from 97 2 to 99 0 F.

Horvath, Menduke and Piersol made a controlled study on normal men and women. *The mean of the temperature for men in the morning* was 98.2 F; the mean for the women in the morning was 98 6 F The difference was 0.4 F The standard error of this difference was 0 15 F. In addition to having a higher mean temperature, women exhibited greater variability in their mean temperatures than did men

The difference between the rectal and oral temperatures for men was 0 84 F, for women, 0.76 F The mean range of rectal temperatures in men was 1.2 F and in women 1.5 F. The mean range of differences between rectal and oral temperatures was 1 0 F for men and 1 4 F for women.

Both men and women had a significantly higher mean evening rectal temperature than a mean morning rectal temperature There is no single "normal" temperature value for all men. Neither is there a single "normal range" of temperature for all men These statements are equally true with respect to the differences be-

on the destructive metabolisms, mainly processes of oxidation, which are constantly going on throughout the tissues of the body. The skeletal muscles and the glands, especially the liver, constitute the chief seats of heat production.

Heat dissipation (thermolysis) takes place mainly through the expired air, and by conduction, convection, radiation, and evaporation from the skin. *Since from* 77 to 85 per cent of the total heat lost passes off from the cutaneous surface, the skin must be considered as the principal factor in heat dissipation.

There are four factors in the atmospheric environment *which affect* loss of heat from the body in the following order of importance: (1) the temperature of the

air, (2) its moisture content, (3) air movement and (4) radiation transfer between the body and its immediate environment. The *temperature* of the body and the air is expressed as the dry bulb temperature

Through the efforts of the United States Public Health Service, the United States Bureau of Mines, and the Research Laboratory of the American Society of Heating and Ventilating Engineers, as recorded by Ferderber and Houghten, not only have the effects of these four environmental factors in controlling heat exchange between the body and the atmosphere been evaluated but these factors have been combined into a single comfort index known as the effective temperature. This scale takes into account the temperature of air, its moisture content and its movement. It has been shown that this effective temperature index, particularly in hot atmospheres, is a true measure not only of a person's feeling of warmth but of many of the physiologic reactions, including changes in body temperature, increase in pulse rate and change in leukocyte count of the blood

The average person at rest is ideally comfortable at about 66 F effective temperature during the winter season, but in a summer-cooled space ideal comfort is attained at about 72 F effective temperature This may be observed with 75 F dry bulb at 70 per cent relative humidity, or 80 5 F dry bulb at 30 per cent relative humidity Most persons would be uncomfortably warm and perspiring at an 85 F effective temperature irrespective of the moisture content. Most persons seated at rest will maintain temperature equilibrium with profuse perspiration in an effective temperature as high as 89 F. At higher effective temperatures equilibrium of body heat will not be maintained, body temperature will rise and pulse rate will increase as the effective temperature increases, so that in a condition of 92 5 F effective temperature the average person will have a rise of 1.7 F in body temperature and an increase in pulse rate of 48 per minute in 3 hours. The same physiologic changes will occur at an effective temperature of 96 5 F and 20 per cent relative humidity when the dry bulb is 131 F, or 32 F above body temperature, as would occur in 96 5 F effective temperature with a high relative humidity of about 90 per cent when the dry bulb temperature is only 99 F, or approximately the same as the body temperature

Physiologic reactions follow the effective temperature index rather than the dry bulb temperature As an example, Simpson has shown that induced fever therapy will give a rise in body temperature to 105 F in from 40 minutes to an hour with a dry bulb temperature ranging from 130 to 150 F and a relative humidity from 35 to 50 per cent However, Houghten, Ferderber and Gutberlet have shown that in a saturated atmosphere the same rise in body temperature will occur in about the same time with a dry bulb temperature of approximately 113 F

Air-Conditioning Shock. The discomfort on emerging during the summer season from a cooled, air-conditioned space into natural atmosphere and the reverse has been made the basis of many complaints against air conditioning. There has come into use the term air-conditioning shock, and unfavorable comment has been made that such swift changes promote respiratory diseases.

Mudd, Goldman and Grant demonstrated that chilling of the body surface of human beings causes reflex vasoconstriction and ischemia in the mucous membranes of the nasal cavity and the postnasal space They expressed the belief that this ischemia might cause a lowering of the local resistance, which would allow infection to occur During the course of their experiments, 10 of the subjects developed acute colds and sore throats, and a change in the bacterial flora was demonstrated.

Workers in mines in which the temperature constantly is at 56 F, on leaving such a mine to enter a natural atmospheric temperature, at times of 96 F, may immediately suffer from dizziness, quick fatigue, profuse sweating, flushing of the skin, syncope and other manifestations suggesting cardiovascular weakness evidenced by a quick lowering of the blood pressure.

It is difficult to correlate the foregoing experiences with the number of degrees of change in the environmental temperature, for during the winter season it is not extraordinary to pass from an outside temperature at 0 F into a warm room of 80 F.

Thus a differential of 80 F occurs without profound discomfort either then or soon thereafter. However, the person who enters a warm building from an outside temperature of 0 F or thereabouts removes the overcoat, mittens, overshoes and headdress.

Fever. Fever is a condition indicated by a more than transient rise of body temperature There is implied a disturbance of the normal relation between heat production and heat dissipation, from causes acting on one or the other, or on the heat-regulating mechanism. Heat production in fever is largely increased because of increased rapidity of destructive processes which take place in the body, as evidenced by the larger than normal amounts of urine and carbon dioxide which are excreted, and the larger quantity of oxygen which is consumed. Increased formation of heat alone, however, may not be sufficient to account for the increase of body temperature unless the increased formation of heat is excessive or the loss of heat to the immediate environment is hampered In fever, therefore, it is necessary to assume a disturbance of the thermotaxic mechanism, and this perturbation of heat regulation is perhaps the most characteristic element in the production of fever heat Fever is a complex process or condition of which the presence of an elevated temperature is the most significant and practical indication

In general, fever is caused by or attends, (1) all inflammations, acute, subacute or chronic, the great majority of which are recognized as being dependent on the presence of microscopic or ultramicroscopic organisms in the inflamed area, whence toxic material enters the general circulation, (2) toxemias resulting from the injection or ingestion of toxic or poisonous material or the absorption of toxic or poisonous material from the digestive tube; (3) the formation of toxic aseptic material from the tissue with subsequent absorption, (4) the contact with certain allergins by those who have an allergic state; (5) hemolysis (hemolytic crisis) in certain blood dyscrasias, (6) some instances of disease of the central nervous system (disease or injury to the cerebral cortex, hypothalamic region and spinal cord) in which the heat-regulating mechanism presided over by the autonomic nervous system is interfered with by direct or reflex causes, (7) some instances of advanced malignant lesions, either sarcomas or carcinomas but more commonly the former; (8) dehydration and (9) starvation

An overheated room and the ingestion of food may cause a rise in temperature

Fever may be caused by injury to the upper part of the cervical portion of the spinal cord or by excessive increases in intracranial tension, and terminally in brain tumors An unusually cool room, cold sponging, and the cold tub are fever-reducing agents. If a slow loss of blood occurs, as when menstruation takes place during fever, the temperature is lowered to some extent, and a large, sudden hemorrhage may cause a drop below the normal Persistent subnormal temperature may be present in connection with convalescence from fevers, in acute alcoholism, melancholia, myxedema, starvation (sometimes elevated), wasting diseases, and in various kinds of poisoning Locally, abnormal coldness of an edematous or cyanosed part may be observed

The febrile reaction is characterized by increase in pulse rate (100 to 160 per minute). The cardiac output is increased and the circulation time is decreased. After the chill, if there should be one, there is an extensive vasodilatation in the skin but the decrease in peripheral resistance is well balanced by the increased cardiac output During fever the heart is subjected to strain The systolic blood pressure is usually increased while the patient is in the recumbent position but lowered, in the erect position The greater changes may occur in the diastolic blood pressure, which may become impossible to determine by the ordinary means, particularly in the upright position This decrease in the diastolic blood pressure may weaken the heart from the effects of reduction in the blood pressure.

In a chill associated with an elevated temperature, the surface of the body is

cold and pale. The teeth chatter, the lips and nails are cyanotic, and the skeletal muscles rapidly contract and relax. The fever may reach its highest point during the chill

Many of the symptoms attributed to infections are really the manifestations of fever The symptoms of fever are due partly to tissue changes, partly to increased heat of the body, and partly to functional disturbances of affected organs or tissues Besides the abnormal rise of temperature, these symptoms are: ill feelings, or malaise; sleeplessness; thirst; loss of appetite, mental disturbance, amounting to delirium in excessive fever; increased frequency of pulse and respiration· lessened amount of urine; usually headache and backache; and, if the fever is long-continued, general wasting of the body. There is also likely to be nausea and constipation, and a chill may initiate or accompany a sudden rise of temperature.

The symptoms accompanying fever exhibit considerable variations in severity according to the character and the cause of the fever, and the duration and height of the pathologic temperature There is also a difference in the enduring power of individual patients, more easily recognized than explained, which with equal temperatures and apparently similar causes will allow one patient to continue about his daily work with slight subjective symptoms and will send another to bed in a condition of extreme weakness and discomfort The malaise may be slight or marked. Thirst and dryness of the mouth, together with anorexia, epigastric discomfort and nausea on taking food, and constipation, are due to varying degrees of suppression of the digestive secretions The total fluid intake is often diminished in quantity, the urine is scanty and high colored The pulse rate, as a rule, is increased. However, in meningitis, influenza and typhoid fever the pulse may be slowed. In infections generally the pulse rate and the respirations increase.

Backache, headache, and aching of the limbs are nearly always present, but there is considerable variation in their severity As a rule, they are most marked at the beginning and, as in some of the acute infectious diseases, may possess distinct diagnostic value because of their prominence as symptoms The headache of the rickettsial infections and the backache of variola are examples The mental disturbances of fever may be manifested by an increased activity of the mind, passing into active delirium, or by mental torpor, deepening into a low muttering delirium. The degree or character of the delirium or mental disturbance does not appear to depend entirely on the height of the temperature, but rather on the nature and amount of the toxins circulating in the blood and their effect on the nervous system. Personal idiosyncrasy and age modify the liability to the occurrence of delirium.

Fever temperatures are referred to according to type and height The terms employed to designate the types of fever are self-explanatory For example, there are continued, remittent, intermittent, recurring, and irregular fevers

If a fever ends by a sudden drop of the temperature to or below the normal, the termination is by *crisis*, and is usually accompanied by profuse sweating and an increased flow of urine

If the decline of the fever is slow and gradual, several days elapsing before the temperature reaches normal, the termination is by *lysis*

A temperature below 97 2 F is subnormal, and 95 F is the temperature of collapse.

Changes in the temperature are much more easily produced when it is already abnormal Consequently, if fever exists, agencies which in health would cause little or no alteration in the temperature will give rise to marked oscillations of the temperature If hourly temperature recordings are made for 24 hours, in almost any case of fever, irregularities will be revealed which cannot be explained by past events or future developments

A rise of temperature to an unusual height, 107 to 110 F, is termed hyper-

pyrexia, which may develop in connection with malarial intermittent or remittent fever, rickettsial infections, hepatitis, sunstroke, tetanus, typhoid fever, yellow fever, and shortly before death from any cause, but particularly in brain tumors. It may also result from trickery by the use of friction, pressure, hot water bags, poultices or inverted shaking of the thermometer.

Localized rise of temperature, except in surgical diseases, is not of great diagnostic importance. The local heat of the surface is increased over a pneumonic lung, and there may be a rise in temperature in areas affected by vasomotor paralysis.

EFFECT OF HEAT ON THE BODY

The injuries to the skin by heat may be primarily induced by contact with hot objects or the skin may be hypersensitive or allergic to heat

The application of heat to the skin or mucous membranes by liquids, solids, flame, steam and radiant heat causes burns These burns are classified as. *first degree* burn manifested by reddening of the outside layers of the skin; *second degree* burn exhibiting blebs and vesicles, *third degree* burn denoting destruction of the skin and often subcutaneous and other superficial tissues First and second degree burns leave no scars

A first degree burn covering a large area, a second degree burn covering a smaller area and a third degree burn covering a limited area of the body surface may cause shock, to be followed by fever, fast pulse and often vomiting and diarrhea Blood may occur in the excreta as the result of a gastroduodenitis or duodenal ulcer (Curling's ulcer) The duodenitis and ulcer may be due to an acute insufficiency of the adrenocortical hormones

Hematuria, granular and blood casts may signify the presence of a lower nephron nephrosis

The toxemia which follows extensive first or second degree burns as well as the toxemia of third degree burns is due to (1) fluid loss (salt and water), (2) oxygen deficiency and (3) adrenal insufficiency.

The diagnosis of burns is obvious. The difficulty may lie in the determination of whether or not the patient had at the time of the burn another disease which caused the loss of postural balance or mental alertness which permitted him to sustain the burn

In the *rescue from distress caused by heat*, the survival time is a less decisive factor than the span of time in which man is still able to act, the escape time. Incapacitation occurs when the average body temperature rises by as little as 1 C.

If *death has occurred in a fire* the blood will almost invariably show a high concentration of carbon monoxide. In addition, particles of soot are usually present on the mucosae of the larynx, trachea and bronchi The presence of true blisters, or of a peripheral zone of hyperemia, associated with burns of the skin indicates life at the time the burns were sustained If death occurred in the fire, analysis of the blood for ethyl alcohol may reveal that escape was rendered more difficult by inebriation Examination of the viscera and extremities will reveal whether injury or disease prevented escape. Certain postmortem artefacts of burned bodies produced by heat may be confused with premortem injuries. These artefacts include splits of the skin which simulate incised wounds, pseudoblisters caused by formation of steam beneath the epidermis, cracks of the outer table of the skull from drying and shrinkage, fractures of the entire thickness of the skull from the generation of steam in the cranial cavity, and epidural hematomas over the vertex of the brain.

Most deaths in conflagrations are due to heat, noxious gases (especially carbon monoxide) or the combined effects of heat and gases. Death from heat is indicated by extensive burns of the body, together with hemorrhages beneath the endocardium

of the septal surface of the left ventricle of the heart. Identification of partially burned bodies may be made from dental peculiarities or from individual physical characteristics, such as congenital abnormalities or residua of disease or surgical operation.

Overcharging of Heat Balance. Heat enters the body from a hot environment mainly through the skin and usually increases the peripheral blood flow. This effect causes an increased heat conductivity of the periphery and, therefore, an increase of temperature of the body. Profuse sweating, which usually commences a few minutes after exposure to heat may, through evaporation cooling, counteract the overheating with air temperatures up to 140 F In moist air this limit will be reached at temperatures less than 140 F. The more heat that enters the body, the greater the imbalance of physiologic factors, such as the temperatures of different parts of the body or of the circulatory system; finally signs of breakdown occur. The rise of the average body temperature seems to be a valuable indicator of this stress

The heat balance of the body seems to be somewhat improved by acclimation. Generally, however, the upper environmental limit in which a person can work is a dry bulb temperature ranging between 93 and 121 F and a wet bulb temperature ranging between 90 and 96 F At this upper environmental limit a narrow range of wet bulb temperature, 4 to 5 F, separates environments in which work is relatively easy from those in which work is impossible. When the wet bulb temperature is below 91 F work is easily and efficiently performed. Between 91 and 94 F wet bulb temperatures, prolonged moderately hard work is possible but efficiency is lost and work is difficult Vigor and alertness are lost Total disability occurs from moderately hard work at wet bulb temperatures of 94 F and higher. Work of a longer duration than 1 hour at these temperatures greatly decreases tolerance. At a dry bulb temperature of 120 F sweating is extremely profuse, averaging 2 to 3 liters per hour This is considered the upper environmental limit for the dry bulb temperature Above these upper environmental limits, there develop, even in acclimatized persons, severe physiological changes and undesirable, frequently disabling symptoms similar to those sustained by unacclimatized persons when working in the heat

There are three clinical syndromes which can be attributed to overcharging of the heat balance. These are (1) sunstroke, (2) heat exhaustion and (3) heat cramps.

Sunstroke. Sunstroke is distinguished from heat exhaustion and from heat cramps.

Exposure to the sun which may not be prolonged, or short exposures to excessive heat indoors, when the humidity of air is high, is the cause of sunstroke The excessive humidity is necessary, for in a dry atmosphere *heat exhaustion* is produced

Schickele made analyses in 198 cases of heat fatalities suffered by soldiers in training in the United States from 1942 to 1944. From these, 157 were selected in whom no cardiac or other disease which would predispose to increase in body temperature could be found, and in whom, therefore, if death occurred it might be presumed to be due only to the effects of exposure to heat Heat deaths were found to be caused by the heat load, as determined by climate, activity and body build "Rapid acclimatization" of 1 week or 10 days or even a month did not confer immunity to heat injury, for there were as many deaths in those who had had 4 weeks' exposure as in those who had had 1 week's exposure The mortality rate and incidence of sunstroke fell off rapidly after longer acclimatization periods Susceptibility to heat stroke appears to be particularly high among persons acclimated to an atmospheric cooling above a certain level (about 600 calories hourly per square meter of body surface) when they are exposed to an atmospheric cooling power reduced below this level

In death from sunstroke the brain is congested and petechial hemorrhages occur under the pia and in the floor of the third and fourth ventricles. Changes are found in the neurons, and degenerative changes in the glia cells are present

The symptoms commence with headache, thirst and vomiting after drinking water. Some may suffer diarrhea as a first symptom.

The skin is flushed and dry; consciousness is soon lost and the patient falls to the ground. Convulsions are frequent. Often there is present a critical and always *a serious elevation of temperature which may reach 110 F and never less than 104 F.* The pulse is quick and full, respiration is rapid and sometimes irregular. The pupils are first dilated and later contracted. As a rule, the muscles are flaccid but they may be rigid. In some patients ecchymoses or petechial hemorrhages are found over the body. In more favorable circumstances loss of consciousness lasts only a short time, but in fulminating instances signs of increased intracranial pressure, such as bradycardia and Cheyne-Stokes respiration, develop very rapidly and the patient may die within an hour. During convalescence there is severe headache. Memory is impaired and there are irritability, loss of emotional control, difficulty in concentration and irregularities of body temperature.

The spinal fluid is under increased pressure and shows a mild pleocytosis. There is usually a moderate percentage of polymorphonuclear cells present at first and often there are a few erythrocytes, but within a few hours lymphocytes are predominant.

The diagnosis of sunstroke is based on the history of exposure to extreme atmospheric heat and humidity in bright sunlight or elsewhere, followed by sudden headache, coma, dryness of skin and high temperature. In heat prostration there are, on the contrary, a subnormal temperature, pale, moist skin and small pulse; consciousness is usually preserved and there are usually no convulsions. Heat cramps give symptoms like those of tetany, in fact, this condition is probably a type of tetany due to depletion of the body chlorides.

The immediate mortality of sunstroke is very high. In mild instances complete and relatively rapid recovery may be expected, but after severe sunstroke, prolonged headache and psychic disturbances may be expected. Sometimes personality changes and an increased susceptibility to heat are permanent.

Heat Exhaustion. In contrast to sunstroke, heat exhaustion occurs *in hot dry weather or in hot dry climates, for instance, in the desert. In those who are conditioned to a hot dry climate two types of heat exhaustion occur.*

The *first type* of exhaustion occurs during the first part of the summer. There is a sodium chloride deficiency and dehydration. Chlorides in the plasma and whole blood are grossly diminished. There is evidence that this type of heat exhaustion occurs in those who habitually secrete sweat containing a higher concentration of chloride than the average. Their salt intake is inadequate for their excessive loss through the sweat.

The onset of the illness is generally with vomiting and muscular cramps.

On examination the patient is pale, collapsed and sweating. On attempting to stand, syncope ensues. The blood pressure is usually normal or low. The pulse pressure is consistently low. The urine is scanty, of high specific gravity, and almost devoid of chloride.

Diagnosis is based on the foregoing findings.

The *second type* of heat exhaustion occurs *late in summer in conditioned persons.*

These persons are salt deficient but not so much so as those who have the first type of heat exhaustion. During the long exposure to the heat it seems that the salt content of the sweat increases, so that they too excrete an excessive amount of salt.

The onset of the illness in these patients is not sudden as in the *first type.* There first appear the prickly heat, defective sweating and polyuria.

On examination there is a healing, desquamating prickly heat. The skin is moist, not dehydrated. There are no changes in blood pressure or pulse pressure. Chloride

content of the plasma is decreased but not so much as in the first type of heat exhaustion During convalescence sweat containing an increased chloride content is secreted.

Diagnosis is made on the foregoing findings. The aged and the debilitated are susceptible to heat exhaustion

Heat Cramps. Heat cramps or muscular cramps due to the effects of heat are a part *of the syndrome of heat exhaustion* (first type heat exhaustion). The affected person is not well conditioned to an excessive exposure to heat and severe muscular cramps ensue.

This type of heat injury was common during the era of steamships that were powered by coal-burning boilers. After a few hours in the boiler room, usually when the ship was making full speed ahead, in temperatures well above 100 F (110 to 120 F), the victim was suddenly seized with moderate to severe pains in anterior thigh and abdominal muscles

The examination of these patients rarely reveals any detectable abnormalities such as fever or blood pressure changes. The cramps soon cease on cooling of the body However, the individual is weak and unable to work for the following 1 or 2 days.

Hypersensitivity to Heat. Sensitivity to heat is created by a number of circumstances A most disabling sensitivity to heat is that which follows severe sunstroke and is manifested by various systemic reactions The milder forms of sensitivity to heat have been described by Duke as comprising three types of reactions. (1) reactions caused by an increase of calories regardless of the source; (2) reactions caused by local increase of temperature and (3) reactions caused by sensitivity to both heat and cold

Sensitivity to heat almost always begins after the age of 40 years. It is likely to follow an acute illness, or a person previously sensitive to heat may become free of symptoms during an acute febrile illness. This sensitivity is most commonly manifested by urticaria (see Chapter 18).

Erythermalgia (Erythromelalgia). Erythermalgia is a disease of unknown etiology which is characterized by an unusual sensitiveness of the skin to warmth. When erythermalgia occurs in association with hypertension, polycythemia vera, gout, certain organic diseases of the nervous system or heavy metal poisoning, it is termed secondary erythermalgia

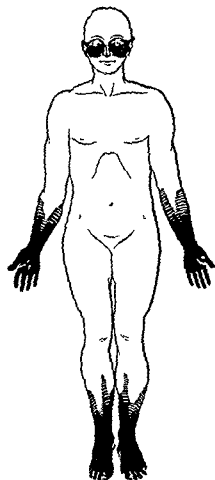
As a rule, the symptoms commence in middle age or later in life in both men and women However, the disease has been observed in children The burning discomfort of the hands and feet which characterizes erythermalgia can be induced by warming the skin and can be maintained when the flow of blood has been brought to a standstill Direct pressure on the skin gives relief. The distress may localize to a small portion of an extremity, usually a foot It comes on when the patient is walking or after getting warm in the bed at night, and may be severe. It may last from a few minutes to several hours and is always *greater during hot* weather It may be relieved by cooling the extremity. Trophic changes, ulceration and gangrene do not occur in primary erythermalgia

Examination of the involved extremity during an attack reveals a painful red region of skin with an increased temperature The pulsations in the peripheral arteries are within normal limits.

The examination in the secondary form of the disease reveals diverse findings, depending on the nature of the primary disease.

The relationship of the episodes of distress to dependency and to relief by elevation and by applications of cold is helpful in making a diagnosis The final diagnosis is based on objective study of the temperature of the skin during an attack.

In the diagnosis of erythermalgia it is essential to demonstrate that the skin temperature and the distress *are related The extremity* may be enclosed within a



tent in which a lighted carbon filament bulb is placed, as soon as the extremity has been warmed sufficiently, the distress will supervene

There is no successful *treatment.*

Erythema Ab Igne *(Fire Shanks).* In fire shanks the skin over the lower anterior aspects of the legs is brown and of a motley appearance. The condition is found in persons habitually exposed to strong heat, such as engine drivers and those who use open fireplaces for heating the house in cold climates. After unduly cold winters in the South, where fireplaces are in common use, the disorder has been observed in both white and colored persons. The configuration of the pied patches is due to the penetrative power of the heat rays which causes dilatation of the deep arterioles and consequent congestion at the limits of the area supplied by each Dermatitis may result in severe cases if there is present an increased sensitivity to heat.

EFFECTS OF COLD

The skin reacts after exposure to cold by exhibiting an *erythema (erythema pernio)* Prolonged exposure to low temperatures causes a destruction of the skin and perhaps of the deeper parts as well, as seen in frostbite The destructive effects of cold are increased by dampness, as in trench foot or immersion foot

Redrawn from Coon, Garn and Birdsell Races, C C Thomas, 1950

Fig 21-1. Surfaces of the body most commonly injured by cold

Extremities having varicose veins or nerve injuries, or those which have been affected by anterior poliomyelitis or hemiplegia, are more susceptible to injury by cold than normal extremities Cold injuries of the skin are bilateral and usually symmetric unless there has been some irregularity of exposure or of nerve injury (Fig 21-1) In the latter case the lesion is more advanced on the previously injured extremity.

The disease syndromes manifested as the result of a cold environmental temperature are (1) pernio syndrome comprising acute pernio (acute chilblains) and chronic pernio (chronic chilblain erythrocyanosis), (2) excessive sensitivity to cold and heat, (3) immersion foot and (4) frostbite

These manifestations are due mainly to vascular injury by cold temperatures

Pernio Syndrome. The pernio syndrome includes *acute chilblain, chronic chilblain,* immersion foot and trench foot.

Acute Pernio. Acute chilblain or acute pernio affects children who are exposed to snowy cold wet weather without adequate protection for their feet and legs. Acute pernio on the shins is common in women who have inadequate protection of their legs while they are exposed to the cold. On returning to a warm room there is an intense itching and burning of the affected region Acute manifestations persist for several days; if lesions have not become infected, they gradually clear up in about a week or 10 days

The manifestations of a more severe acute pernio are characterized by derma-

titis in the affected regions which is bluish red and is associated with slight edema A residual brownish pigmentation persists for several weeks after an acute lesion has subsided. In rare instances a hemorrhagic, purpura-like reaction may appear in the affected region during the acute stage of the lesion. When this reaction appears or the lesion becomes infected, the condition may resemble a dermatitis from some other cause.

When the toes are affected, they burn and itch, and become reddish or cyanotic after exposure to cold. Swelling of the toes may occur and hemorrhagic blebs may supervene

Chronic Pernio (*Chronic Chilblain*) Synonyms for chronic pernio are erythrocyanosis, Bazin's disease, dermatitis hiemalis and lupus pernio.

On repeated exposure to cold, recurring and chronic cutaneous lesions develop which are erythematous, ulcerative and hemorrhagic and on healing leave scarring, fibrosis and atrophy of the skin and subcutaneous tissues The lesions usually clear up during the warm season. However, in some persons who are accustomed to an open fireplace these atrophic pigmented lesions of the skin become permanent, and this condition has been called fire shanks

Repeated vasospasm which is the result of reaction to cold may be responsible for the vascular changes in pernio As the result of vasospasm anoxemia changes in the tissue followed by chronic inflammatory reaction of varying extent and degree occur.

On examination the lower extremities are found cool and often slightly cyanotic and edematous Over the lower parts of the legs there may be many shallow ulcers of varying sizes Scars and pigmented spots from previous healed lesions may be observed The peripheral arteries are pulsating

The lesions of the active stage and a history of the influence of cold and change of season are rather characteristic of chronic pernio During a quiescent period the differentiation of erythema induratum, erythema nodosum and idiopathic nodular vasculitis will have to be made The differential diagnosis of these conditions may be impossible in occasional cases

Peripheral Vasoneuropathy After Chilling. Immersion Foot. Immersion foot is a term applied to a condition produced by long immersion of the feet in cold water, usually associated with immobility of the limbs and constriction by boots or other clothing An exactly similar condition may affect the gloved hands when exposed to water The essential cause of this disturbance is exposure of the limbs to cold insufficient to freeze the tissues. Immersion, according to Ungley and his associates, has no specific action apart from its effect in keeping the parts cold. Webster, however, expressed the belief that the condition may occur to those exposed for long periods in subtropical waters and thus it cannot be classed as a true frostbite.

The following factors influence the occurrence and severity of the injuries incident to immersion foot. (1) time of exposure and temperature of water; (2) footwear which, because of constriction, is harmful for long exposures; (3) immobility; exposed persons who keep moving suffer less than those who sit still; (4) chilling of the body from wind or from repeated wetting; and (5) inadequate clothing.

The immersed limbs become numb and clumsy and may be painful. As the chilling advances, cramps may occur in the calves, and the feet may swell. The skin, red at first, is later pale, mottled, blue or black.

Ungley and associates described three stages after rescue The prehyperemic stage lasts for a few hours to several days The extremities remain cold, somewhat swollen, discolored and numb, with fairly extensive "glove or sock" anesthesia. Peripheral arteries may be pulseless for some hours and remain so in cases going on to gangrene A hyperemic stage follows and may last from 6 to 10 weeks. In

this stage there are vascular disturbances of the skin involving temperature differentials; increase in swelling, especially if the extremities have been warmed, sensory disturbances such as tingling, usually of "glove or sock" distribution; motor disturbances; absence of sweating, and blisters, ulcers and gangrene The posthyperemic stage lasts for weeks or months after the hyperemia has subsided Except for fresh blisters or infections, the extremities are no longer unduly hot in a normal environment. In some for months or years after exposure there may be a cold-sensitive state, giving rise to the Raynaud phenomenon

Trench foot, caused by prolonged wearing of wet shoes, if cold and inaction are added factors, produces changes in the feet comparable to those observed in immersion foot

Frostbite. Cold produces vasoconstriction, and in the extremes death of tissue may result from ischemia. When ischemia is severe and prolonged, there is thrombosis of the smaller arteries which results in death of tissue and possible gangrene Freezing of the cellular fluids with crystallization and formation of ice may cause death of the tissue

In mild frostbite there is a low-grade vasculitis with panniculitis and mild inflammatory reaction In severe frostbite there is an intimitis of the smaller arteries and arterioles The endothelium of the terminal capillaries is damaged so that pathologic permeability of the capillary walls may result Thrombi are formed in the terminal arterioles

When frostbite occurs at higher temperatures and with shorter exposures than usual, and is severe, examination of the extremity often reveals thromboangiitis obliterans or arteriosclerosis obliterans

In high altitudes extremely low temperatures are encountered (—75 to —90 F) which cause an intense degree of vasoconstriction, both direct and reflex The vasoconstriction produces a marked ischemia resulting in severe anoxemia and tissue damage The anoxemia is augmented by the decreased oxygen content of the air at high altitudes.

In mild degrees of frostbite the skin of the affected region assumes a dull yellow color accompanied by numbness and a prickling, itching sensation Ice crystals may be observed in the [illegible]
exposure to cold, [illegible]
within an hour or [illegible]
tissues However, on occasion, the affected region may remain permanently hypersensitive to subsequent exposure to cold

When the deep tissues are involved by frostbite, the affected extremity is frozen stiff After thawing of the extremity, a reactive hyperemia develops. A red wheal surrounds the frozen tissue and gradually spreads over the ischemic, pale skin until the skin over the entire involved part becomes red. This phase is accompanied by tenderness, burning pain and paresthesia Blisters form and edema of the entire part often ensues. The involved tissue may become necrotic Later it may peel off and leave healed skin

In high altitude frostbite the affected part is tense and shiny and the deep tissues become dusky gray and gradually turn dark Subsequently the affected tissues shrivel and a form of dry gangrene appears

The examination reveals the extent and severity of the frostbite

In establishing the diagnosis, there is always the history of exposure to cold, and the objective signs of freezing of tissues are characteristic. The recognition of an underlying occlusive arterial disease if present is important in the prognosis of frostbite.

Hypersensitivity to Cold (Cold Allergy) Certain persons are hypersensitive to local or general contact with cold. The manifestation of this hypersensitiveness can be precipitated (1) by allergy, (2) by auto-antigens, (3) by histamine-like

substances; (4) by underlying vasomotor disturbances and (5) by disturbances in the mechanism regulating the central temperature.

Horton, Brown and Roth demonstrated that a histamine-like substance is the cause of these reactions Lewis and Love demonstrated that histamine-like substance is liberated from the skin when it is irritated by cold.

Even though the sensitivity to cold can be transferred by the intradermal injection of blood serum from a reactor to cold, the true allergic nature of this condition is largely denied.

SYMPTOMS Sensitivity to cold is a systemic as well as a local reaction Among the symptoms are urticarial lesions which develop on portions of the body exposed to cold air, particularly the face, ears, neck, hands, feet, ankles and knees. In some instances the reaction to cold may involve the mucous membranes. For instance, after cold food or cold beverages have been taken, an urticarial reaction, like angioneurotic edema, may affect a hand or a foot.

The systemic reaction is manifested by an increase of pulse rate and a decrease of blood pressure, and occasionally by syncope

Horton has expressed the belief that hypersensitiveness to cold may result in drowning, drowning could result easily before the person so affected recovered from this reaction. However, fright and inability to swim are also common causes of drowning

DIAGNOSIS. The diagnosis is made from the history. It can be confirmed by a simple cold test' A cube of ice is strapped to the forearm. In susceptible persons an urticaria-like reaction will develop.

The regular cold test as described by Hines and Brown is performed by having the patient immerse the hand and arm in water the temperature of which is from 53 6 to 57 2 F (12 to 14 C) Within 5 minutes or less an urticarial and angioneurotic edema type of reaction will occur in the parts exposed to cold. A systemic reaction is manifested by a decrease in blood pressure and an increase in pulse rate. While the test is being performed, the patient should be sitting, for syncope is likely to occur

Exposure to Extreme Cold. Reduction of heat loss in response to a cold environment is initiated by peripheral vasoconstriction If vasoconstriction is insufficient to prevent loss of heat, the body temperature falls As a response to the loss of heat, mechanisms for increased heat production are invoked These mechanisms are shivering, release of epinephrine with resultant mobilization of liver glycogen, increased metabolism of muscle tissue, increase in pulse rate, and added cardiac output Vasoconstriction of the superficial vessels reduces the environmental cooling effect by decreasing the amount of blood reaching the surface to be chilled. In effect, the body surface is permitted to remain cool while the temperature of the body interior is maintained constant as long as possible

A continued exposure to cold is accompanied with reduction of blood volume by successively withdrawing fluid, increasing the viscosity, and then withdrawing plasma protein in proportion to the fluid withdrawn, so that concentration of the protein is maintained within normal limits. Increased viscosity is maintained because of the still slower withdrawal of erythrocytes Heart failure is apparently the cause of death in severe cold exposure, and is due in part to the great increases in viscosity of the blood

The large surface area of the extremities causes them to suffer extreme degrees of decreased blood supply in order to conserve body heat. During such periods the temperature of the extremities approaches that of the environment Severe cold, however, may stimulate dilatation as a reaction to injury. Thus the vasoconstrictor response (to conserve body heat) may be abandoned for vasodilatation as a secondary, protective mechanism to save the severely cooled extremity These alterations in response will not protect the individual when the body temperature falls to 90 F

this stage there are vascular disturbances of the skin involving temperature differentials, increase in swelling, especially if the extremities have been warmed; sensory disturbances such as tingling, usually of "glove or sock" distribution; motor disturbances, absence of sweating, and blisters, ulcers and gangrene. The posthyperemic stage lasts for weeks or months after the hyperemia has subsided. Except for fresh blisters or infections, the extremities are no longer unduly hot in a normal environment. In some for months or years after exposure there may be a cold-sensitive state, giving rise to the Raynaud phenomenon

Trench foot, caused by prolonged wearing of wet shoes, if cold and inaction are added factors, produces changes in the feet comparable to those observed in immersion foot

Frostbite. Cold produces vasoconstriction, and in the extremes death of tissue may result from ischemia When ischemia is severe and prolonged, there is thrombosis of the smaller arteries which results in death of tissue and possible gangrene Freezing of the cellular fluids with crystallization and formation of ice may cause death of the tissue

In mild frostbite there is a low-grade vasculitis with panniculitis and mild inflammatory reaction In severe frostbite there is an intimitis of the smaller arteries and arterioles The endothelium of the terminal capillaries is damaged so that pathologic permeability of the capillary walls may result Thrombi are formed in the terminal arterioles

When frostbite occurs at higher temperatures and with shorter exposures than usual, and is severe, examination of the extremity often reveals thromboangiitis obliterans or arteriosclerosis obliterans

In high altitudes extremely low temperatures are encountered (−75 to −90 F) which cause an intense degree of vasoconstriction, both direct and reflex The vasoconstriction produces a marked ischemia resulting in severe anoxemia and tissue damage The anoxemia is augmented by the decreased oxygen content of the air at high altitudes

In mild degrees of frostbite the skin of the affected region assumes a dull yellow color accompanied by numbness and a prickling, itching sensation Ice crystals may be observed in the affected region If the affected member is not subjected to further exposure to cold, the appearance may become normal within a few minutes or within an hour or two and there will be no evidence of permanent damage to the tissues However, on occasion, the affected region may remain permanently hypersensitive to subsequent exposure to cold

When the deep tissues are involved by frostbite, the affected extremity is frozen stiff After thawing of the extremity, a reactive hyperemia develops A red wheal surrounds the frozen tissue and gradually spreads over the ischemic, pale skin until the skin over the entire involved part becomes red This phase is accompanied by tenderness, burning pain and paresthesia Blisters form and edema of the entire part often ensues The involved tissue may become necrotic Later it may peel off and leave healed skin

In high altitude frostbite the affected part is tense and shiny and the deep tissues become dusky gray and gradually turn dark Subsequently the affected tissues shrivel and a form of dry gangrene appears

The examination reveals the extent and severity of the frostbite

In establishing the diagnosis, there is always the history of exposure to cold, and the objective signs of freezing of tissues are characteristic. The recognition of an underlying occlusive arterial disease if present is important in the prognosis of frostbite.

Hypersensitivity to Cold (Cold Allergy). Certain persons are hypersensitive to local or general contact with cold The manifestation of this hypersensitiveness can be precipitated (1) by allergy, (2) by auto-antigens; (3) by histamine-like

or even to temperatures near 90 F, a fact which is made evident by cold injuries occurring at a body temperature of 95 F. A decrease in the temperature of the interior part of the body may be produced by any prolonged exposure when an excess of heat loss over heat production is operative. For instance, a prolonged immersion of the body in cold water, when the rate of heat loss is twenty times as great as in air, results in depression of body temperature. Molnar has asserted that an exposure of 1 hour in water at 40 F can be expected to kill one half of the persons thus exposed. The more rapid heat loss in water is due to the poorer insulative value and the higher conductivity of water

Hypothermia occurs from exposure to cold air when the body is not protected by adequate clothing Despite proper clothing, children, old and cachectic persons, exhausted persons, and all persons during sleep, undergo heat loss because the efficiency of the temperature regulatory mechanism is reduced Hypothermia is likely to occur if those whose clothing is wet with water are forced to remain exposed to the cold and to a strong wind

In extreme hypothermia often the patient is not seen by the physician until a deathlike state is present In any instance of a deathlike state after exposure to cold, if rigidity of the muscles is absent, the diagnosis of hypothermia is a good probability. There is hope for recovery if proper treatment is administered; therapy for acidosis is very important

In many instances prolonged hypothermia leaves the heart permanently dilated Psychic derangements such as hallucinations and apoplectiform and epileptiform states may ensue as permanent after-effects of a prolonged hypothermic experience.

Cold Injury and Death. Deaths from cold introduce an element of acidosis and shock. The effect of freezing a part of the body is to fix the fluids solid, both in the vessels and in the tissue spaces Life is suspended, and whether it can be resumed again depends entirely on the ability of the tissues involved to survive the complete anoxia which has taken place.

When cold pervades the body, metabolism is lowered and the body temperature may fall to a level at which vital processes cease Death is preceded by a sense of fatigue and drowsiness, and the victim may fall into a confused sleeping state which obscures the bitterness of cold and exposure

Necrospy provides little evidence of these functional changes except where they are localized, as in immersion foot. The outstanding features are capillary dilatation and increased permeability resulting in edema of the tissues. Blebs may develop in the skin Clumped aggregations of erythrocytes are sometimes seen in parts killed by freezing

An interesting phenomenon may occur when freezing has preceded the development of rigor mortis. The muscles may soften as they thaw, and then rigor mortis may pursue its ordinary course

mediate clinical importance. The important feature is the loss of electrolytes (sodium, chloride, potassium) and water The chronic diarrheal states which may cause loss of electrolytes in sufficient amounts to cause symptoms of electrolyte loss of a sufficient degree to be immediately important are pellagra and sprue. In these there is an inadequate diet or inadequate absorption (sprue). An inadequate absorption also may result from loss of sufficient intestinal surface for absorption and this may follow surgical removal or surgical anastomosis in which a long segment of the intestine is left in a malfunctioning state

Diseases of the urinary and genital organs or endocrine glands are not important causes of nutritional deficiency disease if diabetes mellitus or hypothyroidism is discovered and treated Likewise diseases of the nervous system or organs of special senses rarely are complicated by diseases secondary to metabolism. Loss of taste and smell in patients who are not mentally deranged will not greatly interfere with eating Loss of appetite in the insane requires special care not within the scope of this consideration

There are a number of conditions which may cause an increased requirement of food Important among these is increased physical activity, voluntarily or involuntarily imposed In the latter group of conditions is the physical exertion accompanying delirium, convulsive states (status epilepticus) and maniacal states. Pregnancy, lactation, hyperthyroidism and excessive perspiration require increased amounts of food

There are many drugs which interfere with appetite sufficiently to cause deficiency disease or other metabolic disturbances Fortunately, however, only the physicians who are therapeutic enthusiasts continue administration of such drugs long enough to cause serious trouble. Chronic alcoholics and drug addicts frequently develop deficiency diseases

DISEASES DUE TO DEPRIVATION OF VITAMINS

Vitamin A. Vitamin A is a fat-soluble vitamin formed in the liver from the carotenes, and stored in this organ It is a constituent of visual purple (rhodopsin), preserves the integrity of epithelium, and influences calcium metabolism. It is synergistic to the sex hormones and cortin but antagonistic to the thyroid gland and insulin

The minimal daily requirements are 1,500 I U (international units) for infants, 3,000 for children up to 12 years of age, and 5,000 for older children and adults An excess of vitamin A due to overdosage may produce toxic manifestations but this is rare

Hypervitaminosis A. Hypervitaminosis A is reported to occur in the children of parents who are extremely concerned about adequate vitamin administration, and in each instance there is a history of excessive dosage with vitamin concentrates

The storage of vitamin A and the regulation of its blood level are functions of the liver Because of the capacity of the liver to store enormous amounts of the vitamin, Fried and Grand have expressed the belief that the syndrome is caused by hepatic dysfunction rather than by supersaturation of the liver with the vitamin Curves for vitamin A absorption demonstrate the existence of hepatic dysfunction

The predominant symptoms are anorexia, irritability, generalized pruritus and painful extremities, with a reluctance to stand or walk

There is a uniform similarity in physical observations, for all these patients have a yellowish pallor, sparse coarse hair, dry scaly lips with bleeding fissures at the corners of the mouth, and dry excoriated skin, hepatomegaly, tenderness over the long bones, and generalized weakness.

Roentgenologic examination reveals irregularities in cortical structure of the bones such as periosteal elevation with a single layer of subperiosteal new bone

22

DISEASES DUE TO OR ASSOCIATED WITH DISORDERS OF METABOLISM

Metabolism may be considered as all of the physical and chemical processes by which living organized substance is produced and maintained. Diseases due to or associated with disorders of metabolism may be due to lack of food In such instances the ensuing disease is primary starvation. In contrast to primary starvation are those conditions which arise from an inadequate diet and are termed secondary nutritional deficiencies Secondary nutritional deficiency diseases accompany various environmental conditions and bodily states. These may be listed as follows (1) increased food requirements; (2) interference with the ingestion of food; (3) interference with the absorption of the chyme; (4) failure of utilization after absorption; (5) increased excretion of metabolic products, and (6) increased or interrupted destruction of metabolic products

The secondary nutritional deficiencies most frequently follow prolonged inability to partake of a sufficient amount of foods The ingestion of food is limited by a loss of appetite The three commonest conditions initiating loss of appetite are fever, pain and anorexia nervosa Fevers accompany all active generalized infections, certain allergic or chronic anaphylactic states such as rheumatic fever and rheumatoid arthritis, generalized malignant lesions and some of the chronic blood dyscrasias These diseases comprise a large part of all human illnesses

Pain from any cause, particularly if situated about the head, face, neck or abdomen, is very apt to blunt the appetite If pain is severe or of moderately long duration the administration of opiates and sedatives may add to the difficulty of eating

Anorexia nervosa may not be easily detected. Many patients vow that they ingest large amounts of food These assertions are often found not to square with the facts after the alimentary tract has been examined and found to be free of disease.

A systemic review of the causes of the development of nutritional deficiencies reveals that aside from pain, diseases of the locomotor system which interfere with the ingestion of a proper amount of food are referable to ankylosis of the temporomandibular joint and conditions of extreme weakness of the muscles such as occur in myasthenia gravis and in the muscular dystrophies

There are no respiratory diseases which prevent eating except those affecting the pharynx and those creating extreme dyspnea Likewise dyspnea from cardiac disease may prevent eating. Dyspnea may accompany severe anemia from a blood [illegible]

[illegible] sec-

[illegible] tract

[illegible] consisting of narrowed segments occurring anywhere from the esophagus to the anus may cause starvation by degrees as the child grows and requires more foods than are supplied by milk formulas. Of these congenital malformations, congenital hypertrophic pyloric stenosis is common and occurs early in life Acute infections, food poisoning or irritations cause acute gastroenterocolitis accompanied by vomiting and diarrhea. In these acute conditions and in pyloric and intestinal obstruction, it is not the lack of food or the development of a nutritional deficiency that is of im-

It is well to remember that the response of cutaneous lesions to vitamin A, even if the lesions are due to vitamin A deficiency, is slow in contrast to the relief of night blindness in which the response depends on physiologic changes Night blindness is promptly relieved by administration of vitamin A

Vitamin A and Diseases of the Skin. A secondary deficiency of vitamin A has been postulated to have some significance in a few rare cutaneous diseases, for instance, Darier's disease, pityriasis rubra pilaris and ichthyosis. However, in these as well as the vast majority of cutaneous diseases there is little or no direct relationship

If large amounts of vegetables containing carotene are ingested by normal persons and persons suffering from certain diseases such as diabetes, carotene may accumulate in the skin in amounts sufficient to cause a deep yellow color This condition is known as *carotenemia* This skin coloring, so far as is known, is important only from the undesirable aspects of the cutaneous discoloration. Patients who have this discoloration may have false positive icterus index readings

Vitamin B Complex. Vitamin B complex includes a number of well-defined substances All of them are closely associated in nature, are widely distributed in natural foodstuffs, and are water soluble

Thiamine Hydrochloride (B_1). Vitamin B_1 has been synthesized and identified as thiamine hydrochloride. In foodstuffs and in the body vitamin B_1 combines with pyrophosphoric acid and functions as a cocarboxylase, an enzyme which has an important role in the metabolism (oxidation) of pyruvic acid It acts as a catalyst coenzyme in the metabolism of carbohydrate, promotes appetite and the growth of children, and is necessary for proper nerve function The daily maintenance requirement is thought to be about 0.5 to 1 0 mg in children, 1.5 to 2.0 mg in men and women.

Since a deficiency of thiamine results in an increase of pyruvic acid, blood tests are based on quantitative determinations of the latter. Pyruvic acid is stated to vary normally from 3 7 to 5 8 mg per 100 ml of blood with an average of 4 7 mg

Death has occurred immediately after the intravenous injection of thiamine hydrochloride The untoward reactions are in the nature of hypersensitivity to the vitamin

Beriberi. Beriberi in the adult is classified as (1) dry beriberi when degeneration of the nervous system, chiefly a multiple peripheral neuritis, is the outstanding manifestation, (2) wet beriberi when serous effusions and edema are the outstanding features, (3) fulminating beriberi when acute in onset and manifested by acute cardiovascular symptoms A combination of two or more of these types is referred to as mixed beriberi and this form is commonly observed

In acute beriberi the heart is dilated and enlarged In Oriental beriberi the enlargement is most pronounced in the right side of the heart where the muscle is coarse and firm and papillary muscles are especially prominent The valves are normal Degeneration of medullary and myelin sheaths and ganglion cells has been observed.

Symptoms The symptoms of beriberi commence with loss of weight, strength and appetite which precede the neuritis Difficulties in concentration, attention and comprehension, and memory defects too may commence before any evidence of peripheral neuritis

There is an ascending symmetric, peripheral neuritis, of which the initial symptoms are pain, weakness and cramps in the legs. There may be burning and numbness of the ankles and feet and impairment of dorsiflexion of the toes.

Involvement of the phrenic nerve or of the recurrent laryngeal nerve may occur. The sphincter muscles are affected in the late stages of the disease There may be ataxia and in-co-ordination. Contractures are common when paralysis is of long standing

The cardiac symptoms of beriberi are those of congestive failure. There are dyspnea and palpitation on exertion, tachycardia and edema. Acute heart failure

along the midportions of the shafts of the ulna, the clavicle, femur and tibia. There is a significant increase in the concentration of the blood vitamin A above the accepted normal value (50 to 300 I.U. per 100 ml. of plasma).

Vitamin A Deficiency. A deficiency of vitamin A may produce (1) keratinization of epithelium resulting in xerophthalmia, keratomalacia and follicular keratosis of the skin; (2) night blindness or nyctalopia; (3) osseous metaplasia; (4) the formation of renal calculi and, possibly, (5) prolongation of the period of gestation.

Hyperthyroidism may deplete or destroy vitamin A reserves. It seems that the thyroid hormone may participate in the conversion and storage of vitamin A, and thus vitamin A may be destroyed more rapidly when the metabolic rate is increased from any cause

The clinical observation is said to indicate that night blindness and keratomalacia may attend disease of the liver. Patients who have a slowly progressive cirrhosis of the liver may have subnormal powers of adaptation of their vision to darkness This aberration of vision improves on adequate administration of vitamin A.

SYMPTOMS. Most of the symptoms of vitamin A deficiency, except when the disease occurs in epidemics, are not separable from those of commoner diseases. In sporadic cases, therefore, the symptomatology is of little importance in the diagnosis

The loss of visual acuity in dim light is one of the first symptoms of vitamin A deficiency in man. Xerophthalmia is commonest in infancy although it may occur at any age. Night blindness develops in adults before any ophthalmias develop.

EXAMINATION Dryness and scaliness of the skin are early observations in those who have a deficiency of vitamin A One type of cutaneous lesion is characterized by small pustules which appear around the hair follicles on the extensor surfaces of both upper and lower extremities, on the shoulders, on the lower part of the abdomen and on the buttock These pustules vary in diameter up to 5 mm, are hard and deeply pigmented, and have a surrounding area of depigmentation. In the center of each pustule is an epithelial plug which when expressed leaves a crater

In the early stages of the disease the ophthalmologist observes small triangular white areas on the outer and inner sides of the cornea covered by white spots consisting of corneal epithelium which has been shed and has accumulated in this position (Bitot's spots) Photophobia and conjunctivitis appear early, followed by a light brown pigmentation of the conjunctiva. The keratinization of the conjunctiva may extend to the cornea and lead to extreme softness and degeneration of the cornea and to ulceration, perforation and total destruction of the eye (keratomalacia). This disease may destroy the eye rapidly

Vernix caseosa is a manifestation of a vitamin A deficiency in the newborn infant and it represents disturbances in cornification analogous to the dermal changes accompanying keratomalacia and other manifestations of vitamin A deficiency

In the infant, keratinizing metaplasia may appear in the trachea, bronchi, in the renal pelves, in the conjunctivae, corneas, accessory sinuses, salivary glands, ureters, uterus and periurethral glands

DIAGNOSIS. The incidence of vitamin A deficiency in the United States is low and therefore the likelihood of necessity for diagnosis is small. Vitamin A deficiencies are best detected by biophotometric examinations of the eyes There is relation between the biophotometer reading and vitamin A nutrition, but this relation is not definite enough to use as a means of diagnosing subclinical vitamin A deficiency. The small quantities of vitamin A present in the blood stream of man cannot be accurately determined by present methods

If there are cirrhosis of the liver, hyperthyroidism, prolonged pyloric obstruction, severe chronic diarrhea, or a generalized nutritional deficiency from any cause, vitamin A deficiency is a likely diagnosis.

yellowish crust which forms at the angles may be removed without bleeding. If the lesions recur frequently, a cicatrix may be formed, giving the affected area an atrophic appearance. The tongue is reddened and congested.

Often there is conjunctivitis. The eyes itch and burn and there is photophobia, which is often a manifestation of a superficial keratitis. Interstitial infiltration with exudation often gives rise to opacities either punctate or generalized. In some cases there is also involvement of the iris. The ophthalmologist is greatly aided in these examinations by employment of the slit lamp.

On the skin there is often a fine, scaly desquamation on a mildly erythematous base This desquamation may be present on the alae nasi, within the nostrils, and on and about the ears.

DIAGNOSIS The diagnosis of riboflavin deficiency depends on the presence of stomatitis and cheilosis, conjunctivitis and growth of the conjunctival vessels into the cornea, and seborrheic changes in the skin of the face, particularly of the nose and adjacent regions.

Nicotinic Acid. Nicotinic acid or niacin is highly effective in the prevention of pellagra, niacin and nicotinamide together are known as the P.P. (pellagra-preventing) vitamin Nicotinic acid is prepared synthetically

The normal maintenance dose of nicotinic acid has been estimated as varying from 17 5 to 35 mg per day The mean level for whole blood is 438 micrograms per 100 ml The normal range lies within the limits 260 to 573 micrograms per 100 ml of blood (Carter and O'Brien) The blood concentration of nicotinic acid is constant over a period of time but is temporarily increased after the administration of large doses of nicotinamide

Pellagra Pellagra follows a prolonged dietary inadequacy of nicotinic acid and substances physiologically similar The disease is particularly prevalent among the poor and ignorant who are forced to live on an unbalanced diet, usually rich in carbohydrates and fats but low in proteins, minerals and vitamins It occurs too in the ignorant well-to-do who by choice live on this same sort of diet. In these two groups of cases the disease is called endemic pellagra.

Alcohol addicts often subsist mainly on calories derived from alcohol, thus pellagra develops which is termed alcoholic pellagra or pseudopellagra.

[illegible] ave lost

[illegible] disorder attributed to respiratory enzyme systems, coenzymes I and II, occurs In the presence of such a disturbance there arise functional disturbances such as vasomotor instability in the skin, and disorders of alimentation, the nervous system, and the circulatory system The most readily affected systems seem to be those weakened by hereditary predisposition or trauma

SYMPTOMS [illegible]

General muscula [illegible]

of memory, head [illegible]

sations in various parts of the body, vertigo, numbness, nervousness, palpitation, distractability, flights of ideas, apprehension, morbid fears, mental confusion and forgetfulness frequently are present There may be alternating diarrhea and constipation These symptoms are so commonly observed in the neurotic patient that it may be difficult to recognize that they constitute a syndrome of a serious disease.

The clinical symptoms of endemic pellagra may develop in infants and children in pellagra families The distinctions between the symptoms of infant pellagrins and those of adult pellagrins can be made when it is realized that in the adult patient deficiencies affect mature tissues, whereas in the infant or child the rapidly growing tissues are more susceptible to injury than in the adult person

EXAMINATION On examination the cutaneous lesions may appear symmetrically placed They are most frequently observed on the flexor surfaces of the hands, wrists

may occur abruptly, with paroxysmal dyspnea, cyanosis, increased venous pressure, tachycardia, precordial pain and a small thready pulse.

EXAMINATION. The Achilles and patellar reflexes may be diminished and finally absent The weakness in the legs extends proximally, producing toe drop and drop foot. The muscles of the arms usually are not affected, until the symptoms of the lower extremities have become severe

[illegible] il parts of the legs. Appreciation of vibra- [illegible] is present in the lower extremities in a [illegible] by anesthesia.

Atrophy of the muscles of the legs is common. However, the degree of atrophy may be obscured by the presence of edema

Affections of the vagi nerves outside of the cranium may cause difficulty in swallowing and regurgitation There may be vocal disturbances, stridor and dyspnea among many other symptoms, depending on the extent of involvement of various cranial and peripheral nerves

In uncomplicated beriberi the arterial blood pressure is usually normal or low, often with an increased pulse pressure. The venous pressure is generally increased but may be normal Electrocardiographic changes, chiefly of the T wave and QT interval, have been observed

During failure the heart is enlarged, with associated pulmonary congestion The speed of circulation is increased in the cardiovascular type of beriberi, whereas in other congestive failure, except that due to hyperthyroidism, there is usually a conspicuous slowing of the circulation Hydropericardium, hydrothorax and ascites may be present as the result of the primary disease or of heart failure.

DIAGNOSIS Beriberi is a primary deficiency disease In the United States beriberi is associated with functional and organic gastrointestinal diseases, chronic debilitating diseases, pernicious vomiting of pregnancy, chronic alcoholic addiction, diabetes, pellagra, rapid growth, pregnancy, lactation, febrile illness, and hyperthyroidism.

The diagnosis of beriberi is based on the history, the symptoms and the physical findings, for there is no satisfactory diagnostic test for thiamine deficiency The response to an adequately controlled therapeutic test is pathognomonic of thiamine deficiency

Thiamine Deficiency and Hyperthyroidism. Increased requirements for essential factors tend to produce a relative deficiency of thiamine. This relative deficiency of thiamine contributes to the symptomatology of hyperthyroidism. Manifestations which are commonly present in both hyperthyroidism and thiamine deficiency are diarrhea, tachycardia, enlargement of the heart, dyspnea, palpitation, edema, fatigue, loss of muscular strength, neuritis and disturbances in carbohydrate metabolism

Riboflavin (B_2). Riboflavin or vitamin B_2 is also known as vitamin G. It occurs as a fluorescent pigment widely distributed in plant and animal tissues Yeast and liver are its richest sources The minimal requirement for adults has been estimated at 2.2 to 2.7 or about 3 mg. per day

The absence of riboflavin in the urine is indicative of its deficiency According to the method of Strong, in the normal person about 480 to 800 micrograms are excreted in the urine in 24 hours.

Riboflavin Deficiency. Riboflavin deficiency is commoner in women than in men The incidence tends to be higher in the spring and summer than at other seasons of the year. Persons who have other deficiency diseases are likely to have riboflavin deficiency too

SYMPTOMS It is impossible to separate the early symptoms of spontaneous riboflavin deficiency from those of pellagra or beriberi.

EXAMINATION. On examination in the early stages of riboflavin deficiency there may be paleness of the lips, particularly at the angles between the lips. Superficial fissures usually are present at the corners of the mouth The lesions are dry, and a

Subperiosteal hemorrhages are common, and may be confined to the ends of the shaft where the periosteum is separated easily from the bone In advanced stages of rickets the entire length of the periosteum may be separated from the bone

The dentin in adults is resorbed. The pulp reveals atrophy, hyperemia and degeneration. Rarefaction of the alveolar bone results in loosening of the teeth

The skin over the trunk and lower extremities commonly contains perifollicular petechiae. Ecchymoses are commoner about the knees and ankles. Moderate effusions, often blood-tinged, may occur in the pericardial, pleural and peritoneal cavities. Hemorrhage may be found anywhere in the body.

In adult scurvy there occurs fragmentation of the fibers of striated muscles which later become replaced by connective tissue

Infantile Scurvy. [illegible] infants, it develops in some brea[illegible] ages of 8 and 13 months, are n[illegible] as loss of appetite, irregular diarrhea, and failure to gain weight There are associated pallor, apathy, irritability and increased susceptibility to infection. The infant is small for the age and cries when approached

Fever and increased pulse and respiratory rates are common in infants who have manifest scurvy Rapid, shallow breathing, out of proportion to the fever and pulse rate, may be due to painfulness of the ribs and costochondral junctions. Epistaxis, vomiting of blood, and bloody stools may be the chief complaint Hemorrhage may occur in the abdominal organs Orbital hemorrhage may cause proptosis Ecchymoses of the eyelids are common and may be associated with edema Subconjunctival hemorrhage is rare; the eyeballs usually are not affected Hemorrhage into the brain or meninges may cause symptoms of intracranial hypertension

On examination the findings are essentially the same as in adult scurvy

Adult Scurvy. A prolonged period of deprivation of ascorbic acid (vitamin C) is required to produce adult scurvy. There is a great variation in the susceptibility of different persons to scurvy which was first definitely proved among the personnel of ships long at sea

The symptoms may begin with aching pains in the muscles of the calves, and painful swelling of the knees and edema of the ankles.

The gums become swollen and hemorrhagic Hemorrhages in the muscles cause brawny induration and tenderness Petechiae and ecchymoses occur in the skin. Epistaxis, and hemorrhages, conjunctival, retinal, cerebral, gastrointestinal, and urogenital, are rare in adult scurvy

On examination the findings in the infantile and adult forms of scurvy are essentially the same except that they are severer in the infantile form There is loss of weight if there is no edema The tissues are soft and muscle tone is decreased The complexion is pallid and often there are edema of the face and swelling of the pinnae of the ears and of the scalp

The gums appear swollen, congested and dark red or purple In some instances the teeth are buried by the swelling Hemorrhages are present, and additional hemorrhages occur readily on slight trauma to the gums.

Petechiae and ecchymoses of varying sizes are commonest in the lower extremities, in the lower half of the trunk, and in the forearms, face and neck. Miliaria, if present, is not specific for scurvy The tourniquet test is positive

Swelling of the extremities, due to subperiosteal hemorrhage, is commonly present It appears suddenly after mild trauma Pain and tenderness may be localized at the swelling or may extend over the entire extremity. There is a series of tender nodules at the costochondral junctions. In extreme instances the sternochondral plate is displaced posteriorly. Submetaphysial infractions (epiphysial separations) are commonly revealed by roentgenologic examination.

[illegible] on finding. In [illegible] The number [illegible] ually normal,

and feet. The skin over the elbows, knees, face and neck and under the breasts and in the perineal region may be affected. In most instances the area of dermatitis is sharply demarcated from the normal skin In some who have pellagra the cutaneous lesions are absent and this condition has been termed pellagra sine pellagra. The mucous membranes of the tongue, the oral cavity and the vagina may reveal glossitis, stomatitis and vaginitis as early manifestations of the disease

As the disease advances, there are loss of memory, excitement, mania, delirium, and hallucinations, and finally dementia.

DIAGNOSIS. The diagnosis of pellagra is based on the appearance of the cutaneous lesions Lesions of the skin associated with diarrhea and aberrations of the central nervous system affecting both the psyche and the soma are often pellagral in origin. Response to treatment in some cases has to be resorted to for purposes of diagnosis.

Other Members of the Vitamin B Complex. The substances enumerated in the following paragraphs are part of the vitamin B complex. From time to time they have been considered of significance in nutrition, but thus far their role has not been well defined, nor have the daily requirements for human beings been established

Pyridoxine or vitamin B_6 occurs in unrefined cereals, legumes, fish and meats

Pantothenic acid occurs naturally in milk and various vegetables and is prepared synthetically. It can be determined in the whole blood and is stated to vary normally from 0 019 to 0 32 microgram per cubic centimeter

Vitamin B complex includes *biotin or vitamin H, the role of which in human nutrition* is as yet unknown

Animal investigations have indicated that along with pantothenic acid and biotin *para-aminobenzoic acid* may regulate the pigmentation of hair and affect the formation of melanin There appears to be no justification at present, however, for its use in the treatment of premature graying of human beings

Inositol probably influences the growth and maintenance of hair although its value in this connection in human beings is not known

Choline, like nicotine, causes a preliminary stimulation and finally a paralysis of the autonomic ganglia, resulting in a marked drop in blood pressure, increased peristalsis and a general increase in the secretions

Folic Acid and Vitamin B_{12}. Folic acid (pteroylglutamic acid) is the synthetic Lactobacillus casei factor. It occurs naturally in the liver, kidneys and other animal tissues; likewise in yeast, mushrooms, grass and green leaves Vitamin B_{12} is of unknown chemical structure

Microscopic examinations of the blood are the only means of identification of the particular macrocytic anemias in which the compounds have been found of therapeutic value The diagnosis is confirmed if the anemia improves on administration of the vitamin

Vitamin C (Ascorbic Acid). Vitamin C occurs naturally in citrus fruits and in vegetables It is destroyed by exposure to air, alkali and heat Tomato juice, because of its high acidity, can be canned without much loss Most fruit juices can be concentrated in vacuo or by the spray process without appreciable loss of the vitamin.

Vitamin C is cevitamic or ascorbic acid and is prepared synthetically Its unique action in the body is largely due to reducing properties promoting oxidative or respiratory mechanisms in the tissues It maintains capillary resistance and affects the functioning of odontoblasts in the formation of dentin It is synergistic to cortin and insulin The daily maintenance requirements for infants are 10 mg, about 15 to 20 mg for children more than 1 year but less than 12 years of age, and about 30 mg for adults.

Normally from 0.7 to 1.4 mg of ascorbic acid (vitamin C) occurs in 100 ml of blood plasma under fasting conditions, the amount varying with the intake.

The defective osteoid formation is most pronounced in the distal end of the femur, the proximal end of the humerus, both ends of the tibia and the fibula, and the distal end of the radius.

Normal marrow at the epiphysial ends of the bone is replaced by soft fibrous tissue.

woman may have children who become rickety by a man who has had rickets, and she may have healthy children by another man who has not been rickety. The sexes are equally affected

SYMPTOMS. The baby cries abnormally on being handled, particularly when the ankles are handled in changing the diaper. The infant makes no attempt to move the legs or (sometimes) the arms Often the voluntary movements consist solely of tossing the head from side to side while crying

The disease usually is fully developed by the end of the second year of life, and then quickly recedes. However, there are instances of "late" rickets In late rickets the most active stage of the disease is observed in the third or fourth year of life or recurs at the time of puberty In the late forms, coxa vara with high position of the trochanter, shortening of the leg, with limitation of abduction, atrophy of the muscles of the gluteal and femoral regions, genu valgum, flatfoot and spinal curvature are common. Before condemning the pediatrician who has been in charge, it is well for the diagnostician to inquire about the dieting program that an adolescent has been on, because this disorder often is encountered despite good dietary habits and good food.

During the course of infantile rickets tetany may develop.

EXAMINATION Tenderness of the extremities and pain on movement due to hemorrhage are apparent on examination Hemorrhages occur most frequently under the periosteum of the long bones, in the gums, the skin and the mucous membranes, and at the lower end of the femur followed by bleeding in the upper end of the humerus Hemorrhage occurs much less frequently at the ankles and the wrist The hemorrhage under the periosteum may be so great that swelling of the bone may be evident The periosteum of long bones fuses with the perichondrium near the ends and therefore the swelling does not extend beyond the end of the bone or involve the joint The bone thus becomes club-shaped

Changes in the *skull* are often the first to be evident on examination. The bones of the skull are thin and soft The occipital bones may be so soft that they can be dented with the finger tip (craniotabes) On pressure with a finger over such areas parchment-crackling may be present.

The forehead and parietal bosses become prominent from thickening of the frontal and parietal bones. The resulting square forehead formed by prominent frontal eminences resembles in appearance the hydrocephalous cranium.

Dentition is delayed, and the teeth, when they do appear, are small (microdontia) and deformed.

The rachitic rosary, in the *thorax,* arises from thickening at the costochondral junction of the ribs with their cartilages. When well advanced, these enlargements can be palpated Excessive softening of the ribs leads to distortions and deformities of shape of the thorax These deformities consist of outward curving of the margin of the lower aperture of the thorax, vertical grooves on each side of the sternum; horizontal groove at the level of the xiphoid, producing *Harrison's groove;* pectus carinatum or pigeon breast. Kyphosis or kyphoscoliosis are commonly caused by rickets Diminution of the pubosacral diameter and other pelvic deformities in girls may complicate childbearing

The increase in size of the epiphyses proximal to the wrist and ankle are characteristic The long bones of the forearms and of the legs are soft and become curved, producing bowlegs and knock knees. A mild grade of rickets predisposes to frequent greenstick fractures

In rickets the muscles are loose and poorly developed, so that a greater freedom of joint movements is possible than in normal persons These rachitic patients are double-jointed

In adults misshapen heads, bowlegs, thoracic deformities, and, in the female, narrow pelves are often the residua of infantile rickets.

but in severe scurvy prolongation of either or both may occur There may be changes in the values for the serum calcium and inorganic phosphorus, but these changes are not constant. Hematuria occurs with great frequency; oliguria is common Hyaline or granular casts, sometimes blood casts, and pyuria may be present

Characteristic roentgenologic changes in the bones are most helpful diagnostically. A positive reaction to capillary resistance tests and a decreased blood level (normal range 0 7 to 1 4 mg) of ascorbic acid suggest a depletion of vitamin C.

A history which reveals evidence of inadequate intake of foods containing vitamin C is helpful diagnostically If the diagnosis remains in doubt, a therapeutic test is recommended 250 mg. of ascorbic acid should be given parenterally each day The patient is observed for alteration of symptoms and if the symptoms disappear, the diagnosis is established.

Vitamin D. Vitamin D is fat soluble and occurs naturally in fish liver oils as well as in egg yolk, liver, butter and salmon It is produced in the body on exposure to sunlight

At least 10 sterol compounds possess vitamin D activity Two of these, D_2 (calciferol), produced by the irradiation of ergosterol, and D_3, formed by the irradiation of 7-dehydrocholesterol, a precursor of vitamin D present in the outer layers of the skin, are of known importance

Vitamin D is not absorbed from the intestinal tract in the absence of bile Its chief function appears to be concerned with the metabolism of calcium and phosphorus The characteristic changes in deficiency are (1) diminished serum inorganic phosphorus, (2) usually a diminished serum calcium, (3) increased serum phosphatase activity, and (4) a negative calcium and phosphorus balance with excessive elimination of these elements in the feces

The minimal daily requirements of vitamin D are 400 U S.P. units, irrespective of age A deficiency in vitamin D may result in rickets, consequently it is called the antirachitic vitamin

There are no laboratory examinations available for the detection or estimation of vitamin D in the blood or the urine

The concentration of phosphate in the blood is greater in the summer than in the winter The concentration of inorganic phosphate, in rickets, is more constantly lowered than is that of calcium The product of concentrations of calcium and phosphorus is usually in the region of 40 but falls below 30 in the great majority of rachitic infants.

Vitamin D increases the serum phosphate by increasing the intestinal absorption of calcium or by diminishing its re-excretion from the intestinal mucosa Parathyroid extract increases the concentration of serum calcium by withdrawing the element from the bone

Rickets (*Rachitis*) The inheritable rate of growth is a most important predisposing factor in the production of infantile rickets Slow growth encourages the onset of rickets

Breast milk in sufficient quantities largely prevents rickets Metabolized milk and irradiated milk possess antirachitic activity about equal to that of human milk but are of value only in prevention and should not be depended on in treatment of active rickets

During the development of rickets the epiphysial cartilage increases irregularly in width. The basic structural alteration in rickets is not the failure of formation of bone but the failure of calcification

The lower epiphysis of the femur most commonly will reveal a wide, irregular zone of ossification at the junction of the epiphysis and the diaphysis This region is known as the rachitic zone. Growth of the bone is delayed or stopped completely, in proportion to the severity of the process The structural changes in the bone are not identical in all instances. In one type of the disease there is a large medullary cavity with a thin, porous cortex; in another type the cortex is thick but porous and the medullary cavity is small

Rickets is rare in the tropics, at high altitudes, and in northerly regions, though it does occur in any climate provided there is the proper hereditary background A

subcutaneous tissues. Periarticular calcification also has been described in man which may clear up on cessation of the administration of the vitamin.

The mechanism of the disorder is not entirely clear. The manifestations are probably associated with one or both of the known actions of vitamin D: (1) to increase calcium absorption from the gastrointestinal tract and (2) to increase phosphorus excretion in the urine.

The symptoms include anorexia, lethargy and constipation, polyuria and polydipsia.

There are no essential physical findings. There are present albuminuria, hyposthenuria, impaired renal function, hypercalcemia and hyperphosphatemia or hypophosphatemia.

Essential in making the diagnosis is the history of excessive administration of vitamin D and the presence of the afore-mentioned calcifications.

The maintenance dose in human beings is unknown.

Vitamin K. Vitamin K occurs naturally in alfalfa, cabbage, spinach and cauliflower. It is produced synthetically in a form known as K_1 or 2-methyl-3-phytyl-1, 4-naphthoquinone, and as K_2 In man, under normal conditions, the minimal requirements for vitamin K seem to be produced by bacteria in the ileum and the colon Since natural vitamin K is oil-soluble, its absorption cannot occur unless normal amounts of bile are present.

Coagulation of the blood proceeds normally if sufficient amounts of fibrinogen and thrombin are present to produce fibrin Thrombin is formed only from its precursor prothrombin Prothrombin is produced in the liver, provided vitamin K is available. Intravascular coagulation is prevented by antiprothrombin (presumably heparin). In the event of a wound, thrombokinase is liberated by the platelets and tissues and mobilizes thromboplastin The latter fixes antithrombin, and the free prothrombin is then activated by the calcium salts of the blood with the production of thrombin

A deficiency of vitamin K results in hypoprothrombinemia and this, in turn, in prolonged bleeding However, hypoprothrombinemia may be caused (1) by a lack of vitamin K due to temporary sterility of the intestinal tract, (2) by inadequate absorption of vitamin K due to insufficient bile in the intestine, as in biliary and gastrointestinal fistula, obstructive jaundice and intestinal obstruction, or because of impairment in its absorption as in ulcerative colitis and sprue, (3) by imperfect utilization of vitamin K by the liver in the formation of prothrombin due to primary hepatic disease, as in cirrhosis, hepatitis, and acute yellow atrophy, or (4) by surgical removal of long segments of the small intestines.

There are no direct laboratory examinations for the detection of vitamin K deficiency in the blood or urine Several tests are available, however, for determining the prothrombin content of the plasma, for example, that of Quick. By the Quick method plasma normally produces coagulation in 19 to 20 seconds. There is a wide margin of safety, for when prothrombin is reduced in the plasma to between 30 to 40 per cent of normal the prothrombin time is usually at the upper limits of normal or about 20 seconds, when reduced to about 10 per cent of normal, it is likely to be around 40 seconds, and when reduced to 5 per cent, around 70 seconds.

A determination of the prothrombin concentration of the blood may be a reliable index of hepatic function, provided the intake of vitamin K is adequate.

PHYSICAL FINDINGS OF VITAMIN DEPRIVATION

In the preceding paragraphs the diagnosis of nutritional deficiency diseases has been based largely on the presence of certain physical findings such as conjunctival thickening, corneal vascularization, hyperkeratosis, cheilosis, glossitis, swollen and bleeding gums, petechial hemorrhages and neurologic manifestations. In a recent review, Darby pointed out the fallacy of relying on such physical findings only and cited a number of diagnostic errors that have arisen from lack of experience and judgment of those who make such medical appraisals A thicken-

DIAGNOSIS The diagnosis can be made and often is made on the basis of physical findings alone After the disease has developed, or perhaps after it has healed, roentgenographic evidence is often diagnostic.

Rickets may resemble infantile scurvy, purpura simplex, congenital syphilis, chondrodystrophy, osteogenesis imperfecta, cretinism, congenital dislocation of the hip and hydrocephalus.

Osteomalacia (*Adult Rickets*). The term osteomalacia is used to designate the existence of a skeletal disease characterized by bone softness. It is generally agreed that osteomalacia and infantile rickets are the same disease (see Diseases of the Bones, Chapter 6) In the adult who has osteomalacia the same kind of proliferation of cartilage is present in the cartilage-shaft junctions as that observed in children who have rickets.

Osteomalacia occurs most frequently during gestation and lactation. When the disease does occur in nonpregnant women or in men, it is not severe.

The beginning of the symptoms of osteomalacia are not definite because the patient has been weakened by repeated gestations or by a debilitating disease. It is not until a deformity of the spinal column or distortion in shape of some other bone or bones is observed that the condition can be suspected clinically. The disease may be detected when a roentgenogram is made of a fractured bone

The diagnosis of rickets can be made by clinical examination The diagnosis of osteomalacia is established by roentgenologic examination Both diseases are confirmed in advanced cases by roentgenologic examination The concentrations of serum calcium and serum phosphate are normal or low The serum alkaline phosphatase concentration is often increased during the active stages of both diseases.

Milkman's syndrome differs from osteomalacia only quantitatively It illustrates that an osteomalacia may exist when the only evidence of the presence of the disease is the multiple transparent stripes of absorption or zones of decalcification present in long and flat bones revealed by roentgenologic examination

Rickets and Osteomalacia Secondary to Other Diseases (*Avitaminosis D*). The symptoms of avitaminosis D may be superimposed upon some other disease. Rickets or osteomalacia may develop in a patient who has a capricious appetite and therefore does not eat, or who is able to take a sufficient amount of food but owing to steatorrhea and diarrhea loses vitamin D, calcium and phosphorus in the feces

In rare instances the patient may be resistant to vitamin D Vitamin D resistance may be observed in celiac disease, sprue, chronic jaundice or chronic pancreatitis. In these patients steatorrhea is often present to a severe degree

The loss of calcium and of vitamin D in the feces may explain the occurrence of rickets and osteomalacia in patients who have nontropical sprue.

In certain instances of defective function of the lower nephron with decreased renal functional activity, excretion of calcium in the urine is increased and osteomalacia or rickets may ensue In these patients there is an increase in the serum chlorides, a moderate decrease of serum calcium and a great decrease in the serum phosphorus The carbon dioxide of the serum too may be decreased.

Roentgenograms may reveal multiple regions of calcification limited to the renal pyramids.

For diagnosis of rickets or osteomalacia occurring in association with or sec-

or low phosphorus concentration An increased concentration of alkaline phospha-tase of the serum is present in active rickets or osteomalacia.

Hypervitaminosis D (*Vitamin D Poisoning*). The administration of large doses of vitamin D may be attended by metastatic calcification in the kidneys, bronchi, alveoli of the lungs, mucous membrane of the stomach, blood vessels, and

the group average is then expressed as pounds overweight or underweight. All these standards involve some major uncertainties The designation "healthy" in the reference group means only the absence of obvious disease and defect, and all persons in the reference group are presumed to be equally healthy. Further it is assumed implicitly that the average connotes the best

The main concern in all examinations of height and weight is the proportion of the body represented by fat In very emaciated and in very obese persons the principal difference is in the amount of fat Outside of these extremes the relation of fat to weight is less exact In the ordinary person with no great extreme of either emaciation or obesity, there is no correlation between true fatness and the degree of overweight or underweight calculated from height-weight tables.

True ideal weights are not known The level at which loss of weight or departure from standard average becomes important is not known Tables 22-1 and 22-2 give average weight for specified height and age

The rate at which weight is lost in undernutrition is of consequence In general, it seems that the more rapid the loss of weight the more serious is the disability at equal total losses of weight

The Specific Gravity of Healthy Men. Corporeal density can be accurately measured provided a correction is made for the air in the lungs. The values for specific gravity for healthy men ranging in age between 20 and 40 years are between 1 021 and 1 097 Behnke and associates believe that if it were required that the specific gravity of the body be not lower than 1.060, the obese would be excluded

Low values for specific gravity indicate obesity and, conversely, high values denote leanness Difference in the circumferential measurements of chest and abdomen, when the abdominal circumference exceeds the thoracic, serves as a criterion of obesity and can be correlated with specific gravity. In the absence of obesity the variation in the percentage of bone in relation to body weight may not produce more than small deviations. Individual loss of body weight is associated with an increase in specific gravity

The method for the determination of the specific gravity of the body mass is not generally feasible, in practice, but these investigations temper enthusiasm for too strict adherence to height-weight tables in diagnosis of fatness or leanness.

Obesity. Obesity is an abnormal increase of fat in the tissues In origin obesity may be alimentary, metabolic or endocrine The influence of heredity in the origin of obesity is difficult to evaluate. There is a definite heritable characteristic in human families This characteristic is known as the somatic type. The somatic type is genotypic (see Races, Chapter 16)

The observation that somatic type is a heritable character is not limited to the genus homo A common and well-known field wherein somatic type is of great importance is the breeding of hogs For the production of good bacon it is known to be essential that pigs be selected which have long bodies, these will produce a good-sized corner gammon, prime back and flank The pig with the long body requires more muscle for support of the abdominal viscera than does the pig with the short body Consequently the muscles of the abdominal wall must be larger and thicker, therefore there will be wider lean streaks in the bacon

In a study of more than 500 obese children in Stockholm, Sweden, where the population possesses racial homogeneity valuable for such investigations, Mossberg observed no thyrogenous obesity, and cerebral disease could be implicated in only 19 cases The study revealed that more obese children have obese parents than do normal children, and that the more obese the child, the more likely is one or both parents to be obese, especially the mother, that familial predisposition could result from either constitutional or environmental factors, but that a constitutional heredofamilial factor definitely exists and is common; and that children from families with more than one obese member are likely to become obese before the age of 6

ing of the conjunctiva cannot be used as the main indication of chronic vitamin A deficiency. Darby continued his discussion by pointing out that if such limited criteria were admissable as indicative of vitamin A deficiency a large part of the population who belonged to the middle and older age groups would be judged as having vitamin A deficiency Ophthalmologists have known and have described the conjunctival changes common in presenile or senile patients, but they do not believe that these changes are due to vitamin A deficiency. These conjunctival alterations are subepithelial infiltrations, the epithelium being unaffected, and they may occur in the presence of normal concentrations of vitamin A in the blood. Furthermore, vitamin A therapy in persons showing such conjunctival thickening is entirely without effect. Similar diagnostic errors ensue if hyperkeratosis follicularis is not differentiated from keratosis pilaris Keratosis pilaris is described by dermatologists as a common disease in children less than 12 to 13 years of age; the disorder is not related to a lack of vitamin A, nor does it respond to vitamin A therapy.

Corneal vascularization was, at one time, considered to be due to riboflavin deficiency Although corneal vascularization does occur in ariboflavinosis, the incidence is not necessarily correlated with the riboflavin intake or with other signs suggestive of riboflavin deficiency, and the condition may not respond to therapy with large doses of riboflavin

Darby continued with the enumeration of other physical signs that may be erroneously interpreted as indicative of a specific nutritional deficiency disease. He mentioned that cheilosis as evidence of riboflavin deficiency, glossitis as indicative of pellagra, swollen and bleeding gums as significant of scurvy, and neurologic manifestations alone without other manifestations are of limited value in the detection of nutritional deficiency diseases Important additional knowledge besides these physical findings comprises the dietary and medical history, and results of laboratory studies and therapeutic tests

FATS AND OBESITY

The Nutritive Value of Various Fats. There has been no agreement about the nutritional merits of various fats It is suggested by some that milk fat possesses a specific nutritive quality not present in vegetable fats. Others contend that experimental evidence shows that the vegetable oils possess all the nutritive qualities of milk fat (butter) Experimental evidence is now at hand which from the point of view of clinical significance suggests that nutrition may be well served by both milk fat and vegetable fats Economy and general effectiveness dictate that milk fat, the most easily obtained of the fats, is best taken in the form of whole milk, for whole milk supplies all the valuable nutrient essentials of milk, including butter fat

Digestibility of Fats. Fat yields 9 3 calories per gram in metabolism and is therefore the richest source of food energy Furthermore, the absorption of some fat is essential for the entrance of certain of the vitamins into the body. Reliable scientific evidence shows that fat is as well digested as [illegible] proteins if not better, and that the source of the fat is of lit[illegible] ld be made between real digestibility and satiety [illegible] at.

Body Weight and Fat. In the diagnosis of fatness or leanness dependence on whether or not loss of weight or gain in weight has been sustained is usually based on the height-weight relationship. This means comparison with some set of standards. It is essential to recognize the derivation and limitations of such standards. Since there are as yet neither theoretic nor experimental bases for establishing ideal or optimal relationships between height and weight, recourse is had to averages of supposedly healthy groups which are taken as the standards. The body weight of a given person is then compared with the average of a group of healthy persons of the same sex, age and height. The difference between the individual and

obesity and all leanness are alimentary, is some partially formulated irony The physician suspects that he has not told the whole story The irony will remain until due consideration is given to somatic types, to the fat and the lean, and the heritability of these characteristics.

* When taking measurements remove the outdoor clothing, shoes and coat. Age is taken to the nearest birthday For those of slender-frame somatic type deduct 10 pounds and for those of large broad-frame somatic type add 10 pounds (Reprinted from Medico-Actuarial Mortality Investigation, Vol 1, New York, 1912.)

Alimentary Obesity. Alimentary obesity is storage of fat in excess of the normal amount. It is not always easy to demonstrate that the patient indulged in excessive eating Overeating in many instances results from an innate appreciation

years, while in the families of those who become obese after 6 years there are usually fewer than 2 obese members

It remains, however, to be demonstrated in man whether the gene or the environment is the more important factor in the production of obesity. It has been

* When taking measurements remove the outdoor clothing, shoes and coat Age is taken to the nearest birthday For those of slender-frame somatic type deduct 10 pounds and for those of large broad-frame somatic type add 10 pounds (Reprinted from Medico-Actuarial Mortality Investigation, Vol. 1, New York, 1912.)

easy for physicians to put the blame for obesity and likewise for leanness entirely on the patient by constantly reminding the patient that *all* obesity and *all* leanness are alimentary in origin. Underlying the partial truth of this aphorism that all

deference to objective data on its effects and action It is true that many obese persons have a low basal metabolic rate, but if the results of the basal metabolic test are recalculated in accordance with the ideal weight of the patient rather than his total weight, it will be found that the metabolic rate is either normal or slightly elevated The pharmacologic effect of thyroid in stimulating the combustion of fat may be effective, but often the dose approaches toxic levels. The administration of thyroid to an obese person may result in a loss of weight, but there may be a rapid regain because the intake of food has not been controlled adequately In many instances the patient may take large amounts of the drug without the desired effect. In a few patients there may actually be an increase in weight due to the development of a bigger appetite through the toxic effects of thyroid, productive of nervousness and irritability.

The gonads control the distribution of the fat of the body to conform with the sex of the individual The gonads do not control the degree of general obesity.

Often patients will escape from social competition or responsibility because of their obesity These factors are not specific causes for overeating, but they influence the release of nervous energy into the channel of overeating in those persons who tend in that direction

There has been much publicity in the lay magazines in recent years warning the public against the harmful effects of benzedrine (amphetamine) These harmful effects have been vaguely termed overstimulation of the heart, addiction and nervous upsets It is true that a certain type of person with chronic fatigue, who receives significant mental and physical stimulation from this drug, may find a constant need for it and thereby have an addiction to it much the same as that acquired for many other commonly used drugs Warnings against amphetamine for patients with hypertension have been made by the Council on Pharmacy and Chemistry and the Food and Drug Administration

The Heart in Obesity. Among obese persons embarrassment of the heart and circulation is prone to occur There is an excess amount of fat deposited beneath the epicardium This adipose tissue may encase the heart partially or completely and penetrate into the musculature of the heart The penetration occurs between the muscle bundles and, at times, between the muscle fibers, but not into the muscle cells The right ventricle always is involved to a greater extent than the left ventricle This status impairs the function and nutrition of the myocardium

The increase in body weight by obesity increases the work of the heart The increase in adipose tissue throughout the body and the increase of body surface associated with obesity require an extension of the arterial periphery which, in turn, imposes greater work on the heart

Disturbances of Cellular Lipid Metabolism (Xanthoma, Xanthomatosis, Reticuloendothelial Lipidosis) ***Xanthoma.*** Xanthomas usually are localized infiltrations of the skin and viscera, and they may be primary or secondary. In either case the xanthomas increase in size by addition of cells, not by cell division. The contained lipid gives them their yellowish color A xanthoma heals by undergoing fibrosis and scar formation

Xanthomas of the skin, termed xanthoma tuberosum, appear as small yellowish tubercles with predilection for the extensor surfaces Similarly xanthoma tubercules may invade the vascular system, larynx, lungs, tendons and synovial membranes. When the gallbladder is the site of xanthomatosis, it is known as strawberry gallbladder Complete obstruction of the common bile duct by xanthomas occurs Angina pectoris may follow involvement of the coronary arteries.

Xanthomatosis. It has been stated that xanthomatosis may be either primary or secondary

The *primary xanthomatoses* are characteristically diseases of childhood, though they sometimes occur in adults, and are considered to be congenital errors in lipid

of good food, exquisitely prepared, and artistically arranged on the table and served.

There are many factors which intensify the appetite Some of these are unconscious, while others are recognized by the patients and can be controlled by them When the urge to eat is dependent on unconscious tensions, the patient cannot restrict the intake of food Some of these unconscious drives are so powerful that no incentive for reduction of weight can induce the patient to refrain from overeating. Commonly a patient will say "I would rather die than starve." This attitude is much the same as that of the repentant alcoholic addict who realizes that he is a social disgrace but can do little to control his appetite for alcohol Similarly the tobacco habit is controlled with difficulty, even though a patient may be advised that it is injurious to his or her health

Anything which increases the emotional tonus, such as sorrow, nervousness, irritability, anxiety or an emotional upset, may increase the desire for food. In others, emotional upsets, anxiety, irritability and sorrow will create anorexia nervosa with ensuing sitophobia Persons who have a tendency to be obese eat larger meals or eat more frequently when nervous or worried, or eat more when they are idle, bored or tired A few such examples are found in families in which some of the adult members are overweight Men who conduct their affairs over the dinner table are constantly exposed to rich foods and are influenced to overeat. Women who spend time at cards may obtain excessive calories from the candy, cake and ice cream which are served.

In the presence of a lack of interests or distractions from dullness, escape may be sought in eating This occurs in housewives who break the daily routine by eating frequently It is also seen in such persons as traveling salesmen, who drive long distances and vary the monotony of their trips by stopping for food every hour or so. A great many overeat when they are idle and away from the distracting influences of work

Patients who are confined to the bed or whose activities are restricted may continue to eat according to the habits established when they were active and will thus put on weight because of the temporary decrease in their expenditure of energy Any condition, for instance, an anemia, which induces fatigue may result in a condition of inertia and in relative overeating and obesity.

Anything which makes a patient worried or anxious, such as a social upset, domestic difficulty, or illness or death in the family, may result in overeating However, a loss of weight is considered to be, and is, the classic response to such an occurrence.

Endocrine Obesity. The designation endocrine obesity is used to describe the regional situation of the excess fat For instance, in pituitary obesity, Frohlich's syndrome, and gonadal and adrenal cortical disturbances the fat is characteristically distributed (see discussion of these diseases in Chapter 14). The abdomen, upper arms, and thighs may show accumulations of fat while the face remains thin and the calves and ankles, feet, forearms and hands maintain trim lines. The whole upper part of the body and arms may remain thin and the lower half become fat. Fat in the face and neck is seen in disorders associated with pituitary basophilism of Cushing. These features alone are not diagnostically important in endocrine disorders In fact, some of these distributions of fat may be the result of the so-called lipoid dystrophies which are of unknown etiology.

Only in rare cases is obesity of endocrine origin. The two commonest endocrine dysfunctions found to be responsible for overeating are the climacteric, which results in an increased nervous tension and thus leads to overeating, and premenstrual tension, which also increases tension but which occurs for only about one week before menstruation Puberty and pregnancy are conditions which commonly precipitate overeating through the development of anxieties, fears and new drives

Thyroid for the reduction of weight has been used in tremendous quantities in

Large masses of the characteristic tissue may form within the cranium giving rise to symptoms indistinguishable from those due to neoplasm. Optic atrophy, papilledema, convulsions and palsies of the cranial nerves are sometimes present

Roentgenologic examination reveals large irregular regions of destruction of the bones of the skull, pelvis and extremities.

The diagnosis depends on the presence of exophthalmos, diabetes insipidus, defects in the skull, and xanthomas. Increase of the blood lipoids, especially the blood cholesterol, loss of teeth, and the stomatitis are diagnostically helpful However, biopsy with histologic study is the only conclusive diagnostic procedure. In about one third of the cases the disease is fatal.

Gaucher's Disease This disease is neither definitely familial nor definitely hereditary. It is characterized by enlargement of the spleen and the liver as a result of deposits of kerasin in the reticuloendothelial cells.

The spleen, liver, lymph nodes, bone marrow and sometimes other tissues are infiltrated by large round cells with one or more small nuclei. The cytoplasm of these cells is distended by accumulations of fine granules which do not stain easily and which are believed to be composed of kerasin. The brain contains lesions which resemble those of amaurotic idiocy.

Several siblings are likely to be affected The onset is usually enlargement of the spleen before the first year of life has passed However, the disease may occur at any age and in the aged There are personality changes such as apathy and slowing of movement The eyes do not function properly though there is no failure of vision and the optic fundi are normal The face becomes immobile and the mouth is held open Pseudobulbar phenomena are prominent with attacks of laryngospasm, stridor, difficulty in swallowing, and trismus. There may be an increase of muscle tone and the tendon reflexes

In adults the disease is more chronic than in children The nervous system may or may not be involved. The skin is often deeply pigmented. Anemia is a characteristic feature There may be splenomegaly, hepatomegaly and hemorrhagic tendencies Spontaneous fractures and conjunctival thickenings ensue.

Sternal aspiration or puncture of the spleen and histologic examination of the tissue removed is the preferred method to establish the diagnosis Niemann-Pick disease is distinguished from Gaucher's disease only by studies of the difference in the staining reactions of the lipoid deposits.

In all cases the disease is believed to be fatal within a year or more.

Laurence-Moon-Biedl Syndrome. The Laurence-Moon-Biedl syndrome consists of mental deficiency, retinitis pigmentosa, hypogenitalism, obesity and polydactyly and appears to be inherited as a recessive trait.

Morgagni-Stewart-Morel Syndrome. The Morgagni-Stewart-Morel syndrome (hyperostosis frontalis interna) is inherited as a dominant character. It is manifested by internal hyperostosis of the frontal bone and by headache. The headache is a constant feature Frequently the disease is manifested by obesity, impotence, amenorrhea, benign hypertensive cardiovascular disease, hirsutism, psychosis of indefinite nature or psychoneurosis, fatigability and weakness, and sometimes by disturbances in olfaction, Bell's palsy, diplopia and amblyopia. There is no good evidence of endocrine dysfunction or of a disturbed fat metabolism which might cause the obesity

Diagnostically it is important to remember that hyperostosis frontalis interna or benign frontal exostosis is a common condition which is without clinical significance

Lipodystrophy. Lipodystrophy may be of either congenital or acquired origins.

Lipochondrodystrophy (Hurler's disease, gargoylism), is a rare congenital and familial disease characterized by dwarfism, skeletal deformities, a large head, with grotesque dwarflike face, clouding of the corneas, kyphosis, stiffness of the joints,

metabolism since each of them is distinguished by an excess storage of a particular lipid in the reticuloendothelial system in the spleen, liver, lymph nodes, bone marrow and other organs. These diseases are associated with a particular type or types of lipoid deposits in the reticuloendothelial cells and with the name of a man or the names of two or more men. Some of these may be enumerated: phosphatide lipoidoses (Niemann-Pick disease) in which lecithin and sphingomyelins are deposited in all tissues including those of the nervous system; cholesterol lipoidoses (Schuller-Christian disease) in which cholesterol and its esters are deposited in membranous bones, connective tissues, and in the brain where it is associated with demyelination, and cerebroside lipoidoses (Gaucher's disease) in which kerasin is deposited in the spleen, liver, lymph nodes, bone marrow and nervous system.

Secondary xanthomas occur in the presence of other diseases when there is a disturbance of cholesterol metabolism Xanthomas may involve the skin of a diabetic patient A less extensive xanthomatous involvement of the skin is seen in obstructive jaundice, myxedema, hypertension, and nephrosis The concentration of cholesterol in the blood may or may not be increased

Lipidosis. Under the heading lipidosis or neuronal lipidosis some of the xanthomatoses also are included The diseases included under all of the foregoing headings are (1) Niemann-Pick disease, (2) Schuller-Christian disease and (3) Gaucher's disease The neuronal lipidoses add to the list many more names which will not be considered here In addition to these diseases common in the categories of xanthomatosis and lipidosis are the Laurence-Moon-Biedl syndrome and the Morgagni-Stewart-Morel syndrome

Niemann-Pick Disease This is a familial disease of Hebrews There is an enlargement of the liver and the spleen due to deposits of lipoids in these organs, and sometimes there are lesions in the nervous system.

Girls are affected more frequently than boys The onset is often between the third and the sixth month of life, and almost always before 1 year of age. Brown pigmentation of the skin is often mixed with a waxy pallor.

Both liver and spleen are palpably enlarged Symptoms referable to the nervous system when present are identical with those of amaurotic idiocy. There are mental deterioration, blindness and eventually generalized paralysis and spasticity The cherry red spot in the retina is considered rather characteristic The blood lipoids may be increased. The disease proves to be rapidly fatal

The diagnosis is suspected in Hebrew children in whom enlargement of the liver and spleen develops prior to 1 year of age Sternal aspiration or puncture of the spleen and the demonstration of foam cells is conclusive.

Schuller-Christian Disease. This disorder, known also as *essential xanthomatosis, lipoid reticuloendotheliosis*, and *Letterer-Siwe disease*, is characterized by destructive lesions in the membranous bones and in other tissues. The lesions contain foam cells filled with lipoids There is often present the triad of defects in the skull, exophthalmos and diabetes insipidus, and retarded growth

The disease affects boys more frequently than girls and has no racial preferences or familial tendencies It begins in childhood, often with fever and yellowish or bronze discoloration of the skin There are deposits of the xanthomatous cells in the eyelids, and in the skull, giving rise to soft tumor-like swellings over the cranium There may be symptoms of involvement of the tuber cinereum and the hypophysis such as failure of sexual development, obesity of specific type, diabetes insipidus and Frohlich's syndrome Deposits in the orbits may cause exophthalmos, paralysis of the extra-ocular muscles and optic atrophy. The teeth are often imperfectly formed and may fall out.

The blood is low in hemoglobin and often contains an excess of total lipoids which is sometimes due to a very high blood cholesterol The liver and the spleen are not enlarged as in Gaucher's and Niemann-Pick disease.

SYMPTOMS There is the history of long duration of the intermittent passing of many soft, copious stools possessing a greasy or oily appearance and the ability to float on water. Loss of body weight, weakness and anorexia are important symptoms Muscular cramping of the hands (carpopedal spasms) and the feet is often present, as are severe pains in the arms and legs The abdominal discomforts experienced by some are severe Many of these patients have been on opiates for relief. The abdominal discomforts are variously situated but often they are in the right side of the abdomen

EXAMINATION On examination the evident loss of weight may be the only finding In the presence of tetany positive Chvostek and Trousseau signs are elicited and the blood calcium concentrations are decreased.

The skin is dry, often pale and glistening Frequently, scattered bruised spots appear which are part of a hemorrhagic tendency, noted fairly often in this disease. This tendency is probably related to the deficient absorption of vitamin K As an expression of an avitaminosis B, the tongue may be reddened along its edges and stomatitis is present At times there are cheilosis and dermatitis like those of pellagra. Polyneuritis may be present Some of the younger patients have lens opacities. Edema may be absent, slight or advanced Skeletal lesions observed on roentgenologic examination are osteomalacia, rickets, dwarfism, bending deformities and spontaneous fractures There may be an increased concentration of serum phosphatase in some patients who have steatorrhea.

In the blood there may be microcytes and elongated poikilocytes. There may be some macrocytes and polychromatophils, which indicate a feeble effort to form hemoglobin-containing corpuscles The number of these cells is increased after the administration of iron Reticulocytes are normal in number. An occasional normoblast and microblast may be found The hemoglobin is reduced out of proportion to the erythrocyte count and volume of packed red cells. The erythrocyte count may be normal or even somewhat above normal when the hemoglobin is as low as 8 gm per 100 ml of blood It is the hemoglobin and the volume of packed red cells which reach the low levels The platelets are usually normal in number and small The plasma protein content is often reduced. The leukocytes may be normal in number or slightly reduced Achlorhydria is a common finding The bone marrow is hyperplastic and shows a relative as well as an absolute increase of normoblasts

Some patients with this disease have a fasting hypoglycemia. The blood sugar during a glucose tolerance test fails to increase above the fasting figure by more than 40 mg per 100 ml of blood These abnormalities in sugar metabolism have some diagnostic import Alimentary glycosuria is very rare in idiopathic steatorrhea

The concentration of the blood cholesterol is low or normal in this disorder The concentration of the plasma protein is often decreased The concentration of albumin in the serum may be critically low Urea nitrogen concentrations are usually low in celiac disease, averaging between 8 and 10 mg per 100 ml. of blood.

The total volume of feces excreted in 24 hours by patients who have idiopathic steatorrhea may be increased To measure the fecal excretion of fat and nitrogen, it is advisable to use a standard test diet (the Schmidt diet). By the Fowweather method of analysis in the normal person not more than 25 to 30 per cent of the total dry fecal matter should be composed of fat. The neutral fat should not exceed 12 per cent of dry matter or 60 per cent of the total fat If the amount of total fat exceeds 30 per cent of the dried stool and 75 per cent of the total fat present is hydrolyzed (soaps and free fatty acids), a fault of absorption is assumed

Sigmoidoscopic and roentgenologic examinations are necessary to eliminate the possibility of ileitis, tuberculous colitis, ulcerative colitis and other organic colonic or small intestinal lesions which may very rarely be associated with steatorrhea.

flexed hands, hepatomegaly, splenomegaly and, in most cases, mental deficiency. The disease seems to be a lipoid disturbance of the germinal plasm transmitted in accordance to mendelian rule. The patients are fragile. They frequently suffer from respiratory infections. The majority have cardiac disease which terminates fatally The clinical diagnosis is easy and is confirmed by the skeletal abnormalities and wide involvement of bones as shown by roentgenologic examination. The prognosis is unfavorable.

Lipodystrophia progressiva (Barraquer-Simons disease) occurs in both infantile and juvenile forms In the infantile form of this disease, beginning at about 6 years of age, girls and boys are about equally affected. In the juvenile form, which is the commoner and begins at puberty, girls are predominantly affected.

The cause of lipodystrophy is unknown The condition frequently follows some acute infection, such as measles, pertussis, influenza, pneumonia, and tonsillitis. It has been suggested that the disease is a disturbance of subcutaneous areolar tissues or trophic nerve mechanism having to do with fat metabolism The marked increase of serum fat after high fat intake, the creatinuria, and the lower dextrose tolerance present in some instances suggest a general metabolic disturbance

There is a progressive loss of subcutaneous fat from upper extremities, thorax, face and neck In girls there may be an accompanying increase in fat over the lower part of the body The buccal fat pad disappears in lipodystrophy. There are no other symptoms The change in personal appearance gives rise to various psychologic disturbances. self-consciousness, tension, phobias and insomnia

Examination reveals no abnormalities until atrophy of the fat is evident After weeks or months the atrophy of fat is complete, and the emaciation of affected areas is in striking contrast to the real or apparent increase of fat elsewhere

The condition is evident. It must be distinguished from organic wasting diseases such as tuberculosis, cancer, and pituitary cachexia, and from adiposis dolorosa (Dercum's disease), in which the fat deposits are asymmetric and painful.

Whipple's disease (*intestinal lipodystrophy*) often occurs in middle-aged men The duration of symptoms before death has usually been from 1 to 5 years, though sometimes longer. A history of "arthritis" affecting more than one joint may be obtained. The disease begins with stabbing central abdominal or epigastric pains Fever is not always present In many instances bleeding by rectum occurs Increasing lassitude, loss of weight, diarrhea and steatorrhea, brown pigmentation of skin and oral mucosa, and hypotension may be present. Anemia, achlorhydria, signs of vitamin deficiencies, hypoproteinemia, ascites and edema may be terminal events.

Insulin lipodystrophy occurred in the early days of the use of insulin Subcutaneous fat disappeared in the region of repeated injections of insulin

Idiopathic Steatorrhea and Nontropical Sprue. Idiopathic steatorrhea, called also celiac disease, nontropical sprue, and Gee or Gee-Herter disease, is the passage of a sufficient amount of fat in the bowel movements to give rise to nutritional defects. Nontropical sprue is the designation for the disease when it occurs in adults.

The following etiologic factors have been postulated (1) a deficiency in pancreatic enzymes; (2) a defect in intestinal absorption related to slowing in the process of phosphorylation, depending on deficient function of the adrenal cortex A diminished activity of the adrenal cortex is also associated with avitaminosis B, (3) deficiency in the secretion of bile and (4) mechanical obstruction to lymphatic channels. Among these etiologies a deficiency of pancreatic enzyme is probably not present. Likewise the rest of these theories cannot be proved

The disease occurs during the early years of childhood as a celiac affection. The adult type, also known as *nontropical sprue*, is more likely to be seen in young adults, rarely occurring in patients beyond middle life. Girls and women are most often affected.

There are trophic changes in the intestinal mucosa, a decrease in the weight of the viscera, and a diminution in the amount of intestinal and subcutaneou[illegible]

SYMPTOMS. There is the history of long duration of the intermittent passing of many soft, copious stools possessing a greasy or oily appearance and the ability to float on water. Loss of body weight, weakness and anorexia are important symptoms. Muscular cramping of the hands (carpopedal spasms) and the feet is often present, as are severe pains in the arms and legs. The abdominal discomforts experienced by some are severe. Many of these patients have been on opiates for relief The abdominal discomforts are variously situated but often they are in the right side of the abdomen.

EXAMINATION. On examination the evident loss of weight may be the only finding In the presence of tetany positive Chvostek and Trousseau signs are elicited and the blood calcium concentrations are decreased.

The skin is dry, often pale and glistening. Frequently, scattered bruised spots appear which are part of a hemorrhagic tendency, noted fairly often in this disease. This tendency is probably related to the deficient absorption of vitamin K As an expression of an avitaminosis B, the tongue may be reddened along its edges and stomatitis is present At times there are cheilosis and dermatitis like those of pellagra. Polyneuritis may be present Some of the younger patients have lens opacities Edema may be absent, slight or advanced. Skeletal lesions observed on roentgenologic examination are osteomalacia, rickets, dwarfism, bending deformities and spontaneous fractures There may be an increased concentration of serum phosphatase in some patients who have steatorrhea.

In the blood there may be microcytes and elongated poikilocytes. There may be some macrocytes and polychromatophils, which indicate a feeble effort to form hemoglobin-containing corpuscles The number of these cells is increased after the administration of iron. Reticulocytes are normal in number. An occasional normoblast and microblast may be found The hemoglobin is reduced out of proportion to the erythrocyte count and volume of packed red cells The erythrocyte count may be normal or even somewhat above normal when the hemoglobin is as low as 8 gm. per 100 ml of blood It is the hemoglobin and the volume of packed red cells which reach the low levels. The platelets are usually normal in number and small The plasma protein content is often reduced The leukocytes may be normal in number or slightly reduced Achlorhydria is a common finding The bone marrow is hyperplastic and shows a relative as well as an absolute increase of normoblasts

Some patients with this disease have a fasting hypoglycemia. The blood sugar during a glucose tolerance test fails to increase above the fasting figure by more than 40 mg per 100 ml. of blood These abnormalities in sugar metabolism have some diagnostic import Alimentary glycosuria is very rare in idiopathic steatorrhea

The concentration of the blood cholesterol is low or normal in this disorder The concentration of the plasma protein is often decreased The concentration of albumin in the serum may be critically low Urea nitrogen concentrations are usually low in celiac disease, averaging between 8 and 10 mg. per 100 ml. of blood

The total volume of feces excreted in 24 hours by patients who have idiopathic steatorrhea may be increased To measure the fecal excretion of fat and nitrogen, it is advisable to use a standard test diet (the Schmidt diet). By the Fowweather method of analysis in the normal person not more than 25 to 30 per cent of the total dry fecal matter should be composed of fat. The neutral fat should not exceed 12 per cent of dry matter or 60 per cent of the total fat If the amount of total fat exceeds 30 per cent of the dried stool and 75 per cent of the total fat present is hydrolyzed (soaps and free fatty acids), a fault of absorption is assumed

Sigmoidoscopic and roentgenologic examinations are necessary to eliminate the possibility of ileitis, tuberculous colitis, ulcerative colitis and other organic colonic or small intestinal lesions which may very rarely be associated with steatorrhea.

Dilatation of the colon, amounting at times to a marked megacolon, has been observed in instances of steatorrhea.

DIAGNOSIS. The diagnosis is made by exclusion. Results of roentgenoscopic examination may be very suggestive if the patient did not take mineral oil the day prior to examination The subjective and objective signs in steatorrhea may be caused by a number of diseases.

The differentiation between pancreatogenous and idiopathic steatorrhea may be difficult There is no increase in the excretion of fecal nitrogen in idiopathic steatorrhea

Once the diagnosis is well established, the course is intermittently slow, and progression is certain, until in the final stages the patient cannot be maintained on any program, parenterally or otherwise.

UNDERNUTRITION, MALNUTRITION AND STARVATION

The term undernutrition by definition implies that the patient has had an inadequate food supply or that there has been a failure to ingest, to assimilate or to utilize any or all of the necessary food elements. The term malnutrition implies an imperfect assimilation of the food elements though an adequate caloric intake has been practiced The term starvation implies the act of starving from (1) a lack of food as in famine, (2) failure to utilize any one or all of the food elements or (3) failure to assimilate after ingestion. Starvation therefore is the more general term and usually is employed to designate a widespread food shortage as the result of famine.

Undernutrition and Caloric Requirements. The term caloric requirements is widely used but so far has not been precisely defined and probably cannot be so defined With any reasonable definition the requirement will be dependent on body size, age, sex, climate, occupation, personal habits, previous state of nutrition, and perhaps race

In a given person caloric balance can be maintained over a rather wide range of body weight and caloric intake, and it is not possible to determine whether the optimal condition would be toward the upper or the lower end of a range amounting to perhaps 10 per cent or more of the average body weight Changes in body weight are significant, and a person not previously obese who loses 10 per cent or more in weight and continues to lose weight is clearly calorically deficient as the result of starvation or he is ill from disease

In the United States, studies on caloric intake reveal surprisingly low values in some instances in which there is no clinical indication of inadequacy Therefore, human beings seem to have a varying innate capacity to partake of or abstain from food with or without significant loss or gain of body weight.

Undernutrition is present in the majority of patients who suffer from advanced chronic infections, blood dyscrasias, or neoplasms. Temporary undernutrition results from most severe infectious diseases and from major injuries and surgical operations. Anorexia of some degree is common in all of these conditions. A small supply of *exogenous carbohydrate* suffices to prevent ketosis. Thus ketosis and ketonuria do not ordinarily appear in chronic undernutrition, but ketosis will develop in a few days of fasting Associated with this difference in respect to ketosis are differences in the respiratory quotient, in acid-base balance and in the blood sugar concentration

Of the principal organic constituents of living matter the *proteins* in insufficient amounts are the most important cause of undernutrition because of multiplicity of their biologic functions

The recommendations of the League of Nations and the National Research

Council tend to fix on 1 gm. of protein per kilogram of body weight as the normal requirement for adults More recently, however, after studies on nitrogen balance by the National Research Council, it was decided that a man weighing 70 kg could live on a 50 gm. protein diet and maintain approximately 30 per cent margin above requirements.

Pure protein deficiency, with adequate calories and vitamins, is seldom encountered, and little is known about it That it retards growth and leads to hypoproteinemia and anemia is definite

When an inadequate number of calories are ingested a protein intake to fulfill the usual function of protein metabolism is hindered because protein tends to be used as fuel in place of fat and carbohydrate and therefore does not fulfill its specific function. When an inadequate caloric intake prevails the substitution of protein for carbohydrate in the diet has no effect on the balance, and the nitrogen loss from the body continues

Labile protein reserves (depot nitrogen) in the body are small, and a large negative nitrogen balance for more than a day or two is taken to mean either depletion or destruction of tissue With rest in bed, the panacea in all forms of disease and injury, the nitrogen balance becomes negative on the usual diet. It will become negative even in the absence of disease or injury. On the resumption of normal activity on the same diet the nitrogen balance becomes positive. Rest in bed attended by disease which causes a destruction of tissue may permit a positive nitrogen balance if the protein intake is great enough. Decreases in hemoglobin and plasma protein may occur in infections even though nitrogen balance is normal.

Some of the differences in value of the vegetable and the animal proteins are differences in digestibility and absorption Other discrepancies in these proteins are related to metabolic utilization Inadequacy of an essential amino acid may limit the synthesis of a tissue protein Accordingly, protein deficiency may follow from lack of a single amino acid

The necessity for an essential amino acid is not limited to protein for formation of new tissue The metabolic employment of methionine for detoxication and for the formation of choline and creatine exemplifies this observation Metabolic functions of comparable importance can be assigned to tryptophan aside from its part in formation of tissue protein and promoting growth.

The ingestion of tryptophan increases the content of niacin derivative in the urine, thus indicating that some niacin can be synthesized in the body from tryptophan

The protein fractions of the plasma are (1) albumin, 55 per cent; (2) globulin, 38 per cent, and (3) fibrinogen, 7 per cent The 38 per cent of globulin is composed of alpha globulin, 13 per cent, beta globulin, 14 per cent and gamma globulin, 11 per cent. Traces of protein are left in the mother liquid consisting of hormones, for instance, the follicular-stimulating hormone of the anterior pituitary.

Plasma proteins are normally synthesized from food proteins. In starvation they may be formed from tissue protein Albumin and globulin have different amino-acid patterns Protein having its source in muscle and viscera favors albumin formation whereas protein having its source in plants and grain proteins favor globulin formation The presence of infection depresses both albumin and globulin formation.

In the blood plasma there are two albumins and three globulins—alpha, beta and gamma—in addition to fractions contributing to blood coagulation and blood typing Of the globulins, the gamma fraction is concerned with the phenomenon of immunity, for in this fraction of normal and convalescent plasma are found the substances which give high antibody titer.

Normally the blood plasma contains 3 6 to 5 6 gm. of albumin and 1 3 to 3.2

gm. of globulin (euglobulin 0 7 gm.; pseudoglobulin 1.7 gm.) per 100 ml, giving a ratio of 1 5 to 2 5·1 The total protein concentration of the plasma (albumins plus the globulins) varies from 6.0 to 8.0 gm.

Primary alterations in abnormal states occur more commonly in the albumin than in the globulin fractions of the plasma Variations in the one are usually associated with compensatory changes in the other.

The albumins are formed in the liver, but until recently the origin of the globulins remained uncertain. Various degrees of hepatic damage cause a reduction of the plasma albumin. Antibodies are present in the lymphocytes and it seems that the lymphoid tissue is the site of antibody formation Attempts to separate the antibody portion of the plasma from the gamma globulins have proved unsuccessful. However, antibodies are specific modifications of the gamma globulins and these occur in the lymphocytes, with the antigen serving as the stimulus for the modification of the gamma globulin Thus it appears that the gamma globulins are formed in the lymphoid tissue (see Diseases of the Hemic System, Chapter 12)

A chief function of albumin and globulin is the maintenance of a normal colloid osmotic pressure in the capillaries (25 to 30 mm. of mercury) for a normal distribution of fluids between the blood and the tissues, the crystalloid osmotic pressure of the plasma being balanced by that of the tissue fluids. Since the plasma has a higher protein content than the tissues, there is a tendency for fluids to flow from the tissues into the blood which normally is counterbalanced by capillary blood pressure (16 to 35 mm of mercury) In hypoproteinemia the colloid osmotic pressure in the capillaries and venules is reduced, a condition conducive to the production of edema of nephritis as well as in nutritional edema. The albumin and globulin aid in the regulation and maintenance of a normal acid-base or hydrogen-ion equilibrium of the blood

Manifestations of Undernutrition. *Skin, Hair and Eyes* Undernutrition tends to produce a thin, dry, scaly, inelastic, pallid and grayish skin

At the University of Minnesota, Keys and others conducted an experiment on undernutrition over a period of almost 2 years A substantial proportion of the subjects, young men who volunteered for the study, subsisting on a European type of famine diet, exhibited rough gooseflesh-like areas of skin, most often on the extensor surfaces of the thighs and the upper arms. The condition resembled the follicular hyperkeratitis and folliculosis sometimes associated with vitamin A deficiency. The cause did not seem to be clearly related to the state of vitamin A nutrition

A peculiarity of the skin in starvation is a splotchy, dirty brownish pigmentation, appearing anywhere on the body but most often seen on the face The mechanism of the production of this famine pigmentation is unknown It is not related to nicotinic acid deficiency or pellagra

The hair in starvation is usually dry and dull The eyes look dull and dead On closer inspection it is seen that the sclera and cornea are unusually devoid of blood vessels.

Subcutaneous Tissues The edema of undernutrition is ordinarily only moderate and is of the soft, dependent type This edema is present in the face and the lumbar region in the morning and shifts to the lower extremities during the day. Ascites is not present except when there is severe anemia, intercurrent infection, heart failure or decided hypoproteinemia. The latter appears when the diet is unusually devoid of protein and there is less than 5 gm of total protein to 100 ml. of plasma. During recovery from malnutrition edema tends to appear and disappear, being affected by exercise and posture as well as by the food intake. Recently Berkman and associates have shown that in starvation edema resulting from anorexia nervosa the edema is due to retention of salt and water It is evident from the observations of Keys and his co-workers and, independently, of Berkman, that the edema in these

malnourished subjects cannot always be explained by the old theory of hypoproteinemia.

In regard to the belief that one of the controlling factors in the accumulation of ascitic fluid in persons who have cirrhosis of the liver is the concentration of serum protein, particularly the serum albumin, it is well to be aware of the observations of Hoagland. Hoagland and his associates investigated ascites in patients who had cirrhosis and who had been given a special liver extract They expressed the belief that the plasma protein concentration of patients suffering from hepatic cirrhosis does not solely determine whether ascites will or will not be present (Keys)

Muscular Tissues Muscular wasting is a prominent feature of severe undernutrition Most of the wasting seems to be a result of shrinkage of the individual muscle fibers, but in late stages actual destruction of the cells may occur

In both acute and chronic undernutrition the heart shrinks in volume and in weight, the loss being essentially in proportion to the total loss of weight of the body. In the Minnesota experiment the average gross volume of the heart, at systole, measured from teleroentgenkymograms, decreased 17 per cent when the body weight decreased 24 per cent.

Blood Volume. In the Minnesota experiment the plasma volume remained constant or increased slightly in starvation. In proportion to the body weight however there was a definite blood plethora

Blood Cells In the Minnesota experiment progressive moderate anemia occurred in every man during semistarvation

The erythrocytes tend to become slightly larger; the anemia is of the macrocytic type The cause of the anemia in undernutrition is not clear, iron deficiency is not primarily responsible The possibility that excessive peripheral destruction of the erythrocytes is involved is suggested by the presence of hemosiderin deposits in the tissue A definite but moderate leukopenia is the rule in severe undernutrition

In rehabilitation following prolonged undernutrition the correction of the anemia requires months

The Gastrointestinal Tract Gastrointestinal disorders frequently contribute to the disability and death of famine victims Edema of the mucosa of the stomach and intestine may contribute to the anorexia so prevalent in states of undernutrition

Extreme pathologic changes are often found in the intestinal mucosa of those who have severe undernutrition. An increase in the incidence of peptic ulcer is [illegible]

[illegible]

the rate while at rest

In beriberi there may be bradycardia when the patient is resting, but slight physical exertion initiates tachycardia The bradycardia of starvation is not due to heart block, the rhythm is of the sinus type and is regular

[illegible] undernutrition. These [illegible]

[illegible] ll preserved Though there is a tendency to slight peripheral cyanosis, there are usually no complaints referred to the heart and no signs of impending or actual failure except in the terminal state In starvation it is common to observe fainting and giddiness, particularly in the upright posture.

The restoration of cardiocirculatory function during recovery from undernutrition may be complicated by signs of relative cardiac insufficiency or even congestive failure at the time when the rate of gain of weight and of the basal metabolic rate are advancing most rapidly.

The Basal Metabolic Rate. When the food intake is reduced below the prevailing level for the subject, the basal consumption of oxygen declines, and this alteration

tends to be progressive if the inadequate diet is continued. The progress of the undernutrition itself progressively decreases the caloric deficit so that there is a tendency toward adaptation or compensation.

During the convalescence from undernutrition the basal metabolic rate rises synchronously with the gain in body weight.

Brain and Nervous Tissue. The brain and nervous tissue loses little or no weight during starvation. This does not mean that these tissues are unaffected by undernutrition. The changes in weight are limited because the gross structure is preserved with replacement of cytoplasm, or even of cells, by water. The changes in the spinal cord are similar to those in the brain and may be even more pronounced in the anterior horn cells The peripheral nerves are not immune to the effects of starvation, though the medullated fibers are only slightly affected morphologically.

There is no evidence for a decline in basic intellective capacity. In the Minnesota experiment exhaustive studies on memory, reasoning power, verbal and arithmetical facility, and so on, revealed no changes in spite of the subjective impression of most of the men that their mental powers had been reduced

During nutritional rehabilitation from undernutrition the return of a sense of well-being is associated with an increase in voluntary physical activity. However, the habit of conserving energy is not quickly broken. An effort of will or coercion is often necessary to promote recovery in physical fitness by exercise. In former times when starvation was the prevailing treatment of typhoid fever, a year was frequently required to get some of these patients to resume work

All psychomotor functions deteriorate in severe undernutrition, and the result is a serious impairment in working capacity Simple muscular strength, as measured in a single maximal exertion, declines steadily but not so dramatically as does the capacity for continued muscular exertion (endurance) Neuromuscular co-ordination is impaired by caloric undernutrition, but the relative deterioration is less than in purely muscular capacity

Severe undernutrition causes changes in the personality and the subjective state These changes are manifested by apathy, depression, introversion and hypochondriasis As the physical state improves, the tendencies toward depression and hypochondriasis diminish, [illegible] rate of recovery The return of [illegible] bility.

Undernutrition and Resistance to Infection. [illegible] undernutrition about which there is a more fixed common belief—and less objective evidence—than the question of the effect on resistance to infection However, undernutrition is not necessarily productive of a lowered resistance or a heightened susceptibility to infectious diseases in general. Tuberculosis seems to be the exception

The morbidity and mortality of tuberculosis are increased by caloric deficiency. Tuberculosis is a most serious disease in the presence of prolonged and severe undernutrition In some viral diseases a state of undernutrition seems to decrease susceptibility to infection, for instance, poliomyelitis

Examination in Undernutrition. The findings on examination for the detection of undernutrition depend on the deficiency or the combination of deficiencies present. It is rare to have undernutrition present which is due solely to a deficiency of calories and proteins Therefore, the findings present in vitamin, caloric and protein deficiencies will be considered here

In niacin deficiency, a pellagrous type of dermatitis may be present If a riboflavin deficiency predominates, there may be seborrheic lesions in the nasolabial folds, behind the ears and in other intertriginous areas of the skin In vitamin A deficiency hyperkeratosis in the hair follicles is present. Deficiencies of vitamin C may be expressed by the presence of subcutaneous hemorrhages. In general vitamin B deficiency there is an ichthyosis over the knees, elbows and perhaps over the buttocks and anterosuperior spines of the ilia

The angles of the mouth may be fissured in riboflavin deficiency. The angles of the mouth, also the oral cavity, the tongue and the buccal surfaces may be affected by a scarlet, inflammatory-appearing process in niacin, vitamin B_{12}, riboflavin, and ascorbic acid deficiencies In chronic long-standing deficiencies of these substances, especially of vitamin B_{12} (pernicious anemia), atrophic glossitis and atrophy of the buccal mucous membranes may be found

In vitamin D deficiency there are aberrations in metabolism of calcium and phosphorus, and subsequent skeletal deformities (rickets).

The eyes in vitamin A deficiency may reveal xerosis conjunctivae and xerosis of the corneas A keratoconjunctivitis of the vascularizing variety may be present. Central ophthalmoplegia and retrobulbar neuritis occur as the result of vitamin A and vitamin B deficiencies. The value of the dark adaptation test is not certain.

Bilateral symmetric polyneuritis and subacute disease of the posterolateral column result from deficiencies of vitamin B Disease of the posterolateral column is often present in pernicious anemia as the result of vitamin B_{12} deficiency.

Diagnosis of Undernutrition. The diagnosis of undernutrition depends (1) on dietary history, (2) on medical history and results of physical examination, with attention directed toward the manifestations of nutritional deficiency and (3) on results of certain special examinations The history of the patient's dietary intake permits an estimation of the probability of the presence of a deficiency disease.

Chemical analyses of the blood for changes in the values for serum protein and albumin-globulin ratio, serum calcium, phosphorus, alkaline phosphatase and blood prothrombin time (vitamin K) are regularly employed Their respective normal values are discussed in the appropriate places in this text

When the manifestations and thus physical findings of the classic forms of malnutrition, whether from inadequate caloric protein intake or from lack of vitamins, are present, the diagnosis is obvious However, early forms of these diseases have no specific manifestations For instance, the symptom of ease of fatigability is a constant symptom of pellagra, tuberculosis and, most of all, of psychoneurosis The same may be said of anorexia The diagnosis of a dietary deficiency disease is established by the exclusion of other diseases

At times special examinations can be of help in establishing the diagnosis These tests vary in their significance, in the stage in the development of a specific deficiency which they are capable of detecting For instance, those which measure the concentration of a vitamin in the blood or its rate of excretion in the urine are really indicators of the state of saturation of the body stores, and unless their results are correlated with other evidence, cannot in themselves demonstrate that the deficiency has progressed to the point of impairment of function Unfortunately, most of the methods which are capable of detecting disturbance of chemical or physiologic function are relatively nonspecific Their chief value is often as confirmatory evidence of the clinical findings, and in following the changes which occur in response to therapeutic trial It is evident that the accurate diagnosis of undernutrition is still largely in the province of alertness to the possibility of its occurrence.

Often the therapeutic test—that is, giving specific treatment and observing its effects—may be the only means of determining whether or not the patient's complaints are due to lack of a particular food factor. Obviously, it is important that an adequate amount of food or vitamins must be given and for a sufficiently long time if the therapeutic test is to be of value in making the diagnosis

Starvation, Exposure, and Neglect. The physician sees two common forms of starvation, exposure, and neglect [illegible] in elderly or weak-minded persons wh[illegible] [illegible]e in poverty, dirty, unkempt, often ve[illegible] [illegible]ul neglect of children often is accompanied by their starvation

These conditions are more likely to be manifest as vitamin defect, undernutri-

tends to be progressive if the inadequate diet is continued. The progress of the unde nutrition itself *progressively decreases the caloric deficit so that there is a tenden* toward adaptation or compensation

During the convalescence from undernutrition the basal metabolic rate ris synchronously with the gain in body weight.

Brain and Nervous Tissue The brain and nervous tissue loses little or no weig during starvation. *This does not mean that these tissues are unaffected by unde* nutrition The changes in weight are limited because the gross structure is preserve with replacement of cytoplasm, or even of cells, by water. The changes in the spin cord are similar to those in the brain and may be even more pronounced in th anterior horn cells The peripheral nerves are not immune to the effects of starvation *though the medullated fibers are only slightly affected morphologically.*

There is no evidence for a decline in basic intellective capacity In the Minnesot experiment exhaustive studies on memory, reasoning power, verbal and arithmetica facility, and so on, revealed no changes in spite of the subjective impression of mos of the men that their mental powers had been reduced

During nutritional rehabilitation from undernutrition the return of a sense o well-being is associated with an increase in voluntary physical activity. However the habit of conserving energy is not quickly broken. An effort of will or coercion is often necessary to promote recovery in physical fitness by exercise. In forme times when starvation was the prevailing treatment of typhoid fever, a year wa *frequently required to get some of these patients to resume work.*

All psychomotor functions deteriorate in severe undernutrition, and the result i a serious impairment in working capacity Simple muscular strength, as measured in a single maximal exertion, declines steadily but not so dramatically as does the capacity for continued muscular exertion (endurance). *Neuromuscular co-ordination is impaired by caloric undernutrition, but the relative deterioration is less than* in purely muscular capacity

Severe undernutrition causes changes in the personality and the subjective state. These changes are manifested by apathy, depression, introversion and hypochondriasis *As the physical state improves, the tendencies toward depression and* hypochondriasis *diminish*, but they *may be intensified* by disappointment in the rate of recovery The return of physical strength permits of manifestations of irritability.

Undernutrition and Resistance to Infection. There is no aspect of undernutrition about which there is a more fixed common belief—and less *objective evidence—than the question of the effect on resistance to infection. However, under*nutrition is not necessarily productive of a lowered resistance or a heightened susceptibility to infectious diseases in general. Tuberculosis seems to be the exception

The morbidity and mortality of tuberculosis are increased by caloric deficiency. Tuberculosis is a most serious disease in the presence *of prolonged and severe under*nutrition. In some viral diseases a state of undernutrition seems to decrease susceptibility to infection, for instance, poliomyelitis.

Examination in Undernutrition. The findings on examination for the detection of undernutrition depend on the deficiency or the combination of deficiencies present. *It is rare* to have undernutrition present which is due solely to a deficiency of calories and proteins. Therefore, the findings present in vitamin, caloric and protein deficiencies will be considered here

In niacin deficiency, a pellagrous type of dermatitis *may be present If* a riboflavin deficiency predominates, *there may be seborrheic* lesions in the nasolabial folds, behind the ears and in other intertriginous areas of the skin. In vitamin A deficiency hyperkeratosis in the hair follicles is present Deficiencies of vitamin C may be expressed by the presence of subcutaneous hemorrhages *In general* vitamin B deficiency there is an ichthyosis *over the knees*, elbows and perhaps over the buttocks and anterosuperior spines of the ilia.

The angles of the mouth may be fissured in riboflavin deficiency. The angles of the mouth, also the oral cavity, the tongue and the buccal surfaces may be affected by a scarlet, inflammatory-appearing process in niacin, vitamin B_{12}, riboflavin, and ascorbic acid deficiencies In chronic long-standing deficiencies of these substances, especially of vitamin B_{12} (pernicious anemia), atrophic glossitis and atrophy of the buccal mucous membranes may be found.

In vitamin D deficiency there are aberrations in metabolism of calcium and phosphorus, and subsequent skeletal deformities (rickets).

The eyes in vitamin A deficiency may reveal xerosis conjunctivae and xerosis of the corneas. A keratoconjunctivitis of the vascularizing variety may be present. Central ophthalmoplegia and retrobulbar neuritis occur as the result of vitamin A and vitamin B deficiencies. The value of the dark adaptation test is not certain.

Bilateral symmetric polyneuritis and subacute disease of the posterolateral column result from deficiencies of vitamin B. Disease of the posterolateral column is often present in pernicious anemia as the result of vitamin B_{12} deficiency.

Diagnosis of Undernutrition. The diagnosis of undernutrition depends (1) on dietary history, (2) on medical history and results of physical examination, with attention directed toward the manifestations of nutritional deficiency and (3) on results of certain special examinations The history of the patient's dietary intake permits an estimation of the probability of the presence of a deficiency disease.

Chemical analyses of the blood for changes in the values for serum protein and albumin-globulin ratio, serum calcium, phosphorus, alkaline phosphatase and blood prothrombin time (vitamin K) are regularly employed. Their respective normal values are discussed in the appropriate places in this text.

When the manifestations and thus physical findings of the classic forms of malnutrition, whether from inadequate caloric protein intake or from lack of vitamins, are present, the diagnosis is obvious. However, early forms of these diseases have no specific manifestations For instance, the symptom of ease of fatigability is a constant symptom of pellagra, tuberculosis and, most of all, of psychoneurosis. The same may be said of anorexia. The diagnosis of a dietary deficiency disease is established by the exclusion of other diseases.

At times special examinations can be of help in establishing the diagnosis. These tests vary in their significance, in the stage in the development of a specific deficiency which they are capable of detecting. For instance, those which measure the concentration of a vitamin in the blood or its rate of excretion in the urine are really indicators of the state of saturation of the body stores, and unless their results are correlated with other evidence, cannot in themselves demonstrate that the deficiency has progressed to the point of impairment of function Unfortunately, most of the methods which are capable of detecting disturbance of chemical or physiologic function are relatively nonspecific. Their chief value is often as [illegible] dence [illegible]
to ther [illegible]
largely [illegible] to the possibility of its occurrence.

Often the therapeutic test—that is, giving specific treatment and observing its effects—may be the only means of determining whether or not the patient's complaints are due to lack of a particular food factor. Obviously, it is important that an adequate amount of food or vitamins must be given and for a sufficiently long time if the therapeutic test is to be of value in making the diagnosis.

Starvation, Exposure, and Neglect. The physician sees two common forms of starvation, exposure, and neglect. Self-neglect and starvation occur in elderly or weak-minded persons who, irrespective of their means, choose to live in poverty, dirty, unkempt, often verminous, and without adequate food Willful neglect of children often is accompanied by their starvation

These conditions are more likely to be manifest as vitamin defect, undernutri-

tends to be progressive if the inadequate diet is continued The progress of the und nutrition itself progressively decreases the caloric deficit so that there is a tender toward adaptation or compensation

During the convalescence from undernutrition the basal metabolic rate ri synchronously with the gain in body weight

Brain and Nervous Tissue The brain and nervous tissue loses little or no weig... during starvation. This does not mean that these tissues are unaffected by undernutrition The changes in weight are limited because the gross structure is preserved with replacement of cytoplasm, or even of cells, by water The changes in the spinal cord are similar to those in the brain and may be even more pronounced in the anterior horn cells The peripheral nerves are not immune to the effects of starvation, though the medullated fibers are only slightly affected morphologically.

There is no evidence for a decline in basic intellective capacity. In the Minnesota experiment exhaustive studies on memory, reasoning power, verbal and arithmetical facility, and so on, revealed no changes in spite of the subjective impression of most of the men that their mental powers had been reduced.

During nutritional rehabilitation from undernutrition the return of a sense of well-being is associated with an increase in voluntary physical activity. However, the habit of conserving energy is not quickly broken. An effort of will or coercion is often necessary to promote recovery in physical fitness by exercise In former times when starvation was the prevailing treatment of typhoid fever, a year was frequently required to get some of these patients to resume work.

All psychomotor functions deteriorate in severe undernutrition, and the result is a serious impairment in working capacity Simple muscular strength, as measured in a single maximal exertion, declines steadily but not so dramatically as does the capacity for continued muscular exertion (endurance). Neuromuscular co-ordination is impaired by caloric undernutrition, but the relative deterioration is less than in purely muscular capacity

Severe undernutrition causes changes in the personality and the subjective state. These changes are manifested by apathy, depression, introversion and hypochondriasis. As the physical state improves, the tendencies toward depression and hypochondriasis diminish, but they may be intensified by disappointment in the rate of recovery The return of physical strength permits of manifestations of irritability.

Undernutrition and Resistance to Infection. There is no aspect of undernutrition about which there is a more fixed common belief—and less objective evidence—than the question of the effect on resistance to infection However, undernutrition is not necessarily productive of a lowered resistance or a heightened susceptibility to infectious diseases in general Tuberculosis seems to be the exception

The morbidity and mortality of tuberculosis are increased by caloric deficiency. Tuberculosis is a most serious disease in the presence of prolonged and severe undernutrition In some viral diseases a state of undernutrition seems to decrease susceptibility to infection, for instance, poliomyelitis

Examination in Undernutrition. The findings on examination for the detection of undernutrition depend on the deficiency or the combination of deficiencies present It is rare to have undernutrition present which is due solely to a deficiency of calories and proteins. Therefore, the findings present in vitamin, caloric and protein deficiencies will be considered here

In niacin deficiency, a pellagrous type of dermatitis may be present. If a riboflavin deficiency predominates, there may be seborrheic lesions in the nasolabial folds, behind the ears and in other intertriginous areas of the skin In vitamin A deficiency hyperkeratosis in the hair follicles is present Deficiencies of vitamin C may be expressed by the presence of subcutaneous hemorrhages. In general vitamin B deficiency there is an ichthyosis over the knees, elbows and perhaps over the buttocks and anterosuperior spines of the ilia.

Hyperproteinemia due to an increase of plasma globulins occurs in multiple myeloma, amyloidosis, and occasionally in lymphogranuloma venereum, kala-azar, malaria, filariasis, schistosomiasis, trypanosomiasis, leprosy, syphilis, sarcoidosis and the leukemias.

Fibrinogen. The fibrinogen concentration of the plasma is not affected by fasting or by the protein content of the diet so it is not affected by changes in the protein reserves and undernutrition.

Plasma fibrinogen is increased in infections and after trauma if the liver functional activity is normal. It influences the sedimentation rate of the blood.

Fibrinogen is concerned with blood clotting. The plasma contains from 1.9 to 3.3 *gm per 100 ml.* When blood is *drawn from a* vein the fibrinogen is converted to fibrin by the newly formed thrombin.

BENCE JONES PROTEINURIA

Bence Jones protein is a constituent of normal bone marrow, and perhaps leukocytes are concerned in its production. It is an endogenous protein with such a small molecular weight and size that it can easily escape in the urine. Formerly its presence in the urine was considered pathognomonic of myeloma It does occur in the majority (66 per cent or more) of those who have multiple myeloma. It may occur in other conditions such as osteogenic sarcoma, osteomalacia and carcinomatous metastasis to the bone It may be present in the urine of those who have either a lymphoid or a myeloid leukemia. It has been observed in the urine of patients who have pyelonephritis. It may be present in the urine from unknown causes.

OXALURIA

The excretion of excessive amounts of oxalic acid as calcium oxalate in the urine is called oxaluria Normally, the acid occurs in acid, alkaline or neutral urine in crystalline forms A heavy glycosuria is associated with a decreased excretion of oxalic acid

The deranged gastric digestion of carbohydrate that occurs in achlorhydria results in the formation of oxalic acid in its free form which is readily absorbed and

... Calcium oxalate stones most frequently form in the renal pelves and are hard and rough. *Such stones due to their rough surfaces* find it difficult to pass through the ureter even when the stone is small.

Tenosynovitis referable to the precipitation of calcium oxalate ...

... oxalate in the greatest concentration.

URATURIA

Uric acid is an end product in purine metabolism and is excreted in the urine as sodium, potassium and ammonium urates. These urates ...

the urine unless the ...

the

are ... However, in such diseases as gout and

leukemia, in which there is increased excretion of uric acid, no calculous formation occurs, because the organic acid is held in solution as a salt.

Uraturia does not produce symptoms unless uric acid crystals are present in

tion or malnutrition with some superimposed infection than as a state of simple gross starvation There are dehydration and a loss of subcutaneous fat, reaching states of extreme emaciation. The skin is thin, dry, sometimes fissured and sore, and drawn tight over the bony prominences The cheeks are hollow, the eyes sunken, the abdomen is carinated, and the legs and arms are but skin and bones. Pigmentation may vary from mere sallowness to distinct melanosis. The organs are atrophied and the walls of the stomach and intestines are thin, almost transparent, from disuse. Only the gallbladder is enlarged, filled with unwanted bile; the intestines lack the waste matter and chyle which might have caused them to empty.

Great care must be taken to exclude natural disease as a contributory cause or even as a sole cause for such changes Obstruction of the esophagus or stomach, even functional obstruction like the Plummer-Vinson syndrome, and wasting diseases such as tuberculosis, diabetes, Addison's disease, or hyperthyroidism are excluded Starvation and neglect are words which the physician should never use on a death certificate, for they have far-reaching consequences They demand inquiry, must be referred to the coroner, and will undoubtedly necessitate necropsy at his direction Postmortem examination will help to confirm the suspicions aroused, or, on the contrary, will reveal some natural disease which affords a satisfactory explanation of the state of the body

Without food the body loses about a twenty-fourth of its weight each day, and survival is unlikely to continue after about 10 days. If water is provided, life may be prolonged for as long as 50 or 60 days

Hypoproteinemia (Less Than 6.0 gm. per 100 ml. Plasma). A reduction in the total amount of proteins in the plasma is designated as hypoproteinemia. Hypoproteinemia may result in the production of edema because of a reduction in the colloid osmotic pressure of the plasma and particularly since there is but little evidence of an effective compensatory increase of fibrinogen. There are variations in the degree of hypoproteinemia in relation to edema because of the influences of tissue and plasma sodium chloride balance and acid-base equilibrium However, it appears that a reduction of total protein to less than 5.5 gm. per 100 ml. favors the presence of edema Hypoproteinemia, with reduction of serum albumin, may occur in the loss of protein by the excessive and prolonged albuminuria of acute nephritis as well as in chronic active glomerulonephritis, the reduction possessing prognostic significance in acute glomerulonephritis In advanced cirrhosis of the liver with or without ascites the serum albumin may be decreased, although sometimes there is an actual increase of the serum globulin The increase in serum globulin may be ascribed to coexisting malnutrition or to impairment of the liver in the synthesis of the plasma proteins. Hypoproteinemia with decrease in albumin and increase in globulin is common in acute hepatitis and especially in acute yellow atrophy of the liver.

Partly owing to low protein intake, hypoproteinemia is commonly present in states of malnutrition such as diabetes mellitus, anemia, malignant disease, and tuberculosis It occurs in states accompanied by excessive loss of protein in prolonged diarrhea or vomiting; in lipoid nephrosis; sometimes during pregnancy and lactation, in the toxemias of pregnancy, and sometimes in congestive heart failure with edema and anasarca.

Hyperproteinemia (More Than 8.0 gm. per 100 ml. Plasma). An increase

tion from diarrhea, intestinal fistulas, severe vomiting as in high [illegible] obstruction as well as after marked restriction of fluid intake, and in diabetic acidosis High protein values are obtained in extensive burns and in the rare disorder designated Addison's disease.

Congenital porphyria is a rare inborn error of metabolism, inherited as a recessive mendelian characteristic. It is characterized by excretion of large amounts of uroporphyrin, by discoloration of the teeth and bones by these pigments, and by sensitivity of the skin to light.

Often the first symptom is a pink or red or black color of the urine, which may darken after exposure to light The enamel of the deciduous teeth and sometimes the bones of the hands become brown to pink. The bone color is revealed by transillumination

Ultraviolet radiation brings out the cutaneous lesions in childhood. The eruptions consist of brownish pigmentation of the skin, erythema, papules, vesicles and perhaps large bullae filled with a colorless or blood-stained fluid These lesions are situated on the hands, neck and face. The bullae heal with scar formation. In some patients there is hirsutism Enlargement of the spleen and the liver is observed as the disease progresses.

The susceptibility for development of *acute porphyria* has been observed in successive generations, and it is commoner in women than in men. It is inherited as a mendelian dominant characteristic

Acute porphyria with prior manifestations may commence with abdominal colic, constipation and vomiting The colic or neuralgia-like pains may extend down the legs Soon there may be associated with the pains drop foot and wrist drop or a symmetric progressive ascending paralysis of the Landry type. Disturbances of the cranial portion of the central nervous system may consist of amaurosis and facial nerve paresis. Psychic disturbances may occur and the patients may become delirious Death from respiratory failure may rapidly ensue.

Acute porphyria may be associated with a polymorphonuclear leukocytosis and in its manifestations resemble an acute appendicitis or other acute abdominal emergencies. Prior to surgical intervention, if porphyria is suspected, the urine should be boiled with 25 per cent hydrochloric acid, and if porphyrins are present an intense black color develops Porphyria or an acute hemolytic crisis is suspected if there is an intense dark red-brown discoloration of the urine. Demonstration of uroporphyrin in the urine is a definite proof of porphyria. Demonstration of uroporphyrin may be difficult because of simultaneous presence in the [illegible] of a [illegible] luble

[illegible] particularly sedatives, as well as surgical exploration is contraindicated in *acute porphyria*. Ether or sedatives, especially barbiturates, may cause the deranged metabolism to become worse, with a fatal termination

The acute attacks tend to recur.

The *chronic forms* of porphyria run a prolonged course and are characterized by a heavy urinary excretion of porphyrin and usually by sensitivity to light These phenomena may follow the prolonged administration of the barbituric acid compounds.

Porphyrinuria may be initiated by sulfonamide compounds, arsenicals, alcohol, phosphorus, selenium and lead Anesthesia, hemorrhage and destruction of tissue may place an additional load on the already disturbed metabolism, and collapse and death may follow. Gastrointestinal symptoms such as cramps, vomiting and constipation occur episodically in chronic porphyria. The urine is dark. Chronic porphyria may prove fatal. In those who survive, recovery is usually slow. In contrast to acute porphyria, in which the porphyrinuria clears up in about a month, the porphyrinuria in chronic porphyria may persist.

The diagnosis of porphyria depends on the [illegible]onstration of excessive amounts of [illegible] a red urine before boiling with [illegible] boiling with hydrochloric acid

an abundance of uric acid. The symptoms then are those of urethral irritation or calculous disease. Restriction of the purine-containing foodstuffs lowers excretion of urate. Alkalization of the urine may be beneficial treatment.

CYSTINURIA

The amino acid cystine occurs in small amounts in the urine of normal persons The designation cystinuria implies an excessive secretion of cystine. All but small amounts of cystine are normally changed into urea and inorganic sulfates before excretion. The cystinuric person possesses the ability to break down cystine, but there is present an inborn error in the intermediary metabolism which permits of excessive excretion

The error in intermediary metabolism occurs in both sexes, at all ages, and follows a recessive mendelian characteristic It has been reported in three generations of a family. A positive family history was present in half the cases studied by Hammer and Thompson

Cystinuria, unless excessive, does not cause symptoms When symptoms appear, if at all, they are those of calculi which have formed in the urinary tract. Cystine lithiasis is a disease of the young, and occurs in only a very small percentage of cystinuric individuals The stones frequently are multiple and bilateral, and after removal tend to recur Ureteral colic, hematuria and albuminuria occur. The urine is acid and of a high specific gravity

Diagnosis is established by finding the characteristic hexagonal crystals of cystine in the urine, or by analysis of urinary calculi removed at surgical operation. The inborn error of metabolism cannot be corrected

PORPHYRIA

Porphyrins are pigments which occur in both plants and animals. Protoporphyrin combined with iron and globin is the basis of hemoglobin The two porphyrins which are important in porphyria are coproporphyrin, which occurs in normal feces after having been excreted by the liver, and uroporphyrin, which is found in small quantities in normal urine The uroporphyrin excreted by the kidneys normally is a very small amount Excessive excretion of uroporphyrin and coproporphyrin may be present in the urine and the feces as in the disease porphyria, or it may be a persistent embryonic type of pigment metabolism An increased porphyrinuria occurs in the disease porphyria, in the aged, in diabetes mellitus, in pellagra, after roentgen therapy and in certain occupational diseases.

The identity of chemical substances used in the formation of the porphyrins in the body has not been accomplished It is now known, however, that a number of respiratory pigments, including hemoglobin, the cytochromes and catalase, contain the porphyrin group Porphyrins may be synthesized in vitro from amino-acetic acid and formyl acetone with perhaps amino acids since they contain four pyrrole rings and perhaps include proline Porphyrin synthesis on a human subject, using the isotope tracer technic, has been done by the administration of amino-acetic acid which contained isotopic nitrogen Samples of blood withdrawn at intervals for 99 days revealed a relatively high value for the isotopic nitrogen content, thus demonstrating the participation of amino-acetic acid in the synthesis of porphyrin in the human subject The present indications are that the porphyrins are synthesized in man from relatively simple chemical substances, including amino-acetic acid and possibly acetic acid.

The disease porphyria is classified according to the age at onset, and the rapidity of onset and duration, into congenital, acute and chronic forms.

Congenital porphyria is a rare inborn error of metabolism, inherited as a recessive mendelian characteristic. It is characterized by excretion of large amounts of uroporphyrin, by discoloration of the teeth and bones by these pigments, and by sensitivity of the skin to light.

Often the first symptom is a pink or red or black color of the urine, which may darken after exposure to light The enamel of the deciduous teeth and sometimes the bones of the hands become brown to pink. The bone color is revealed by transillumination.

Ultraviolet radiation brings out the cutaneous lesions in childhood. The eruptions consist of brownish pigmentation of the skin, erythema, papules, vesicles and perhaps large bullae filled with a colorless or blood-stained fluid. These lesions are situated on the hands, neck and face. The bullae heal with scar formation In some patients there is hirsutism. Enlargement of the spleen and the liver is observed as the disease progresses.

The susceptibility for development of *acute porphyria* has been observed in successive generations, and it is commoner in women than in men. It is inherited as a mendelian dominant characteristic

Acute porphyria with prior manifestations may commence with abdominal colic, constipation and vomiting. The colic or neuralgia-like pains may extend down the legs. Soon there may be associated with the pains drop foot and wrist drop or a symmetric progressive ascending paralysis of the Landry type. Disturbances of the cranial portion of the central nervous system may consist of amaurosis and facial nerve paresis. Psychic disturbances may occur and the patients may become delirious Death from respiratory failure may rapidly ensue.

Acute porphyria may be associated with a polymorphonuclear leukocytosis and in its manifestations resemble an acute appendicitis or other acute abdominal emergencies Prior to surgical intervention, if porphyria is suspected, the urine should be boiled with 25 per cent hydrochloric acid, and if porphyrins are present an intense black color develops. Porphyria or an acute hemolytic crisis is suspected if there is an intense dark red-brown discoloration of the urine. Demonstration of uroporphyrin in the urine is a definite proof of porphyria. Demonstration of uroporphyrin may be difficult because of simultaneous [illegible] of a [illegible] luble

[illegible] sedatives, as well as surgical exploration is contraindicated in acute porphyria. Ether or sedatives, especially barbiturates, may cause the deranged metabolism to become worse, with a fatal termination

The acute attacks tend to recur.

The *chronic forms* of porphyria run a prolonged course and are characterized by a heavy urinary excretion of porphyrin and usually by sensitivity to light These phenomena may follow the prolonged administration of the barbituric acid compounds

Porphyrinuria may be initiated by sulfonamide compounds, arsenicals, alcohol, phosphorus, selenium and lead. Anesthesia, hemorrhage and destruction of tissue may place an additional load on the already disturbed metabolism, and collapse and death may follow. Gastrointestinal symptoms such as cramps, vomiting and constipation occur episodically in chronic porphyria. The urine is dark. Chronic porphyria may prove fatal In those who survive, recovery is usually slow. In contrast to acute porphyria, in which the [illegible] the [illegible] in about a month,

of p [illegible] excessive amounts [illegible] presence of a pink or a red urine before boiling with hydrochloric acid, or a pink, red or black urine after boiling with hydrochloric acid

suggests in the former the presence of a hemolytic crisis, in the latter the presence of porphyria. These manifestations of an acute abdominal emergency preclude surgical operation until further investigations can be made to determine the nature of the illness. The presence of hematoporphyrins and uroporphyrins are of more diagnostic significance than coproporphyrins. The presence of coproporphyrins may not signify clinical disease.

Porphyrins in Occupational Diseases. Maloof found that the value for coproporphyrin was increased in almost every instance in which the concentration of lead in the urine was significant (see Lead Poisoning, Chapter 19). Coproporphyrinuria, although consistently observed in workers who absorb dangerous amounts of lead, is not specific for lead poisoning, since it is observed in many other illnesses. A coproporphyrin test, therefore, should not supplant urinary analyses for lead but should be used in conjunction with them. The early detection of coproporphyrinuria makes it possible to prevent clinical lead poisoning. Coproporphyrinuria may be present before there is stippling of erythrocytes in instances of lead poisoning. However, counts of stippled erythrocytes should be conducted along with analysis of the urine for porphyrin Increase in the number of stippled erythrocytes remains a valuable aid in prevention and diagnosis of lead poisoning

PHENYLKETONURIA

This disease is known also as imbecillitas phenylpyruvica (Folling), phenylketonuria (Penrose), and phenylpyruvic oligophrenia (Jervis).

The disease is due to morbid heredity The abnormal genes are transmitted through heterozygotes who themselves do not manifest any symptoms. Consanguinity is not etiologically definitely important. In some instances, however, the parents of the patients have been first cousins

The essential feature is the urinary excretion of about 1 gm. daily of phenylpyruvic acid, a ketonic acid The excretion is usually continuous throughout life and has been observed in infancy. Those affected are imbeciles or idiots.

The distinctive physical features are dwarfing of stature and reduced cephalic diameters as compared with the normal average. Blond hair and blue eyes are common characteristics The quantity of the acid excreted can be increased by feeding either levophenylalanine or dextrophenylalanine The excretion of the acid can be temporarily abolished by a protein free diet.

ALKAPTONURIA AND OCHRONOSIS

Alkaptonuria is a harmless congenital error of protein metabolism, resulting in the excretion of homogentisic acid in the urine The two amino acids which have been implicated as the source of abnormal metabolism resulting in alkaptonuria are tyrosine and phenylalanine which are the source of homogentisic acid

An hereditary etiologic factor has been considered to be important in those who have alkaptonuria. It is now known that consanguinity is not important etiologically The disease is more common in boys and men than in girls and women.

The majority of instances of alkaptonuria are manifested by the presence of the pigment in the urine This anomaly of protein catabolism is only occasionally associated with ochronosis.

The pigment of ochronosis lies in the fibrocartilagenous structures, the scleras, the tendons, and the skin In a good many patients the scleras have a diffuse gray color, and frequently a semilunar or V-shaped patch of pigmentation occurs in each sclera. Sometimes this pigmentation becomes 0 5 cm. in size and is situated midway between the margin of the cornea on the outer or the inner canthus. The color may vary from deep brown to black.

The pigmentation of the cartilages and fibrous tissues is visible only in certain situations, the most characteristic of which is the ear. The skin of the face may be

involved and often is light brown In some patients there is a uniform yellow-brown color with intensification over the cheeks. In other cases the skin is black.

A similar tissue staining is due to the prolonged external application of carbolic acid preparations. In still others staining of the cartilages is associated with melanuria. The melanin that discolors the tissues is a derivative of the protein molecule.

In chronic instances of ochronosis there is a tendency for premature systemic arteriosclerosis to develop, and the involved cartilages show degenerative changes, osteoarthritic outgrowths and ultimately arthropathies with deformities.

The diagnosis is usually made in early life from the dark stains on the diapers. The urine, on standing becomes alkaline and turns from brown to black due to the oxidation of the homogentisic acid. Homogentisic acid reduces the alkaline copper solutions (Benedict's and Fehling's) and thus its presence may be confused with glycosuria. Homogentisic acid does not reduce an alkaline bismuth solution (Mylander's reagent).

In its early stages ochronosis causes only an undesirable staining of the cartilages. The discoloration of the cartilages, especially those of the ear, is best demonstrated by transmitted light

MINERAL CONSTITUENTS OF BODY FLUIDS

It is well to define some of the common terminologies employed in expressing the concentration of a substance in a system, for there is some variation in the way in which laboratories may report such concentrations

The concentration of a substance in a system of specified size may be expressed in different units, for instance, *mass* in milligrams, *volume* in milliliters, the number of *molecules* in millimols, the number of *electrical charges* in milliequivalents Likewise the size of the system may be expressed in either mass or volume of the total system, for instance, a substance plus solvent plus all other substances in the system, or mass or volume of the solvent, or the total number of molecules of the system. In clinical practice substances in the blood plasma, blood serum, or any other body fluid are expressed in milligrams per 100 ml. of the particular fluid in question If it should be desired to express a substance in another unit, it may be so expressed

The concentration of substance X, which exists in solution as a positive ion, may be expressed in the following ways.

$$\text{Milligrams X per 100 ml. plasma} = \text{mg. per cent}$$

$$\text{Cubic millimeters X per 100 ml. plasma} = \frac{\text{mg X per 100 ml plasma}}{\text{density of X}}$$

$$\text{Millimols X per l plasma} = \frac{\text{10 mg X per 100 ml plasma}}{\text{mol. wt of X}}$$

$$\text{Milliequivalents X per l plasma} = \text{millimols X per l plasma multiplied by the number of electrical charges per ion}$$

$$\text{Millimols X per l water} = \frac{\text{millimols X per l plasma}}{\text{liters } H_2O \text{ per l. plasma}}$$

$$\text{Mol fraction of X} = \frac{\text{millimols X per l. or kg. plasma}}{\text{millimols } H_2O + \text{all other molecules per l. or kg. of plasma}}$$

$$\text{Millimols per kg water} = \frac{\text{millimols per l } H_2O}{\text{density of } H_2O}$$

In recent years the conventional way of expressing concentration in biologic systems is in millimols per l. or kg H_2O. In many cases it is sufficiently accurate to use l. and kg H_2O interchangeably, however, since H_2O in a system is almost always determined by weight it is preferable always to use *millimols per kg. H_2O* Milliequivalents are then easily obtained by multiplication [illegible]

suggests in the former the presence of a hemolytic crisis, in the latter the presence of porphyria These manifestations of an acute abdominal emergency preclude surgical operation until further investigations can be made to determine the nature of the illness. The presence of hematoporphyrins and uroporphyrins are of more diagnostic significance than coproporphyrins. The presence of coproporphyrins may not signify clinical disease

Porphyrins in Occupational Diseases. Maloof found that the value for coproporphyrin was increased in almost every instance in which the concentration of lead in the urine was significant (see Lead Poisoning, Chapter 19). Coproporphyrinuria, although consistently observed in workers who absorb dangerous amounts of lead, is not specific for lead poisoning, since it is observed in many other illnesses A coproporphyrin test, therefore, should not supplant urinary analyses for lead but should be used in conjunction with them. The early detection of coproporphyrinuria makes it possible to prevent clinical lead poisoning Coproporphyrinuria may be present before there is stippling of erythrocytes in instances of lead poisoning However, counts of stippled erythrocytes should be conducted along with analysis of the urine for porphyrin. Increase in the number of stippled erythrocytes remains a valuable aid in prevention and diagnosis of lead poisoning

PHENYLKETONURIA

This disease is known also as imbecillitas phenylpyruvica (Følling), phenylketonuria (Penrose), and phenylpyruvic oligophrenia (Jervis).

The disease is due to morbid heredity. The abnormal genes are transmitted through heterozygotes who themselves do not manifest any symptoms Consanguinity is not etiologically definitely important In some instances, however, the parents of the patients have been first cousins

	= 725 " " " " "	(pernicious anemia)
	= 720 " " " " "	(diabetic coma)

SODIUM, CHLORIDE AND POTASSIUM

The metabolism of sodium, chloride and potassium is intimately related to the water balance and acid-base equilibrium of the body.

Diets inadequate in other respects are almost always liberally adequate in regard to sodium (Na), chloride (Cl), and potassium (K) The average diet in the United States contains 4 to 6 gm of sodium, 6 to 9 gm. of chloride and 2 to 4 gm. of potassium daily. The normal individual can and often does maintain health on much smaller and on much larger intakes. The requirement for potassium is greatest during periods of rapid growth, for it is necessary for incorporation in the new cells In a healthy adult the potassium requirement is almost negligible. This is in sharp contrast with a relatively constantly high intake of sodium and chloride which is desirable throughout life

The concentration of sodium in normal blood serum ranges from 315 to 340 mg per cent (average 330 mg). The potassium concentration is 16 to 22 mg. per cent (average 19 mg.) There is little or no sodium in the red corpuscles, whereas the average concentration of potassium in these cells is about 420 mg per cent. The chloride content of the whole blood normally ranges from 270 to 300 mg per cent (450 to 500 mg per cent sodium chloride) The distribution of chloride between plasma and cells is similar and intimately related to that of carbonic acid. The relationship of concentrations of sodium, chloride and potassium is important in the maintenance of acid-base balances.

In terms of milliequivalents per liter the distribution of base and acid elements in the blood serum is approximately as follows· sodium (Na 142) plus potassium (K 5) plus calcium (Ca 5) plus magnesium (Mg 3) equals a total base of 155 milliequivalents per liter

The total acid in blood serum. chloride (Cl 103) plus carbonic acid (HCO_3 28) plus phosphates (PO_4 2) plus protein (16) plus sulfates (SO_4 3) plus organic acids (3) equals 155 milliequivalents per liter.

The distribution of potassium, sodium, chloride and water between intracellular and extracellular fluids of the body, is influenced by the adrenocortical hormone (cortin) The mechanism of action of cortin in preserving the normal distribution of these electrolytes and water between the extracellular and intracellular phases is not known

Potassium is the chief basic ion of the muscles and of most of the intracellular fluid, whereas sodium is the chief basic ion of extracellular fluids of the body. Although some movement of potassium and water occurs from cells to plasma, particularly when excessive amounts of sodium chloride and water are lost from the body and in disturbances of acid-base balance, the potassium is usually excreted promptly in the urine [illegible]
extracellular [illegible]
ion can entir[illegible]
the functional activity of the cell In low concentrations potassium is excitatory and in higher concentrations it is inhibitory. Under conditions of normal electrolytic balance the effects of potassium are inhibited by calcium

The exact significance of the inequality of distribution of potassium in the cells and sodium in the extracellular fluids and the mechanism whereby it is preserved are not apparent. In recent years it has been learned that there is more flexibility

CONVERSION OF CONCENTRATIONS

Concentration in millimols per liter:

$$\text{millimols/l} = 10 \times \frac{\text{conc. in mg per 100 ml.}}{\text{molecular weight}}$$

Concentration in milliequivalents (hydrogen) per liter.

$$\text{mEq./l.} = (\text{m.Mols./l.}) \times \text{valence}$$

$$= 10 \times \text{valence} \times \frac{\text{conc. in mg. per 100 ml.}}{\text{molecular weight}}$$

Concentration per kilogram water.

$$\text{conc./kg.}H_2O = (\text{conc./l}) \times \text{kg.}H_2O\text{/l.}$$

$$\text{conc./kg } H_2O = 0.997 \times \text{conc./l } H_2O$$

(measurement of volume at room temperature)

When in the judgment of the director of the laboratory it will be advantageous to report the concentration of the substance X in a particular way, he will so do it. In general, however, the laboratory will record the measure of a substance in terms of molecules of that substance and the size of the system in terms of the mass or volume of the solvent, water

CONVERSION FACTORS FOR IMPORTANT ELECTROLYTES

Sodium: $\text{m Mols Na/l} = \frac{\text{mg Na/100 ml}}{2.30} = \text{mEq Na/l.}$

Potassium: $\text{m.Mols K/l} = \frac{\text{mg K/100 ml}}{3.90} = \text{mEq. K/l}$

Calcium: $\text{m Mols Ca/l} = \frac{\text{mg Ca/100 ml}}{4.00} = 0.5 \times \text{mEq Ca/l.}$

Magnesium: $\text{m Mols Mg/l} = \frac{\text{mg Mg/100 ml.}}{2.43} = 0.5 \times \text{mEq Mg/l.}$

Chloride: $\text{m Mols Cl/l.} = \frac{\text{mg Cl/100 ml}}{3.55} = \text{mEq Cl/l.}$

Bicarbonate: $\text{m Mols } HCO_3\text{/l} = \frac{\text{vols \% } HCO_3}{2.24} = \text{mEq } HCO_3\text{/l}$

APPROXIMATE WATER CONTENT OF BODY FLUIDS AND SECRETIONS

It is not necessary always to determine the water content of body fluids and secretions The water content of these fluids can be made by approximation with general limits of error ranging from 0.5 to 1.5 per cent The approximations are made with the assumption that the body fluids are at room temperature, for instance

1 liter urine contains	0.98 kg H_2O	(normal)
" " "	0.99 " "	(polyuria)
" " "	0.97 " "	(nephritis and nephrosis)

1 liter lymph contains 0.975 kg H_2O
" sweat " 0.99 " "
" gastric juice, pericardial fluid, ascitic fluid, bile, succus entericus or cerebrospinal fluid
contains 0.98 kg H_2O

Plasma water and water of plasma exudates, ml. per liter plasma = 980 − (4.75 × gm. protein per 100 ml)

Whole blood water, ml. per liter whole blood = 932 − (2.2 × cell volume %)
= 980 − (5.3 × gm hemoglobin per 100 ml.)
= 980 − (7.1 × vols. per cent of oxygen capacity)

dry skin, parched lips and mucous membranes, and weakness. Mild and then severe mental changes such as profound confusional states and hallucinations ensue

On establishment of the deprivation of water the volume of urine is decreased to 500 to 700 ml. per day and its specific gravity, provided that the renal concentrating power is normal, increases to 1.030 or more Urine chlorides may be slightly increased or [illegible]

In the ea [illegible] the plasma sodium and chloride [illegible] hange in blood viscosity, serum proteins, or hematocrit reading As a result the blood pressure and circulation are well maintained until death is inevitable.

Pure sodium depletion is caused by the inadequate replacement of excessive losses of salt or sodium chloride Since sodium and chloride are lost in approximately chemically equivalent amounts, the acid-base balance is not disturbed. If the acid-base balance should be found to be disturbed, there is more wrong than sodium depletion

Salt is a constant constituent of visible sweat and by this means of excretion large quantities may be lost If excessive sweating is continued and the normal sense of thirst is heeded and large quantities of water are taken, symptoms of sodium chloride deficiency ensue.

Excessive sweating is common in hot climates and as much as 10,000 to 12,000 ml may be lost in a period of 24 hours, particularly by one not acclimated. Losses of sweat are great among campaigning soldiers and those who work in high temperatures in industry

Symptoms of well-established salt depletion consist of lassitude, fatigue and muscle weakness Any food taken by mouth is immediately vomited. There are headache, and unsteadiness of gait and fainting if the patient tries to stand or walk. Too, there are the sunken cheeks and eyes, and the dry skin and mucous membranes, as are observed in pure water deficiency (see Body Temperature Chapter 21).

When salt depletion is severe, the blood pressure is low, the extremities are cold and clammy, and the pulse is feeble and fast In other words, the symptoms of severe salt depletion are similar to those observed in shock. Before these symptoms can develop as a result of salt depletion, there has been an approximate decrease of the plasma volume of 15 per cent A systolic blood pressure of 90 mm of mercury, if due to sodium depletion, is indicative of a reduction in the plasma volume to three fourths of its original volume As the decrease of the plasma volume advances, there is a relative increase in the constituents of the plasma The proteins and the erythrocytes are increased There are increases in blood viscosity and specific gravity which add to circulatory difficulties Under these circumstances, findings on examinations of the blood may not be significant of the degree of salt depletion, there may be, however, an increase in the concentration of the blood urea

Generally, syndromes of pure water depletion and pure salt depletion are not observed There is present a *mixed depletion of salt and water*.

Mixed Syndromes. The mixed syndrome of salt (sodium) and water depletion, better known as *dehydration*, is often accompanied by a disturbance of acid-base balance. The disturbance in acid-base balance is evidence that in addition to dehydration, other factors, such as starvation, associated with an increased production of metabolic acids, loss of free acids or bases from the body, have already occurred.

Acidosis. *Acidosis* is a clinical term which is commonly employed to indicate a decreased concentration of bicarbonate in the blood (normal values 55 to 75 volumes per cent). It may occur as the result of the formation or absorption of acids at a rate exceeding that of their neutralization or elimination or from excessive loss of blood. It may be produced by an increased accumulation of carbon dioxide in the blood (breathing excess amounts of carbon dioxide or inability to expire

of the concentrations of potassium than was formerly believed possible. Potassium is not fixed in its predominantly intracellular position but can move [illegible]

[illegible]

[illegible] plasma when excessive quantities of sodium and water are lost from the body, as in *hemorrhage*, shock, adrenocortical insufficiency, intestinal obstruction and intestinal, biliary or pancreatic fistulas. During increased muscular activities potassium appears in greater concentrations in the blood plasma During rest or anesthesia there is a reduction in the plasma concentrations of potassium.

Sodium, chloride and potassium are concerned with the maintenance of normal water balance and distribution, the maintenance of normal osmotic equilibrium, the maintenance of normal acid-base balance, and the maintenance of normal muscle irritability

The maintenance of normal hydration and osmotic pressure depends in part on the total base content of the body fluids. Since sodium constitutes the largest fraction (142 of the 155 milliequivalents) of the total base of the extracellular fluids, its role is dominant in this function. At any given carbonic acid concentration, the hydrogen ion concentration of the plasma and other extracellular fluids depends mainly on the bicarbonate concentration Since the bicarbonate content depends on the amount of total base present in excess of anions other than carbonic acid, and since chloride constitutes the largest fraction (103 of the 155 milliequivalents) of the total acid of the plasma, it is obvious that the maintenance of the normal pH depends largely on the presence of normal concentrations of chloride and sodium.

Deficiencies of Water, Sodium, Potassium and Chloride. Deficiencies of water, sodium, potassium and chloride may arise from an inadequate intake, from excessive and uncompensated losses, or from combinations of these aberrations of intake and loss

The patient usually has sustained a varying degree of injury from a mixture of inadequate intake and excessive losses So indefinite are the obtainable data on the intakes and losses that often "heads or tails" cannot be made either from the history or from the tangled mass of laboratory data which may be obtained As nearly as is possible the deficiencies of water, sodium, potassium and chloride will be discussed separately as though they occurred in pure form, a phenomenon which is rarely if ever observed in the clinical practice of medicine

Pure water depletion in health is limited to persons lost or forced down on the desert or sea from airplanes, or imprisoned, as from mine disasters or other hazards A normal person can survive without water in a temperate climate from 7 to 10 days.

Even though the intake of water is stopped, there is an inevitable minimal loss of water which continues The continuation of this loss of water decreases the extracellular water and thereby increases the concentration of the extracellular electrolytes The resulting rise in the electrolytic concentration causes an increase in the osmotic pressure which attracts fluid from the cells in amounts which are sufficient to maintain the plasma volume and therefore to keep the circulation functioning in a normal way until the individual ultimately succumbs to the rising tonicity of all the body fluids if artificial replacement is not forthcoming.

In sickness *pure water deprivation* occurs in those who are unable to swallow and in those whose desire for fluids is blunted or annulled by disturbances of the sensorium or by weakness.

The manifestations of water deprivation are thirst and rapid decrease in body weight. The body loses weight at the rate of 2 per cent daily, and a loss of 15 per cent of body weight is usually fatal if due to water deprivation only. The lips, tongue, mouth and throat are dry. The voice becomes hoarse and talking is difficult. Swallowing of solid foods is impossible. Progressively there are hollowing of [illegible]

Wilder water test used for the detection of adrenal cortical deficiency. There is some evidence to indicate that adrenal cortical deficiency is associated with a decreased destruction of, or increased sensitivity to, the antidiuretic hormone

An increased adrenal cortical activity associated with stress (for example, the postoperative state) may result in an alteration of sodium and potassium excretion.

A limitation of tubular function is manifested by a limitation of the capacity of the transport mechanisms to perform osmotic work. For example, glucose is completely reabsorbed when present in the normal concentration in glomerular filtrate, but, if the concentration is greatly increased, the tubular transport mechanism for reabsorption is saturated, and the excess glucose appears in the urine. These tubular transport mechanisms seem to be a specific enzyme function, for after the administration of phlorhizin, glucose reabsorption is prevented and glycosuria occurs in the presence of normal plasma glucose concentrations

The tubular processes of absorption and secretion involve the performance of osmotic work An approximation of the quantity of work applicable to any constituent of urine can be obtained by comparing the concentration of the constituent in the urine with that in the glomerular filtrate

The factors other than the hormones (adrenal cortex and posterior pituitary) and the enzyme (transport) which alter tubular activity are (1) denervation of the kidneys and (2) anoxia and variations in glomerular filtration. For example, unilateral denervation of the kidneys results in increased water and electrolyte excretion. Renal anoxia from increased renal venous pressure decreases sodium excretion without depression of glomerular filtration rate. Variation in the concentration and rate of flow of the glomerular filtrate produces alterations in excretion if tubular function remains unchanged. It is often impossible on the basis of data on excretion of urine to determine the relative role of changes in glomerular filtration and tubular activity in the altered excretion of any particular substances in the urine However, it is axiomatic that the excretion of a cation necessitates the excretion of an equivalent quantity of anions and vice versa

The renal tubules perform important and related tasks: (1) regulate excretion according to the needs of the body and (2) play an important role in the maintenance of a balance between acidic and basic substances in the internal environment Body pH is dependent on a constant ratio of one part carbonic acid to twenty parts bicarbonate in the plasma The lungs control carbonic acid concentration by varying ventilation. The renal tubules help to stabilize the concentration of the bicarbonate. The tubules accomplish this task by conserving all, or nearly all, of the bicarbonate contained in the glomerular filtrate which is equivalent to approximately 1 pound of sodium bicarbonate per 24 hours

The kidneys may conserve base in two ways (1) by conversion of neutral to acid salts and (2) by synthesis of ammonia. For example, disodium phosphate, entering the renal tubules, comes under the influence of a catalytic enzyme system and reacts with carbonic acid to form sodium bicarbonate and sodium acid phosphate The sodium acid phosphate is excreted, and one sodium ion is conserved by the reabsorption of the sodium bicarbonate

The synthesis of ammonia by the distal tubules permits of a supply of ammonia for the conversion of a sodium salt, for example of sulfuric acid, to the ammonium salt. The sodium bicarbonate formed in this reaction is restored to the plasma, and the ammonium salt is excreted [illegible] a person receiving an average diet is 30 to 50 mE[illegible]. The amount of base conserved by the renal tubu[illegible]nerular filtrate to acid urine can be determined by titrating the urine back to pH 7.4 with a base such as sodium hydroxide This measure has been referred to as "titratable acid excretion" and is normally equal to 10 to 30 mEq per day The sum of titratable acid and ammonium excretion has been referred to as the "total renal defense of the bicarbonate reserve." As long as acid production in the body does not exceed the capacity of these mechanisms, the plasma concentration of bicarbonate remains normal.

The components of urine which may be quantitatively deranged in aberrations of acid-base balance are water, bicarbonate, sulfate, phosphate, sodium chloride and potassium.

carbon dioxide as in asphyxia, drug narcosis, asthma, pneumonia, emphysema and congestive heart failure). *When there is a deficiency in the production of alkali* (as in diabetes mellitus, starvation, renal failure, dehydration from excessive vomiting and diarrhea, and *intestinal, biliary, and pancreatic fistulas*), *acidosis ensues.*

Acidemia implies a decreased pH of the blood irrespective of the changes in blood bicarbonate. The normal value *for the pH of the blood is 7.3 to 7.5,* average 7.35

In instances of acidosis from vomiting there is *a severe loss of chlorides from* the plasma. The chloride concentration of the plasma is more severely reduced than the concentration of the plasma sodium and consequently there is *an increase in the* formation of sodium acid carbonate which accounts for the acidosis.

Acidosis follows a sufficient loss of body acid or decrease in the body base that the blood and the extracellular tissues become or tend to become more acid than normal in reaction. Like alkalosis, acidosis may be produced by aberrational functioning of the respiratory apparatus or may result from metabolic disturbances.

Respiratory acidoses are caused by disease of the heart and lungs, asphyxial states and anesthesia A rare cause of this disorder is the breathing of air in poorly ventilated mines, caves or old-fashioned open wells. In the respiratory acidosis there is an increase in the carbonic acid of the plasma.

The common causes for *metabolic acidosis* are chronic impairment of renal functional activity, as in either acute or chronic nephritis, diabetes mellitus, and starvation (from any cause) Metabolic acidosis follows depletion of the plasma of sodium bicarbonate, or it may result from an excessive accumulation of nonvolatile acids in the plasma.

The importance of the *kidneys* in electrolyte balance is obvious when it is realized that in the resting state approximately one fourth of the entire cardiac output passes through the renal vasculature Approximately one fifth of the plasma reaching *the* kidneys is filtered through the glomerular membrane and forms approximately 180 liters *of glomerular filtrate per 24 hours.*

The formation of glomerular filtrate is a physical phenomenon The hydrostatic [illegible] mately

approximately 10 mm of mercury, the actual filtration pressure equals appro[illegible] of 20 mm of mercury Glomerular filtrate is identical with plasma except for the absence *of large molecules such as those of protein. Four fifths of this filtrate is absorbed before* reaching the collecting tubules of the kidney

The *function of the thin segment of the nephron is not clear* Probably its purpose is to permit attainment of osmotic equilibrium by passive back diffusion of water following reabsorption of most of the osmotically active substances in the proximal tubule

In the distal convoluted tubule the antidiuretic hormone of the posterior lobe of the pituitary body normally regulates the rate of tubular reabsorption of water. It seems that a fixed fraction of the filtered fluid and electrolyte escapes the *proximal tubule,* and that in the absence of antidiuretic hormonal activity, all or most of the water reaching *the distal tubule is excreted In posterior pituitary deficiency* (diabetes insipidus), the maximal flow of urine observed equals approximately 15 per cent (27,000 ml) of the glomerular filtrate

Reabsorption of sodium and potassium in the distal tubule is under control of the adrenal cortex Hormones of the type of desoxycorticosterone are effective in causing sodium retention and potassium excretion Hormones of the type *of cortisone* are less effective. Corticotropin (ACTH) acts to stimulate the secretion of these hormones, provided functional *cortical tissue is present* Adrenal cortical insufficiency (Addison's disease) is associated with an increase in sodium excretion and a decrease in potassium *excretion*

Patients who have adrenal cortical insufficiency have a defect in *salt balance and a* decreased diuretic response to ingested water This is the basis for the Power-Kepler-

Wilder water test used for the detection of adrenal cortical deficiency. There is some evidence to indicate that adrenal cortical deficiency is associated with a decreased destruction of, or increased sensitivity to, the antidiuretic hormone.

An increased adrenal cortical activity associated with stress (for example, the post-operative state) may result in an alteration of sodium and potassium excretion.

A limitation of tubular function is manifested by a limitation of the capacity of the transport mechanisms to perform osmotic work For example, glucose is completely reabsorbed when present in the normal concentration in glomerular filtrate, but, if the concentration is greatly increased, the tubular transport mechanism for reabsorption is saturated, and the excess glucose appears in the urine These tubular transport mechanisms seem to be a specific enzyme function, for after the administration of phlorhizin, glucose reabsorption is prevented and glycosuria occurs in the presence of normal plasma glucose concentrations

The tubular processes of absorption and secretion involve the performance of osmotic work. An approximation of the quantity of work applicable to any constituent of urine can be obtained by comparing the concentration of the constituent in the urine with that in the glomerular filtrate

The factors other than the hormones (adrenal cortex and posterior pituitary) and the enzyme (transport) which alter tubular activity are (1) denervation of the kidneys and (2) anoxia and variations in glomerular filtration For example, unilateral denervation of the kidneys results in increased water and electrolyte excretion Renal anoxia from increased renal venous pressure decreases sodium excretion without depression of glomerular filtration rate Variation in the concentration and rate of flow of the glomerular filtrate produces alterations in excretion if tubular function remains unchanged It is often impossible on the basis of data on excretion of urine to determine the relative role of changes in glomerular filtration and tubular activity in the altered excretion of any particular substances in the urine However, it is axiomatic that the excretion of a cation necessitates the excretion of an equivalent quantity of anions and vice versa.

The renal tubules perform important and related tasks: (1) regulate excretion according to the needs of the body and (2) play an important role in the maintenance of a balance between acidic and basic substances in the internal environment. Body pH is dependent on a constant ratio of one part carbonic acid to twenty parts bicarbonate in the plasma. The lungs control carbonic acid concentration by varying ventilation The renal tubules help to stabilize the concentration of the bicarbonate. The tubules accomplish this task by conserving all, or nearly all, of the bicarbonate contained in the glomerular filtrate which is equivalent to approximately 1 pound of sodium bicarbonate per 24 hours.

The kidneys may conserve base in two ways (1) by conversion of neutral to acid salts and (2) by synthesis of ammonia. For example, disodium phosphate, entering the renal tubules, comes under the influence of a catalytic enzyme system and reacts with carbonic acid to form sodium bicarbonate and sodium acid phosphate The sodium acid phosphate is excreted, and one sodium ion is conserved by the reabsorption of the sodium bicarbonate

The synthesis of ammonia by the distal tubules permits of a supply of ammonia for the conversion of a sodium salt, for example of sulfuric acid, to the ammonium salt The sodium bicarbonate formed in this reaction is restored to the plasma, and the ammonium salt is excreted. The amount of ammonium formed by a person receiving an average diet is 30 to 50 mEq. (540 to 940 gm of NH_4) per day The amount of base conserved by the renal tubules in the conversion of alkaline glomerular filtrate to acid urine can be determined by titrating the urine back to pH 7.4 with a base such as sodium hydroxide This measure has been referred to as "titratable acid excretion" and is normally equal to 10 to 30 mEq per day. The sum of titratable acid and ammonium excretion has been referred to as the "total renal defense of the bicarbonate reserve." As long as acid production in the body does not exceed the capacity of these mechanisms, the plasma concentration of bicarbonate remains normal.

The components of urine which may be quantitatively deranged in aberrations of acid-base balance are water, bicarbonate, sulfate, phosphate, sodium chloride and potassium.

The metabolic waste products of the body can be excreted in 600 to 700 ml. of urine per day. When there is excessive production of waste products or a decrease in concentrating power of the kidneys, an increase in volume of urine results or retention of the waste products ensues Starvation, fever and diabetic acidosis are examples of conditions associated with an increase in excretory products Thus with normal renal functional activity the urine becomes dark in color and appears thicker in consistency.

Bicarbonate is the most labile of the plasma anions because of its easy conversion to and formation from carbon dioxide. Its concentration in the plasma is determined by the total concentrations of base and fixed acids. The normal concentration of bicarbonate in plasma is 27 mEq per liter. At lower concentrations than 27 mEq. per liter all bicarbonate through the tubules is reabsorbed At concentrations more than 27 mEq per liter some bicarbonate is excreted. This apparently stable threshold is reduced by hyperventilation and increased in the presence of a low plasma chloride concentration.

Sulfate is for practical purposes quantitatively reabsorbed at normal concentrations and filtration rate. Any increase in the quantity filtered exceeds the reabsorptive capacity, and increased amounts of sulfate appear in the urine. However, a decrease in glomerular filtration with relatively less damage to tubular function may result in inadequate sulfate excretion. In chronic renal disease, sulfate retention occurs earlier than an elevation of blood urea.

There is a definite tubular reabsorptive capacity for phosphate so that this compound is maintained as a constant plasma concentration so long as the rate of phosphate production and filtration rate remain constant. Reabsorption of phosphate by the renal tubules is depressed in the presence of great increases in plasma levels of glucose or certain amino acids with which it shares transport mechanisms

Most of the sodium and chloride is reabsorbed in the proximal tubule It has been mentioned earlier in this discussion that the excretion of sodium and chloride is conditioned by filtration rate, plasma concentration, and hormones of the adrenal cortex and possibly the posterior pituitary There is considerable evidence to indicate that the fraction of filtered sodium reabsorbed in the proximal tubule tends to increase with a decreasing filtration rate and to increase with increases in plasma concentrations. However, excretion is not simply a threshold phenomenon The ability of the tubules to transport sodium is an intrinsic one This rate of transport is regulated by hormonal and other factors Excretion of sodium and chloride not only is influenced by tubular activity but also is dependent on rate of glomerular filtration.

In the absence of any change in body content of water and salt, the daily excretion [illegible] ials ingestion. The average [illegible] The body's mechanism for [illegible] the 140 mEq per liter contained in the glomerular filtrate may be absorbed by the tubules so that the urinary concentration may fall below 1 mEq. per liter.

The amount of potassium excreted is normally less than the amount contained in the glomerular filtrate Secretion of potassium by the tubules can and does occur The present concept is that extensive potassium reabsorption occurs in the proximal tubule and may be supplemented by tubular excretion in the distal tubule and that the distal process, normally small, is increased during increased ingestion or liberation of potassium when increased plasma concentrations prevail

The behavior of potassium in the body is not well known It is for this reason that it is thought that simultaneous reabsorption and tubular excretion of potassium may occur.

The importance of the kidneys in the body economy is made obvious and the disaster which follows the slowly progressive loss of renal functional activity can be observed as a chronic glomerulonephritis advances

Approximately 24 gm of urea, constituting nearly one half of the total solids of the urine, is excreted daily in the urine of a normal person consuming 80 gm. of protein per day.

Urea is completely filtered through the glomerulus; but the amount actually excreted equals only 30 to 60 per cent of that contained in the glomerular filtrate, depending on the rate of flow of urine. The discrepancy between the amount of urea filtered and the amount excreted in the normal person is apparently due to diffusion from the lumen of the tubule through the tubule cells into the blood stream.

Retention of urea in the patient with advanced glomerulonephritis is the result of reduction in the rate of glomerular filtration. The smaller daily volume of filtrate presents a reduced quantity of urea to the tubules, and the slower passage causes an increase in the percentage of the urea which is passively reabsorbed Consequently, the rate of excretion in the urine is reduced The concentration of urea in the blood (and in the subsequent filtrate) therefore rises until excretion equals formation In the early stages of a chronic renal failure, this elevation of the blood urea usually goes unnoticed because of the wide variation in protein intake and the range of the accepted normal

During the early stages of glomerulonephritis tubular function is seldom greatly impaired except in the nephrotic phase of the disease, and even then the proteinuria is believed to be due to an increased permeability of the glomerular membranes.

The relatively slow passage of the reduced volume of filtrate through the tubules permits reabsorption of an abnormally high percentage of sodium and water. The excretion of sodium and water is more greatly reduced than is glomerular filtration. This retention of sodium and water contributes to the edema which may be present in acute glomerulonephritis It is an indication for restriction of sodium intake at this stage of the disease.

A low level of plasma protein (particularly albumin) with retention of sodium results in edema in chronic nephritis and this may be termed the *nephrotic phase* of the disease

The low osmotic pressure of the plasma and the increased glomerular permeability combine to cause an abnormally high rate of glomerular filtration. Apparently there is an even greater increase in rate of reabsorption of sodium and water so that these substances are retained also.

Eventually in the progress of chronic glomerulonephritis, a stage is reached in which there is nitrogen retention in the plasma There is a reduction in renal blood flow, glomerular filtration, and capacity for tubular work Tubular injury seems to exceed the glomerular disorder The diminished capacity for tubular work manifests itself by increased volume of urine having a low specific gravity, impaired or absent synthesis of ammonia, and defective reabsorption of base The latter two defects may result in the loss of large amounts of sodium and potassium Anion retention, especially sulfate, may occur relatively early in the course of renal insufficiency

Necrotizing nephrosis, crush syndrome and lower nephron nephrosis are terms applied to the syndrome involving the kidneys that may follow crushing injuries, transfusion of incompatible blood, poisoning or necrosis of tubule cells. Renal blood flow is impaired by reflex vasoconstriction, and there may be mechanical obstruction of tubules from precipitated heme pigment, from drug (i e, sulfonamide) cellular debris, or from a combination of these substances

Here the presence of anuria does not necessarily mean that glomerular filtration has ceased There is evidence that lack of flow of urine from the kidneys may be due to complete back diffusion or reabsorption of the filtrate into the blood through the walls of the tubules, and anuria ensues.

If the patient survives the anuric or oliguric phase of necrotizing nephrosis, diuresis begins from 7 to 21 days after onset. The diuretic urine may approach the

glomerular filtrate in composition, indicating a lack of selectivity in tubular reabsorption The body thus may be depleted of sodium and especially potassium

In a patient with anuria, from any cause, (1) sodium, potassium, and chloride should be excluded from the diet so far as possible, except for the amounts necessary to replace loss by vomiting, diarrhea, or excessive perspiration; (2) administration of water should be limited to an amount equal to that lost as insensible perspiration, through the lungs, and in the excreta (the water content of food and water of oxidation should be considered in this calculation); and (3) protein ingestion should be at a bare minimum, with an adequate caloric intake to minimize breakdown of body protein

During the phase of diuresis, supplementation of oral intake of water and electrolytes may be necessary to keep up with the loss.

In shock associated with extensive tissue damage (for example, crushing injuries), the release of large quantities of myohemoglobin is a contributing factor. In burns there may be a similar release of noxious materials which may cause intravascular hemolysis. Allergy and disturbances in electrolyte balance may, in some instances, be important in the etiology of acute renal failure.

Chronic congestive heart failure is accompanied with a reduction in glomerular filtration manifested by a decreased capacity for excretion of sodium, chloride, and possibly water

Since the retention of fluid in congestive heart failure is associated with no great change in concentration of sodium or chloride, it follows that water has been retained in a relatively fixed ratio to these electrolytes. That sodium rather than chloride is the important ion is demonstrable by the diuretic effect of ammonium chloride and the increase in edema produced by ingestion of sodium bicarbonate.

In recognition of a decreased capacity for sodium excretion as the primary defect, regardless of its exact mechanism, the obvious therapeutic approaches are (1) limitation of sodium ingestion and (2) use of measures to increase the excretion of sodium Therapeutic means of accomplishing the latter include rest in bed, cardiac glycosides, ammonium or potassium chloride or nitrate, mercurial diuretics, xanthines, and sodium-removing resins

During the course of cirrhosis of the liver and especially when liver function is greatly impaired there is a decreased renal excretion of water and salts manifested by ascites. This tendency toward ascites formation is favored by an increase in portal pressure However, there are other factors concerned with the formation of ascites in cirrhosis of the liver. These factors are: (1) increased pressure in the capillaries of the portal circulation, (2) decreased plasma osmotic pressure, (3) decreased glomerular filtration rate, (4) an increased amount of circulating antidiuretic hormone, (5) increased intra-abdominal and renal tissue pressure and (6) increased capillary permeability. The importance of these factors when taken all together in the production of ascites is definite, for the limitation of the intake of the sodium ion does reduce edema and ascites in cirrhosis as it does in congestive heart failure

The task of regulating the electrolyte concentration of the plasma by the kidneys is great in diabetes because in this disease there are (1) excessive production of acid substances and (2) deficiency of base and water for their removal.

Lack of insulin in some manner results in hepatic production of beta-hydroxybutyric and acetoacetic acids in larger quantities than can be removed by body metabolism and renal excretion. These substances accumulate in the blood and, because of their acidity, displace plasma bicarbonate Excretion of sugar and ketone bodies requires an increased renal loss of water and base (sodium and potassium). The resulting dehydration is often accentuated by decreased food and fluid intake and by vomiting Dehydration, if severe, results in a decreased plasma volume,

hypotension, and decreased glomerular filtration. Thus, the capacity for excreting the accumulating abnormal metabolites is further diminished

On physical examination in acidosis there are observed shallow and irregular respirations and often an increased irritability of the neuromuscular system. The urine at first is alkaline in reaction but as the acidosis progresses it becomes acid

There is a marked decrease in plasma chlorides (normal values 340 to 370 mg. per 100 ml.). In severe acidosis the plasma chlorides may be less than 185 mg. per 100 ml Accompanying the decrease in plasma chloride there is an increase in the plasma bicarbonate to 90 to 110 (normal 55 to 75 volumes per cent). The carbon dioxide-combining power of the plasma decreases so that in slight acidosis it is 55 to 45 volumes per cent, in moderate acidosis, 40 to 30 volumes per cent; and in severe acidosis, 25 to 10 volumes per cent.

Alkalosis. Alkalosis is a chemical term employed to indicate an increased blood bicarbonate with a tendency toward alkalemia The term alkalemia indicates an increased pH (above 7 5) irrespective of the concentration of the bicarbonate of the blood.

The common cause for alkalosis is hyperventilation or overbreathing (sighing syndrome) by the hysteric patient Hyperventilation depletes the plasma of carbonic acid Alkalosis may result from an increased intake of alkalies, as in peptic ulcer, or from a loss of hydrochloric acid

In hysteria often there is a sensation of being unable to breathe or to take a long breath The patient does actually breathe deeply and at an increased rate with a resulting hyperventilation The patient may complain of attacks of "unconsciousness" if the alkalosis is severe In severe instances of hyperventilation Chvostek's sign, Trousseau's sign, cardopedal spasm and vocal stridor may be present. The syndrome is caused by an excessive excretion of carbon dioxide A similar condition may be observed in certain instances of encephalitis.

The metabolic forms of alkalosis are usually more easily identified because of a definite history of ingestion of excessive bicarbonate as in the treatment of peptic ulcer or of vomiting or diarrhea.

When alkalosis is present, there has been a loss of body acid or an increase in body base to a sufficient degree that the blood and extracellular tissues tend to become more alkaline in reaction. In mild alkalosis the carbon dioxide-combining power of the plasma, according to the Van Slyke method, is 70 to 78 volumes per cent (normal values 55 to 75 volumes per cent) which advances with the progression of the alkalosis until a value of 100 or more volumes per cent may be reached

Alkalosis and Tetany. Tetany may be present in alkalosis under the following circumstances. (1) after ingestion of excessive quantities of bicarbonate, (2) after continued pulmonary hyperventilation and (3) after protracted vomiting. The excessive loss of hydrochloric acid results in lowering of the plasma chlorides and increase in bicarbonate

In *bicarbonate tetany* there are an increase in plasma carbon dioxide-combining power and a decrease in concentration of plasma chlorides (gastric tetany).

[illegible]

are unchanged

Water intoxication may be induced in a normal individual by forced ingestion of large quantities of water over a short period of time. It is induced by drinking large quantities of water by an individual who has lost large quantities of sweat. It may occur during the course of diabetes insipidus

Thirst is somewhat conditioned to the ingestion of food. If there is a reduction in the diet, which usually entails a reduction in the intake of salt, and if the reduction in the diet is carried to the extreme so that carbohydrates also are eliminated, there

ensue a salt and water depletion and ketosis. Both salt depletion and ketosis promote dehydration and abate thirst When water alone is taken to replace these deficits, the salt of the body fluids becomes diluted to hypotonic concentrations and the state which follows is known as water intoxication.

The manifestations are variable, however, usually consisting of muscular cramps (see Heat Cramps, Chapter 21), nausea, vomiting, headache, oliguria and convulsions The low salt syndrome of Shaffer is a variant of water intoxication.

POTASSIUM

Potassium is the principal basic ion in the intracellular fluid Aside from its osmotic functions within the cell it possesses functions related to the processes of phosphorylation and deposition of glycogen and the neuromuscular transmission of nervous impulses In the blood plasma in health the amount of potassium varies from 13 5 to 21 5 mg. per cent (3 5 to 5 5 mEq /l.) Departure from this range of normal values may be followed by definite disturbances of neuromuscular functions

Hypopotassemia (Potassium Deficiency) Evidence of potassium deficiency is encountered only as a result of the excessive losses which occur in certain types of illness and also in the condition of familial periodic paralysis In starvation, fever and other conditions which lead to excessive destruction of body protein, potassium, like phosphorus and nitrogen, is excreted in large quantities in the urine In human beings important losses of cellular potassium have been shown to take place as the result of trauma, shock, hemorrhage, severe diarrhea, sprue, diabetic coma, and severe alkalosis due to loss of chloride. Loss of intracellular potassium in excess of that to be expected from protein breakdown is a general response to water depletion from any cause.

The severe vomiting in intestinal obstruction lowers the potassium level The serum potassium may be decreased by protracted vomiting and decreased still further after therapy with saline and dextrose solutions That the depletion involves the serum potassium and intracellular potassium is suggested by the small rise in serum concentration following injection of relatively large doses of potassium chloride

Familial Periodic Paralysis This condition is characterized by recurrent attacks of flaccid paralysis affecting the muscles of the trunk and extremities The majority of cases reported have been members of the same family groups The disease may be transmitted through either men or women who may themselves be free from it

In some cases no significant morphologic lesion can be demonstrated In others the serum potassium concentration falls during the attacks and the symptoms are relieved by administration of potassium salts During the paralytic phase the serum potassium concentration varies considerably in different cases, being usually less than 14 mg per 100 ml. and at times as low as 7.6 mg, although values as high as 17 4 mg per 100 ml have been observed Weakness has been observed to begin, in extremely rare instances, whenever the serum potassium falls below 16 mg per 100 ml Attack may be induced by agents that cause a lowering of the serum potassium concentration, including dextrose, insulin, thyroid extract, epinephrine and ephedrine Excretion of potassium in the urine may decrease markedly during an attack The actual significance of the aberrations in potassium metabolism cannot be interpreted (Duncan).

SYMPTOMS. The disease occurs twice as frequently in males as in females Symptoms usually begin during early childhood or adolescence and tend to become less frequent in later life. First attacks, however, have been reported after 30 years of age. Onset of the attack is often during sleep. If the attack begins during the waking hours, it may be preceded by numbness, formication and fatigue. The paralysis is flaccid and involves all of the voluntary muscles. The muscles of the face, eyes, tongue and organs of speech and deglutition are seldom affected Functions of

bladder and bowels are maintained The deep and superficial reflexes in the affected regions are lost. In severe attacks there is complete absence of reaction to faradic and galvanic stimulation, with a return to normal during intervals between attacks. There are wide variations in the distribution and severity of the paralysis The attacks may last only one-half to 1 hour, but usually persist for a few hours to a few days Motor power and reflexes usually return gradually and the patient feels perfectly well Occasionally the paralysis develops slowly, over a period of a few hours

Diagnosis of Potassium Deficiency. The diagnosis of potassium deficiency is made in the presence of decreased serum potassium concentration when accompanied by the history and findings of starvation and fever from any cause. One of the common causes of potassium deficiency is intestinal obstruction.

The decreased concentration of serum potassium causes the following electrocardiographic changes diminution, depression or inversion of the T wave; the QT interval is prolonged and the ST segment is depressed

Hyperpotassemia (Potassium Intoxication). An increase in the concentration of potassium occurs in acute high intestinal obstruction, uremia, portal cirrhosis with ascites and frequent abdominal paracentesis, severe infections, hyperparathyroidism, in Addison's disease, and in epilepsy and other convulsive disorders.

Flaccid paralyses have been reported to be associated with both low and high concentrations of serum potassium Instances of flaccid paralysis with increased concentrations of serum potassium were not observed by Keith and Burchell in their experience with renal insufficiency The paralysis in uremia is not closely correlated with any critical potassium level of concentration in the serum. Changes in intracellular potassium may occur without obvious changes in extracellular or serum potassium levels

The electrocardiographic pattern is influenced by the intracellular changes in the concentration of potassium For this reason an electrocardiogram serves as a rapid and reasonably reliable index of alterations in intracellular potassium concentration It is useful both in diagnosis and in control of therapy. The sequence of events in the heart muscle as depicted by electrocardiographic studies seems to occur in the following order of appearance increased height of the T wave, a QRS of increased width, loss of P waves; gross intraventricular conduction defects, the electrocardiogram superficially simulating bundle-branch block, cardiac arrest with irregular undulating potentials of low voltage In hyperpotassemia the T wave is exaggerated and eventually the P wave may disappear.

Diagnosis of Potassium Intoxication. The diagnosis of potassium intoxication depends on the presence of paresthesias of the hands and feet after the ingestion of the potassium salts or during the course of severe renal insufficiency and failure. The actual proof of the potassium intoxication rests on the demonstration of a coexisting hyperpotassemia and a characteristic electrocardiogram The plasma concentration of potassium should exceed 21.5 mg. per 100 ml or 5 5 mEq. per liter.

CALCIUM

The normal total serum calcium concentration varies from 8 5 to 11.5 mg per 100 ml ; of this about one half is said to be diffusible calcium The calcium of the blood is contained entirely in the plasma.

The absorption of calcium is decreased by increased alkalinity of the proximal small intestine and by a decreased phosphate content of the chyme with the formation of insoluble calcium soaps, as in obstructive jaundice, sprue and celiac disease.

Hypercalcemia. Increases in the serum calcium or in the plasma calcium occur in hyperparathyroidism, in excessive administration of vitamin D, in diseases of the bone such as multiple myeloma, and occasionally in metastatic carcinoma of the

bone; when there are mild increases in the carbon dioxide of the blood in association with such diseases as congestive heart failure, emphysema, pneumoconiosis and asphyxia; in chronic nephritis, especially during uremia and occasionally in pregnancy. Rare diseases which are uncommon and irregular causes for hypercalcemia are polycythemia vera, Addison's disease, and Cushing's disease

Hypercalcemia, with increased urinary excretion of calcium and phosphorus, may occur as a result of rapid demineralization of bones, especially in the presence of simultaneously impaired renal function Under these circumstances the concentration of phosphate in the serum is either normal or increased

The administration of parathyroid hormone causes an increase in the concentration of the serum calcium and urinary excretion of calcium. Synchronously there are a decrease in serum phosphorus, an increase in urinary phosphorus, and an increase in the serum phosphatase activity The function of parathyroid hormone in maintaining the serum calcium concentration is exerted through mobilization of this element from its storehouse in the bones.

Vitamin D increases the absorption of calcium from the intestine and aids the deposition of calcium and phosphorus in the bones Vitamin D exerts a greater and more immediate influence on phosphorus than on calcium in the blood serum.

Hypocalcemia. Hypocalcemia is one of the most constant and characteristic features of diminished parathyroid function. In some cases of rickets, when infantile tetany develops, hypocalcemia is present. In steatorrhea the serum calcium may be low and tetany, delayed ossification and osteoporosis may occur

Decreased serum calcium values may be associated with hypoproteinemia accompanying the nephrotic syndrome, obstructive jaundice, kala-azar, malignant disease and other cachectic states The diminution in serum calcium occurs entirely in the nondiffusible fraction and is apparently due to the decrease in the concentration of albumin in the serum and not to any disturbance of calcium metabolism.

Hypocalcemia is occasionally observed in nonnephrotic forms of chronic glomerulonephritis in the stage of renal functional failure

The clinical conditions characterized by disturbance of calcium and phosphorus metabolism are those dependent on or associated with abnormalities of parathyroid function and of vitamin D supply or utilization, for instance hyperparathyroidism, rickets, prolonged obstructive jaundice, sprue, celiac disease, hunger osteopathy and occasionally in malignant disease and cachectic states

Tetany. Tetany is characterized by an abnormally increased reaction of the somatic and autonomic motor and sensory nerves to stimuli. As a sequence of these stimuli painful, tonic spasms of groups of muscles or all of the muscles of the body ensue This nerve-muscle phenomenon is due to one or more changes in the body which are associated with alkalosis (which has just been considered in previous paragraphs) or to a reduction in concentration or inactivation of a portion of the serum calcium

Hypoparathyroid tetany follows thyroidectomy or parathyroidectomy and occurs in spontaneous hypothyroidism

Postoperative tetany usually results from the surgeon being unable to discover one or more parathyroid glands during thyroidectomy In rare instances it results from excision of too much parathyroid tissue in parathyroidectomy. Often these postthyroidectomy tetanies are due to temporary suppression of parathyroid function, as a result of trauma, edema or hemorrhage or interference with the blood supply of the parathyroid glands, and they are of brief duration

In those who have tetany postoperatively the symptoms may appear within a few hours, days or even weeks after operation. In the instances in which an interval of several days to a few weeks elapses before the symptoms of tetany appear, there

is often a disturbance of blood supply to the parathyroid glands as the result of fibrous organization of inflammatory exudate or hemorrhage. In these cases the tetany is prolonged or even permanent.

Idiopathic hypoparathyroidism is a rare condition. It has been attributed to inflammation or to hemorrhage into the glands It is chronic and presents essentially the same clinical and metabolic features present in postoperative tetany.

Infantile tetany occurs in rickets It is due to vitamin D deficiency and inadequate intake of calcium. The concentration of serum calcium is decreased The calcium and phosphorus balances are negative or subnormal, owing to excessive loss of these elements in the feces. The serum phosphatase activity is usually increased in proportion to the severity of the skeletal lesions, which vary from mild demineralization to the advanced demineralization present in rickets

Osteomalacic tetany occurs in adults and may be regarded as the counterpart of infantile tetany associated with rickets

In the *maternal tetany* of pregnancy the requirement for calcium, phosphorus and vitamin D is increased, as is indicated by parathyroid hyperplasia If the serum calcium decreases to subnormal concentrations, as it may do occasionally in the late months of pregnancy and during lactation, there will be tetany. The *tetany of the newborn* appears to be related to the existence of tetany in the mother.

Tetany is a common manifestation of *celiac disease, sprue and idiopathic steatorrhea.* It is due to impaired intestinal absorption of fats The calcium unites with these fats, calcium soaps are formed, and large amounts of calcium are thus lost. Impaired absorption of all foodstuffs is hindered by the increased intestinal motility. These abnormalities eventuate in osteoporosis, rickets, dwarfism, osteomalacia, hypocalcemia and tetany The serum phosphorus concentration is also frequently diminished These conditions are usually easily differentiated from other forms of tetany by the excessive fat content of the feces, the presence of anemia and gastrointestinal malfunctions

Tetany from parenteral administration of fluids such as soluble oxalates, phosphates or citrates may result from an induced hypocalcemia Calcium citrate is poorly ionizable and after its administration hypocalcemia does not ensue Tetanic manifestations may follow the intravenous injection of neutral, alkaline or slightly acid sodium phosphate Tetany may occur in advanced forms of renal failure also.

Manifestations of Tetany Tetany occurs in a latent, an acute or a chronic form Latent tetany does not present symptoms, but symptoms may be elicited by stimulation of peripheral nerves Acute tetany is manifested by spontaneous muscular spasms and other manifestations of nervous hyperirritability

Latent Tetany The presence of latent tetany, if there should be any reason for its presence being demonstrated, may be easily detected by mechanical or electrical excitation of the hyperexcitable nerves Electrical or galvanic stimulation elicits Erb's sign, which is a neuromuscular response obtained with weaker currents in tetany than under normal conditions

The Chvostek sign (facial phenomenon), hyperexcitability of the facial nerve to mechanical stimulation, is elicited by tapping the trunk of the facial nerve immediately anterior to the external auditory meatus A positive reaction consists in momentary contraction of the upper lip with associated movement of the nose, or the entire side of the face This sign may occur in normal subjects

The Trousseau phenomenon is elicited by applying the sphygmomanometer with sufficient force to stop the circulation. A positive reaction consists in the production of contraction of the fingers and hand in the obstetric position This sign, like the Chvostek sign, is not pathognomonic of tetany

Acute Tetany. The readily recognizable spontaneous spasms of acute tetany are the carpopedal spasm, laryngospasm and convulsions These may be preceded by and accompanied by paresthesias and intense pain.

In carpal spasm the thumb is inserted into the palm; the fingers, extended at the distal joints, are flexed at the metacarpophalangeal joints; and the wrist is flexed and the hand drawn to the ulnar side. In pedal spasm the feet are extended at the ankle joint in the position of equinovarus. There may be stiffness or spasm and pain in other muscle groups of the extremities. Facial spasm may produce stiffness and rigidity of the face, with the corners of the mouth drawn downward There may be rigidity of the entire body, especially of the neck and back, strabismus, nystagmus, inequality of the pupils and difficulty in speech and swallowing.

Laryngospasm occurs in children and may occur as the result of a very slight reflex irritation such as a cold, emotional disturbance and sudden awakening. There is a loud inspiratory crow due to spasm of the glottis. The attacks vary in severity and frequency and, if repeated, may be accompanied by dyspnea, cyanosis, coma and respiratory failure, which may terminate fatally. Usually the glottic spasm relaxes in a few minutes Diaphragmatic spasm may cause inspiratory or, rarely, expiratory apnea, which may cause death. Bronchotetany may produce attacks simulating asthma, in severe instances there is dyspnea. These respiratory manifestations are relieved by administration of calcium intravenously but do not respond to subcutaneous administration of epinephrine.

Autonomic nerves and smooth muscles may be affected. Spasm has been observed in the iris, the ciliary muscle, and the esophagus, throughout the gastrointestinal tract, and in the bladder Cardiac spasm may cause sudden death Palpitation, tachycardia, and cardiac irregularity occur frequently. Angiospasm results in pallor, especially of the fingers and toes, dermographia and muscle pain. There may be localized regions of puffiness of the skin or edema of the face or of the hands and feet (Duncan).

Chronic Tetany. Hypoparathyroidism is the most important cause of chronic tetany In latent tetany of hypoparathyroidism there may be trophic changes in the hair, skin, nails, teeth, and the crystalline lens of the eye.

The hair becomes coarse in texture and sheds in spots or almost completely. The skin is thickened and roughened and the nails become brittle, ridged, and may be shed The dentin and enamel of the teeth may exhibit small pits and horizontal grooves Both nuclear and cortical lenticular opacities may be recorded by the ophthalmologist on examination with the slit lamp.

The characteristic blood findings of hypoparathyroid tetany are hypocalcemia, normal or increased serum phosphorus concentration, normal serum phosphatase activity, and normal acid-base equilibrium.

Diagnosis of Tetany. The history and physical findings are usually diagnostic Serum calcium concentrations are diminished to 4 to 8 mg. (normal 8.5 to 11 5 mg.) per 100 ml and there is no parallelism between the severity of symptoms and the degree of hypocalcemia Serum phosphorus concentration may be normal (2 to 4 mg per 100 ml) but is usually increased (5 to 10 mg per 100 ml.) The absolute or relative increase in serum phosphorus plays a significant role in determining the precipitation of clinical symptoms of tetany There is a decreased urinary excretion of calcium and phosphorus.

Pathologic Calcification. The term metastatic calcification is applied to the deposition of lime salts in tissues which have not been the site of preceding regressive changes The lesions occur in the tubular epithelium of the kidneys, about acid-secreting glands of the gastric mucosa, and in the alveolar walls and vessels of the lungs, pancreas and other organs. Occasionally there is calcification of the pulmonary veins and the wall of the left auricle, the peripheral arteries, the trachea and the liver, and in some instances all tissues are affected

Metastatic calcification has been observed in hyperparathyroidism, hypervitaminosis D, renal rickets, multiple myeloma, myelogenous leukemia, extensive skeletal metastasis of sarcoma and carcinoma, marble bones and widespread osteomyelitis.

The term dystrophic calcification is applied to deposits of lime salts in dead, degenerated, or devitalized tissue, as in infarcts, regions of necrosis and fatty degeneration, inspissated collections of pus, hyalinized scar tissue, caseating tubercles, and atheromatous patches in the intima of vessels. Dystrophic calcification becomes more extensive in the presence of hypercalcemia, hyperphosphatemia, destructive lesions of bone, and impairment of renal function

Calcinosis is characterized by the deposition of lime salts in and beneath the skin. *Calcinosis circumscripta* is the commonest form of calcinosis In this condition the calcification is superficial, localized to the skin, occurs at any age, usually in the upper extremities, particularly in the fingers, and, because of the resemblance of the deposits to tophi, has been called calcium gout. The concentration of calcium in the blood is not increased.

Calcinosis universalis occurs most frequently before the age of 20 years In this condition there is no regular increase in the calcium of the serum. In addition to deposits in the skin, as in calcinosis circumscripta, widespread deposits occur subcutaneously and in the connective tissue of muscles, tendons, fascia and nerves Calcification may occur in the capsules of lymph nodes. The nodes often coalesce and may break down and ulcerate, discharging a chalklike material Calcinosis of the muscles is termed myositis ossificans (see p 328). Calcinosis about the joints is termed chalk gout.

Scleroderma and manifestations of the Raynaud syndrome, occur in a large proportion of those who have myositis ossificans. Calcinosis circumscripta causes little or no interference with function, but in calcinosis universalis contraction of tendons and muscles interferes with function of joints and muscles, and ulcerations of the skin may become portals of entry for local infections, septicemia, or bacteremia. There are no regular known increases in the blood calcium in these conditions.

PHOSPHORUS

Phosphorus occurs in the blood as inorganic phosphates, as organic phosphates as in the nucleotides, as phosphate esters, and as lipids. In adults inorganic *phosphate in the serum varies normally from 3 to 4.5 mg*, and in infants and young children *from 4 to 6 mg.* per 100 ml of serum The amounts, however, vary directly with the concentration of solar ultraviolet rays, being highest in summer and lowest in winter Following the ingestion of carbohydrates there is a gradual and progressive decrease of serum phosphate which persists during the period of increased glucose utilization, returning to normal in 4 to 5 hours This fall occurs independently of the blood sugar

The concentration of phosphorus in the serum may be increased (5 0 plus mg), *hyperphospheremia,* by therapeutic and by excessive doses of vitamin D, and by irradiation. Increase in serum values for phosphates may occur in hypoparathyroidism, the degree of increase being approximately proportional to the degree of hypocalcemia Hyperphospheremia occurs also in the healing of fractures, chronic

rickets If the concentration of calcium be multiplied by that of phosphorus, each being expressed in milligrams per 100 ml , a product is obtained which, *in the normal child,* ranges from 50 to 60 When the product is less than 30, rickets is usually present, and when it is more than 40, either healing is occurring *or rickets* has probably not been present. These observations cannot be relied upon absolutely.

A primary disease of phosphorus metabolism is commonly observed *in osteitis* fibrosa diffusa due to hyperparathyroidism and resulting from an increased elimina-

In carpal spasm the thumb is inserted into the palm; the fingers, extended at the distal joints, are flexed at the metacarpophalangeal joints; and the wrist is flexed and the hand drawn to the ulnar side. In pedal spasm the feet are extended at the ankle joint in the position of equinovarus. There may be stiffness or spasm and pain in other muscle groups of the extremities. Facial spasm may produce stiffness and rigidity of the face, with the corners of the mouth drawn downward. There may be rigidity of the entire body, especially of the neck and back, strabismus, nystagmus, inequality of the pupils and difficulty in speech and swallowing.

Laryngospasm occurs in children and may occur as the result of a very slight reflex irritation such as a cold, emotional disturbance and sudden awakening. There is a loud inspiratory crow due to spasm of the glottis. The attacks vary in severity and frequency and, if repeated, may be accompanied by dyspnea, cyanosis, coma and respiratory failure, which may terminate fatally. Usually the glottic spasm relaxes in a few minutes. Diaphragmatic spasm may cause inspiratory or, rarely, expiratory apnea, which may cause death. Bronchotetany may produce attacks simulating asthma, in severe instances there is dyspnea. These respiratory manifestations are relieved by administration of calcium intravenously but do not respond to subcutaneous administration of epinephrine.

Autonomic nerves and smooth muscles may be affected. Spasm has been observed in the iris, the ciliary muscle, and the esophagus, throughout the gastrointestinal tract, and in the bladder. Cardiac spasm may cause sudden death. Palpitation, tachycardia, and cardiac irregularity occur frequently. Angiospasm results in pallor, especially of the fingers and toes, dermographia and muscle pain. There may be localized regions of puffiness of the skin or edema of the face or of the hands and feet (Duncan).

Chronic Tetany. Hypoparathyroidism is the most important cause of chronic tetany. In latent tetany of hypoparathyroidism there may be trophic changes in the hair, skin, nails, teeth, and the crystalline lens of the eye.

The hair becomes coarse in texture and sheds in spots or almost completely. The skin is thickened and roughened and the nails become brittle, ridged, and may be shed. The dentin and enamel of the teeth may exhibit small pits and horizontal grooves. Both nuclear and cortical lenticular opacities may be recorded by the ophthalmologist on examination with the slit lamp.

The characteristic blood findings of hypoparathyroid tetany are hypocalcemia, normal or increased serum phosphorus concentration, normal serum phosphatase activity, and normal acid-base equilibrium.

Diagnosis of Tetany. The history and physical findings are usually diagnostic. Serum calcium concentrations are diminished to 4 to 8 mg. (normal 8.5 to 11.5 mg.) per 100 ml. and there is no parallelism between the severity of symptoms and the degree of hypocalcemia. Serum phosphorus concentration may be normal (2 to 4 mg. per 100 ml.) but is usually increased (5 to 10 mg. per 100 ml.). The absolute or relative increase in serum phosphorus plays a significant role in determining the precipitation of clinical symptoms of tetany. There is a decreased urinary excretion of calcium and phosphorus.

Pathologic Calcification. The term metastatic calcification is applied to the deposition of lime salts in tissues which have not been the site of preceding regressive changes. The lesions occur in the tubular epithelium of the kidneys, about acid-secreting glands of the gastric mucosa, and in the alveolar walls and vessels of the lungs, pancreas and other organs. Occasionally there is calcification of the pulmonary veins and the wall of the left auricle, the peripheral arteries, the trachea and the liver, and in some instances all tissues are affected.

hyperparathyroidism, generalized osteoporosis, hyperthyroidism, osteomalacia, metastatic carcinoma involving bone, osteogenic sarcoma, Hodgkin's disease, lymphosarcoma and leukemia with involvement of bone, polyostotic fibrous dysplasia, during the period of healing of fractures, Gaucher's disease with resorption of bone and osteopoikilosis (osteosclerosis fragilis generalisata, marble bones) and, rarely, in renal rickets and multiple myeloma

Normal serum contains small amounts of acid phosphatase, less than 3 units. *Serum acid phosphatase activity* is increased in carcinoma of the prostate with metastasis. The source of this enzyme under these circumstances is the acinar epithelium of the prostate gland. Carcinomatous prostate tissue also contains large amounts of acid phosphatase, and when metastasis occurs, with invasion of lymph or blood channels, large amounts of the enzyme enter the circulation When there is metastasis to bone, the alkaline phosphatase too may be increased

IRON

The absorption of iron from the gastrointestinal tract is normally a controlled process In the healthy, nondeficient adult only a small portion of ingested food-iron will be absorbed each day In an iron-deficient person the absorptive process is much more efficient, and a high percentage of the ingested iron may be taken up Studies of iron absorption in growing children indicate that the efficiency of the absorption process parallels the need for the element Similarly, during the latter half of pregnancy the absorptive efficiency is greatly increased, this being the period during which the fetal stores of iron are built up

Iron exists in the blood in the erythrocytes and in the plasma or the serum. The iron of the erythrocytes, the hemoglobin, has been discussed in Chapter 12. In the normal total iron content of the blood the organic iron is 52 mg per 100 ml, of which 57 per cent is hemoglobin iron The hematin iron is not available for use The interest here is on the plasma or serum iron

It seems probable that all iron which is absorbed must first be reduced to the ferrous state Ascorbic acid reduces ferric iron, and there is evidence that it may serve this role under physiologic conditions

Absorbed iron is transported in the plasma or the serum in the ferric state as one of the globulin fractions Inorganic iron is that part of the iron which remains in the plasma or the serum and can be determined by special methods The normal range of values for plasma iron or serum iron is usually stated to be about 80 to 180 micrograms per 100 ml Low values are encountered in the hypochromic microcytic anemia of iron deficiency and in the anemia of infection Higher than normal values are present in pernicious anemia and hemolytic anemias

Iron which is given intravenously disappears rapidly from the plasma or the serum It seems that iron thus administered is stored, and it is known as available storage iron The measure of the concentration of iron which can be retained by plasma or serum under such circumstances is spoken of as the iron-binding capacity.

The available storage iron is made up of recently absorbed iron plus that recently released during the breakdown of hemoglobin, and a more fixed, less readily available, tissue iron The chief sites of storage iron are the liver, spleen, bone marrow, and kidneys The tissues contain the so-called parenchymal iron also

Practically no iron is excreted in the urine, and the excretory iron in the feces comprises less than 1 0 mg per day

Requirements for Iron. The times of the greatest requirement for iron are during the first two years of life and the rapid growth of adolescence and, in women, throughout the childbearing period After the menopause the requirement drops. The Food and Nutrition Board of the National Research Council has given estimates that a man weighing 150 pounds (68 kg.) requires 12 mg of iron daily. Twelve

tion of phosphate in the urine. Hypophosphatemia may be present in idiopathic steatorrhea, in tropical and nontropical sprue, and in periods of increased carbohydrate metabolism coincident with large amounts of fats in the intestines and with the defective absorption of calcium, phosphorus and vitamin D. Also hypophosphatemia follows the administration of glucose, insulin, epinephrine and parathyroid extract, and is present in uncontrolled diabetes.

Phosphaturia. All normal persons excrete 1 to 3 gm. of phosphoric acid as an alkaline salt in the urine each day. When this excretion is excessive or when the phosphates are precipitated in the urogenital tract, this condition is termed phosphaturia

Almost all (95 to 99 per cent) of the urinary phosphorus occurs as sodium and potassium phosphates which are soluble in both acid and alkaline urine. The calcium and magnesium salts are insoluble in alkaline urine, and it is therefore these salts and the alkaline urine which are responsible for phosphaturia Phosphaturia is commonly present when there is an excessive ingestion of sodium bicarbonate or of certain fruits with an alkaline ash or when urinary infections and bone diseases occur.

Other than a slight burning on micturition there are no symptoms unless calculi are present The turbidity of the urine due to phosphates occurs only in a neutral or alkaline urine To be significant, the deposit must be heavy in a freshly voided urine

PHOSPHATASE

An enzyme phosphatase which does not contain phosphate is normally present in the bones, kidneys, striated muscles and blood This enzyme liberates inorganic phosphate by hydrolysis of phosphoric esters for the deposition of calcium phosphate in the bones It exists in both alkaline and acid forms

Serum alkaline phosphatase activity is reported from the laboratory in terms of units. A unit of alkaline phosphatase activity as defined by Bodansky is "equivalent to the actual or calculated liberation of 1 mg of phosphorus as the phosphate ion during the first hour of incubation at 37 C and pH 8.6, with the substrate containing sodium beta-glycerophosphate, hydrolysis not exceeding 10 per cent of the substrate "

Phosphatase activity is low at birth, rises to a maximum during the first month of life, and remains fairly high during the second year, the values in later childhood falling gradually to adult levels. High protein diets cause a decrease, and high carbohydrate diets an increase in phosphatase activity of the serum The range of normal values for plasma or serum alkaline phosphatase activity in adults is 1 5 to 4 units per 100 ml and for children 5 to 14 units (Bodansky).

Serum phosphatase activity is increased in a large proportion of patients who have obstructive types of jaundice (to 60 units), portal cirrhosis, metastatic carcinoma involving the liver, and biliary fistula

Increased serum phosphatase activity occurs during periods of calcification of hemorrhages in scurvy, in active tuberculosis and Boeck's sarcoid, and in chronic myeloid leukemia

Serum alkaline phosphatase activity is increased chiefly in certain diseases of bone and in certain disorders of the liver and the biliary tract. In the former it appears to be related in most instances to the extent of osteoblastic activity or to the intensity of attempts at formation of bone

It is consistently increased in active rickets (20 to 190 units) The degree of increase may be regarded as a reliable criterion of the severity of the condition High values (15 to 125 units) are obtained rather consistently in osteitis *fibrosa cystica*, or slightly increased activity (to 25 units) may occur in cases of localized involvement of one or two bones. A moderate increase (20 to 40 units) is observed in

is a consistent increase in its incidence. A decline in the incidence is observed after the age of 55 years. Women are rarely affected before the age of 50 years. The disorder affects men from 20 to 25 times as often as it affects women (Duncan).

Once the hemochromatosis has become established, it is a progressive chronic disorder manifested by an abnormal deposition of hemosiderin in the skin and viscera, cirrhosis of the liver, diabetes mellitus and in some instances by deposition of iron in the myocardium.

SYMPTOMS. Perhaps the most constant manifestation is cirrhosis of the liver. There are lassitude, discomfort in the epigastrium, and a sensation of heaviness and distention in the abdomen due to ascites and enlargement of the liver These symptoms may appear late in the course of the disease but usually are the most significant. In the final stages of the disease hematemesis, purpura, icterus, diarrhea, dyspepsia, and vomiting may be present. The presence of symptoms of a complicating myocardial failure, pulmonary tuberculosis and carcinoma of the liver may render the symptomatology complex and difficult to recognize.

Diabetes mellitus may result from hemochromatosis It is an early manifestation in less than one third of these patients The diabetes mellitus of hemochromatosis is usually controllable for a while In rare instances it may be exceedingly severe from the onset and difficult to control. The patient passes through a state of increasing insulin resistance to one in which insulin is completely ineffective.

Heart block and heart failure are occasional manifestations of a heavy deposit of hemosiderin in the myocardium

Asthenia is a common symptom of hemochromatosis from beginning to end. It may be secondary to disturbances in the function of the adrenal glands, to the cirrhosis of the liver, to diabetes or to myocardial failure

EXAMINATION. The pigmentation of the skin is evident in approximately 8 of every 10 patients who have hemochromatosis It is the first sign of the disease in about one fourth of all who have it The skin is bronzed, bluish metallic, gray, or slate color. The color is more obvious about the genitalia and perineum, and in the folds of the skin, in scars and on exposed portions than elsewhere, but it affects to a degree all of the skin The face, the extensor surfaces of the forearms, and the extensor surfaces of the hands are commonly deeply pigmented Pigmentation of the buccal mucosa occurs in 1 of every 8 who are affected. The conjunctivae also may be pigmented Often there are nail marks from scratching of the intensely itching skin

Xanthoma and xanthomatous eruptions of the skin may be present. Often there is considerable loss of hair from the scalp and the axillary and pubic regions

The liver usually is enlarged, smooth, firm and not tender In late stages of the disease the liver shrinks and cannot be palpated. The spleen is palpable in about one half of the cases Ascites appears frequently as a late manifestation.

A moderate hypochromic anemia, hyperglycemia, hypercholesterolemia, glycosuria, and reduced serum albumin with a reversal of the albumin-globulin ratio are common findings. Abnormal results of tests of hepatic functional activity, particularly bromsulfalein-retention, are present. Icterus, though an unusual complication of this disorder, may be present and cause an increased concentration of the serum bilirubin. Moderate increases of the basal metabolic rate are common.

DIAGNOSIS The diagnosis is most easily made by hepatic biopsy. However, the presence of cirrhosis of the liver, diabetes mellitus and pigmentation of the skin is rarely mistakable for anything other than hemochromatosis

The disorders which may resemble hemochromatosis are argyria and Addison's disease. Pigmentation is the only characteristic which these three conditions have in common The history and physical examination should establish the correct differentiation. Hemochromatosis and Addison's disease do occasionally occur in the same patient.

milligrams of iron daily is required by a nonpregnant woman weighing 123 pounds (about 56 kg.). During the second half of pregnancy and during lactation she requires 15 mg. daily. The requirements for iron increase from 6 mg. daily during the first year of life to 15 mg. daily until the age of 20 years is reached. After the age of 20 years the requirements for adults prevail.

Iron Deficiency. In the infant, iron deficiency is most often of dietary origin. In the adult the deficiency is conditioned by chronic loss of blood.

The clinical evidence indicates that by the time adulthood is reached even the poorest dietary regimens which are likely to be encountered are sufficient to prevent iron deficiency in the absence of chronic loss of blood. Iron deficiency results from repeated losses of blood The commonest sources of these losses are: menorrhagia; bleeding peptic ulcers, hemorrhoids; menopausal menorrhagia; abortion, miscarriage or bleeding after delivery; hookworm disease; and loss of blood secondary to malignant changes in the gastrointestinal tract, in the nasopharynx or in the urogenital tract

The iron-deficient person usually is easily fatigued and listless. Palpitation on exertion, a sore tongue, angular stomatitis and dysphagia may be present, and hypochromic microcytic anemia is usual (the Plummer-Vinson syndrome). Koilonychia may also be seen Any combination of these conditions may be encountered Signs other than the anemia are not usually encountered in children. The oral lesions occur in one degree or another in about 10 per cent of iron-deficient adults Plasma iron levels are low Iron absorption, however, is increased, as can be demonstrated by use of the radioactive iron technic.

The presence of a low hemoglobin level is not alone sufficient for the diagnosis of iron-deficiency anemia, whether in a particular person or in a group of the population. The findings indicative of the anemic state may be cardiac abnormalities such as hemic murmurs, cardiac enlargement, symptoms of angina pectoris, palpitation and even electrocardiographic changes. Dyspnea and edema are not infrequently observed.

Hemochromatosis *(Bronze Diabetes). The cause of hemochromatosis is obscure* Minute quantities of iron in excess of body needs are retained and accumulate over a period of years The retention may be due to an inherited abnormal inability of the cells to rid themselves of iron

Hemochromatosis has been observed to occur as the result of a familial and hereditary predisposition. Whatever the cause, there is an abnormal retention of iron The total iron content of the body may be from 5 to 10 times the normal content of 3 gm in the normal person

In hemosiderosis iron pigments deposited in the tissues are used again in the formation of blood, whereas in hemochromatosis the hemosiderin is not used again Hemosiderosis originates from excessive destruction of blood. In no stage of development of hemochromatosis is there detectable evidence of excessive erythrocyte destruction

Hemosiderin as well as some hemofuscin are deposited in the propria of the sweat glands and in the deeper strata of the malpighian layer of the skin The liver is enlarged and the capsule is thickened The surface is firm and nodular and there are accumula- [illegible] ated with [illegible] tion and actual loss of acinar and islet tissues Deposits of hemosiderin are present in the spleen, the lymph nodes, the pituitary, thyroid, and salivary glands, and in the myocardium. Hemofuscin is found in the cells of glandular organs, in *connective tissue*, in smooth muscle, and particularly in the walls of the medium-sized and small arteries

The melanin of the deeper layers of the epidermis is increased in amount The skin coloration in this disease is not due to deposit of excessive iron-containing pigments

Hemochromatosis occurs in patients between the ages of 45 and 55 years The condition is unknown before the age of 20 years but from this age to 40 years there

The prognosis in hemochromatosis depends on how well the cirrhosis of the liver and the diabetes mellitus respond to treatment in the absence of cardiac complications After diabetes mellitus is fully manifested life rarely lasts more than 1 year.

GLYCOGEN DISEASE (GLYCOGENOSIS)

Glycogen disease is rare It is inherited as a mendelian recessive character. This disorder of metabolism is characterized by the storage of normal glycogen within the liver, heart and kidneys, and usually by retardation of growth and of the development of sex characteristics

As a result of the immobility of the hepatic glycogen, the systemic blood sugar concentrations are low, 60 mg. per 100 ml. or less. There are no hyperglycemic symptoms A glucose tolerance test reveals a moderate delay in glycogen storage and a retarded return to a mild hypoglycemic level. There is a tendency toward acetonuria owing to incomplete oxidation of fat.

The first symptom is enlargement of the abdomen. The liver is enlarged and smooth The kidneys too in some instances are enlarged and easily palpated

In an obese child the findings of a low fasting blood sugar value, acetonuria, and an increased concentration of cholesterol in the blood (up to 400 mg per 100 ml) in association with hepatomegaly are suggestive. The epinephrine test fails to reveal the usual rise in the blood sugar. The glucose tolerance curve is abnormal The concentration of glycogen in the blood is increased Sudden death may occur from severe hypoglycemia or from cardiac failure.

THE AUTONOMIC (VEGETATIVE) NERVOUS SYSTEM

References have been made to functional disorders which occur in association with most of the organs and all of the systems of the body. The remarks in regard to these disorders imply a diagnosis of a psychoneurosis or a disorder attributable to aberrations in psychic control. When a diagnosis of a psychoneurosis is made, too frequently all of the manifestations or queer reactions of the patient are attributed to the psychoneurosis. Cold wet hands, hypersensitiveness to heat and cold, change in the size of the pupils and often pupillary reactions, aberrations in tendon reflexes, irregular respirations, irregular heart beating, digestive disturbances and many other irregularities are considered as a part of the prevailing psychoneurosis However, some of these manifestations are present in normal persons. When these manifestations are found in the normal individual without being the subject of complaint they are dismissed by the experienced physician. These manifestations may be the source of needless examinations, perhaps treatment both operative and medical by the [illegible]

It does not matter whether the patient has a psychoneurosis, is enjoying good health without complaints or whether he is organically sick, if he has cold wet hands, hypersensitiveness to heat and cold, irregular sweating over various parts of the body, vasomotor rhinitis, irregular size of the pupils and often irregular pupillary reactions, bronchial spasm, nervous dyspepsia, irregular heart beats, irregular urinations, defecations and sexual functioning, the cause for these departures from health is an imbalance of the autonomic nervous system.

Anatomy. The autonomic system consists in part of a series of nerve centers situated in the diencephalon, mainly in the hypothalamus, the floor of the third ventricle and the periaqueductal gray matter. In health these centers are influenced but not controlled by the cerebral cortex.

The autonomic nervous system has two great subdivisions—the *sympathetic system* or the thoracolumbar outflow, and the *parasympathetic* which includes the craniocervical and sacral outflows of nerves These autonomic subdivisions are not as separately distinct functionally as they are anatomically. The functional overlapping has been explained on the basis of chemical mediators utilized in the transmission of nerve impulses When choline is the dominant chemical mediator the nerves (parasympathetic) are designated cholinergic and when epinephrine is the dominant chemical mediator the nerves (sympathetic) are designated adrenergic nerves.

It may be of etiologic significance to observe that the impulses of both of these subdivisions of the autonomic system are mediated by hormones The sympathetics are mediated by the hormone epinephrine and the parasympathetics by the hormone acetylcholine of plant origin, a vitamin.

Sympathetic Division. The sympathetic division or thoracolumbar outflow of the autonomic system consists of a series of ganglia connected by a trunk of nerve fibers situated one on each side, and in front of the vertebral column, and extending from the atlas to the coccyx where they fuse in a ganglion

Each trunk consists of nerve cells which only give off involuntary efferent nerve fibers,

variations. It is usually benign Neurofibroma (von Recklinghausen's disease) usually involves the peripheral nerves. However, the cranial nerves may be affected and particularly the vagi. These tumors are benign

The benign autonomic tumors are usually accidental, surgical or necropsy findings.

In most instances imbalance is of a mild degree and therefore goes unnoticed by the patient. In some, however, the imbalance is excessive and is the cause of complaint or of manifestations Imbalance of each division of the autonomic system will be discussed in its appropriate place.

Symptoms. Stimulation of the *sympathetic* nerves occurs in many normal reflex reactions of the body, for instance, during emotional states and severe pain Stimulation occurs in association with the mobilization of epinephrine and thus it is termed adrenergic reactions.

The signs of stimulation are best observed in the eye. These signs are often present in exophthalmic goiter (Graves's or Basedow's disease). Stimulation of these sympathetic nerves may be artificially induced by the administration of a few drops of a solution (5 to 10 per cent) of cocaine. Soon after administration of this drug there is a dilatation of the pupil, exophthalmos, proptosis, or forward projection of the eyeball; widening of the palpebral aperture (Dalrymple's sign); infrequency of involuntary blinking (Stellwag's sign); oculopalpebral asynergia, producing delayed descent of the upper lid when the patient looks downward, leaving a band of white sclerotic visible between the upper lid and the cornea (von Graefe's sign); and deficient convergence of the eyeballs (Möbius' sign).

Stimulation of the sympathetic nerves produces, in addition to the eye signs, tachycardia, sweating, dryness of the mucous membranes of the nose and mouth, dyspnea, hyperglycemia, atonic intestines, impotence and spermatorrhea.

In former years a congenital form of hyperactivity of the sympathetic nerves was recognized and described, and termed *sympathicotonia*. This congenital sympathicotonia was supposed to produce a definite somatic type.

It was thought that preponderance of sympathetic nerve activity was inheritable. Those inheriting sympathicotonia are adrenergic individuals who have very active (but still within normal limits) adrenal glands Such a person is lively and excitable, with rapid heart, bright eyes, mobile and dilated pupils, rosy color, deficient acidity of the gastric juice, and a warm, dry skin Sympathicotonic individuals are specially sensitive to epinephrine, to thyroid secretion and to posteropituitrin, any one of which exaggerates all their characteristics The oculocardiac and carotid-sinus reflexes are often diminished or absent

The important reflexes which the craniocervical outflow of *parasympathetic* fibers subserves are the pupillary reflex, the secretion of saliva and gastric juice, the maintenance of muscular tonus of the alimentary canal, the vagus control of insulin secretion, and the tonic vagal slowing of the heart rate

Parasympathetic stimulation is manifested by miosis, slowness and diminished force of the heart, contraction of the uterus, ureters, bladder, and bronchial muscle; contraction of the colon with relaxation of the internal rectal sphincter, paresis of the intra-abdominal blood vessels, lowered blood pressure, pallor of the skin, and increase of glandular secretions. There are lacrimation, nasal congestion, salivation, priapism, pollakiuria, gastric hyperacidity, and hypermobility and spasm of the pylorus and the esophagus

The parasympathetic fibers and end organs are specially stimulated by insulin.

Like the sympathetic subdivision with its congenital form of sympathicotonia an increased activity of the parasympathetic nerves causes a *parasympathicotonia* which is usually termed vagotonia.

Vagotonia may be a family characteristic. It may be generalized all through the body, or, more commonly, it is a localized vagotonia, limited to the cranial, the cervical, or the sacral division of the parasympathetic system.

The parasympathetic, cholinergic, or vagotonic type of individual, with low

to gland tissue, to blood vessels, and to organs which possess unstriated muscle fibers. Each cord or trunk is connected with the spinal cord by both white and gray rami communicantes

Parasympathetic Division. The parasympathetic division of the autonomic nerves has its cells of origin in special nuclei in the brain stem, in the midbrain and nucleus lateralis in the medulla, which are homologous with the intermediolateral nuclei in the spinal cord Through the vagus nerves fibers are distributed to the thorax and the abdomen The anteriorly situated autonomic nuclei are associated with the control of parasympathetic reflexes

The sacral outflow of parasympathetic fibers emerges from the spinal cord through the second, third, and fourth sacral nerves of the cauda equina The white rami are given off from the nerve roots after they have emerged through the sacral foramina The parasympathetic pelvic nerves (nervi erigentes) run directly into the hypogastric plexus in the hollow of the sacrum, and thence to the muscular walls of the colon, rectum, bladder and urethra and the genital organs, affording reflex paths for the emptying of these hollow organs in the presence of the continuous, tonic, or postural influence of the sympathetic nerves

The parasympathetic division is distributed to ganglia arranged in peripheral plexuses on the surface of the individual viscera supplied, for example, in the intestine, Auerbach's plexus between the two layers of the muscular coat, and Meissner's plexus in the submucosa

Autonomic Reflexes. The autonomic nervous system is concerned with two classes of reflexes In one, the centripetal path runs in a cerebrospinal nerve, and the stimulus, on reaching the brain stem, is reflected peripherally along a fiber of the autonomic system Examples of these reflexes are salivation, sweating, flushing of the skin and the genital reflex In the other class of autonomic reflex both afferent and efferent paths are outside of the brain stem. This reflex arc is contained in the peripheral plexuses and regulates the movements of hollow organs such as the gastrointestinal tract, uterus, ureters and bladder

Etiology of Autonomic Disorders. All disorders of the autonomic nervous system are caused by imbalances of activity between the two subdivisions irrespective of whether the subdivisional separation has been made on the bases of anatomy or physiology The functions of the divisions are, in health, synergistic. This synergism is maintained by (1) acid-base equilibria, (2) vasosensory mechanisms, (3) endocrine and exocrine secretions, (4) autonomic reflexes and (5) central controls.

Pathology of Autonomic Disorders. In most instances it is impossible to establish a direct anatomic or a histologic relationship between the neural lesions and the clinical manifestations of autonomic hypertonus or imbalance.

The changes described in the autonomic cells present in the aging patient are termed senile degeneration In acute or chronic disease in younger patients, chromidial alterations, pigment increases, changes in the pigments and their distribution within the cells, vacuoles in ganglion cells, neuronophagia, hyaline degeneration, hydropic alteration, shrinkage, neurofibrillar changes, modification of the dendrites and changes in the interstitial cells have been observed to be incident to many acute and chronic infections and vasospastic conditions

A common cause for lesions of the hypothalamus is infection, both bacterial and viral. As has been stated in various parts of this text hypothalamic disturbances are often associated with epidemic encephalitis. In instances of measles associated with encephalitis there are present perivascular demyelinization, glial proliferation, congestion and hemorrhage in the hypothalamus The less common causes for hypothalamic disorders are: scarlet fever, pertussis, diphtheria, mumps, typhoid fever and lymphocytic meningoencephalitis.

Imbalance of the autonomic nervous system may be due to tumors Tumors are commoner in the autonomic nervous system than in the central nervous system and also commoner in the parasympathetic division than in the sympathetic division of autonomic nerves Both benign and malignant tumors occur in both divisions

Benign tumors of autonomic nerves are ganglioneuroma, paraganglioma and neurofibroma The ganglioneuroma is usually benign but may become malignant if there are present groups of immature cells within the tumor The paraganglioma exhibits many

is due to the narrowed palpebral fissure, the drooping of the upper eyelid and to a distinct elevation of the lower lid. On palpating the two eyeballs the intra-ocular tension is observed to be diminished on the affected side.

When the cervical sympathetic is paralyzed, the ciliospinal reflex is abolished; pinching or pricking the side of the neck will not produce a dilatation of the pupil. A few minims of a 5 to 10 per cent solution of cocaine in the eye on the affected side will not cause the pupil to dilate, neither will the upper lid retract, nor will the eyeball be pushed slightly forward.

In an occasional instance of cervical sympathetic palsy, some degree of facial hemiatrophy may occur, but this is never so pronounced as in idiopathic facial hemiatrophy (see the Face, Chapter 4).

Horner's syndrome must be differentiated from Adie's syndrome, a condition not known to be due to any lesion of the central nervous system, characterized by a pathologic pupil reaction (pupillotonia) In Adie's syndrome there is a myotic condition on accommodation, the pupil on the affected side contracts on near vision more slowly than does the pupil on the opposite side, and it also dilates more slowly. The affected pupil does not react to direct or indirect light or it may do so in abnormal fashion

Skin, Mucous Membranes and Joints All autonomic skin disturbances except for those of the face are sympathetic in origin. The sympathetic paths arise in the brain stem and descend along extrapyramidal tracts of the spinal cord, to end in the lateral horns, where lower autonomic centers are situated, which affect circulatory, vasomotor and sudomotor activities

Sweating is produced by direct stimulation of the sympathetic reflex centers in the spinal cord, medulla, hypothalamus or cerebral cortex Sweating is increased by (1) rise of external or internal body temperature, (2) emotional states, (3) exercise, (4) nausea, vomiting, asphyxia, anoxia and often during normal sleep The quantity of sweat which can be produced in an hour is between 1,500 and 2,000 ml

Interruption of continuity of a cutaneous nerve produces an area of abnormal dryness corresponding to that of the sensory loss The skin becomes thin and glossy. The nails are hardened, become ridged and brittle, and grow more rapidly than normal nails Incomplete disruption of mixed nerve trunks, such as the median or sciatic, is associated with excessive sweating of the affected hand or foot Alopecia often follows lesions of the autonomic nerves

The hemiplegic state caused by lesions of the capsule is attended by excessive sweating of the hand, foot and axilla on the paralyzed side If the hemiplegia is due to a striatal lesion the face shares in the hemihyperidrosis

Transections of the spinal cord may be associated with abnormalities of sweating Above the level of the lesion, profuse sweating is induced, whereas the skin of the trunk and legs remains dry up to the level of the transection.

Localized symmetrical sweating of the palms and soles may be occasioned by mental exertion and emotional excitement. In the rest of the body the skin remains dry

The cutaneous [illegible]
nomenon, acrocya [illegible]
stimulation eviden [illegible]
ciation with the peripheral vascular diseases (Chapter 6).

Gustatory sweating affecting the face or other parts of the body (i e., the knee or knees) occurs in some otherwise normal persons; unilateral or bilateral redness and sweating of the face may occur when chewing substances of particular flavor. Other cases of unilateral flushing and sweating of the face occur after injury to the parotid gland on the same side, chiefly in the area of the auriculotemporal nerve.

Angioneurotic edema (Quincke's disease) depends on a vasomotor disturbance associated with the absorption of toxins, exogenous or endogenous, to which the

suprarenal activity, is reserved and "cold-blooded," with slow pulse, low blood pressure, contracted pupils, deep-set eyes, cool, pale skin which sweats easily and sometimes patchily; also clammy hands and feet. Vagotonic individuals often show other evidence of excessive vagal activity in the form of gastric hyperacidity, bradycardia, asthma, mild respiratory arrhythmia of the heart, and spastic constipation, analogous to the asthmatic bronchial spasm. Sugar tolerance is high, so that relatively large amounts of glucose can be taken without inducing glycosuria Also, the blood shows a tendency to eosinophilia.

The oculocardiac and carotid-sinus reflexes are especially active in vagotonic individuals

Vagotonic women sometimes have a masculine distribution of the pubic hair, which, instead of being bounded above by a horizontal line, extends upward along the linea alba toward the umbilicus. Such women have small mammary glands and often a ring of hair around the nipples.

The manifestations of parasympathetic paralysis are: decreased secretion of the skin of the face, mucous membranes of the mouth, nose, throat, eyes, respiratory passages, salivary glands, stomach and pancreas. All unstriped muscle except arterial walls seems to be affected when the inhibitory power of the vagus is removed.

EYE. In the eye sympathetic fibers innervate the radial or dilator fibers of the iris, the smooth muscle of the upper lid and the blood vessels of the eyeball. The pupil-dilating fibers arise from a cortical center in the frontal lobe, and descend by way of the hypothalamus and the brain stem into the lateral column of the spinal cord. They pass from the cord as preganglionic fibers through the anterior roots of the first and second thoracic segments, and to the inferior cervical ganglion by white rami communicantes They now ascend in the cervical sympathetics to the gasserian ganglion, and thence to the orbit along the ophthalmic division of the fifth cranial nerve, through the long ciliary nerves to the pupil.

The parasympathetic craniocervical outflow arises from laterally placed nuclei in the midbrain and passes with the oculomotor nerve to the ciliary ganglion and thence to the iris and ciliary muscle, or from the medulla passes along with the nervus intermedius, glossopharyngeal, and vagus nerves to the sphenopalatine, otic, and submaxillary ganglia The parasympathetic fibers innervate the constrictor muscle of the iris and ciliary muscle. The latter mediate the light reflex and accommodation

Horner's Syndrome. A unilateral lesion with paralysis of the cervical sympathetic nerves causes Horner's syndrome. This syndrome may be caused by a variety of lesions at different sites, for instance. (1) lesions of the brain stem; (2) intramedullary lesions of the spinal cord at or about the level of the first thoracic segment, (3) extramedullary lesions of the spinal cord; (4) lesions involving the peripheral portion of the cervical sympathetic

On examination in unilateral paralysis of the cervical sympathetic the eyelid on the side of the lesion droops and the affected side of the face flushes less than the normal side and there may be gustatory hyperhidrosis of the affected side of the face From paralysis of the dilator pupillae the affected pupil is smaller than the other. The affected pupil does not dilate when protected from the light; yet it contracts promptly to light and on convergence. Contraction and convergence of the pupil are affected by the sphincter pupillae which is innervated by the third cranial nerve through the ciliary ganglion The affected upper lid droops owing to paralysis of the unstriated (involuntary) part (tarsalis superior) of the levator palpebrae The voluntary, striated fibers of the levator, inserted into the skin of the upper lid and supplied by the oculomotor nerve, are unaffected, and the patient is therefore able to elevate the lid voluntarily to its full extent. The drooping of the affected upper lid therefore, is not a true ptosis, but a "pseudoptosis"

The affected eye seems to be sunk into the orbit This apparent enophthalmos

at irregular intervals. There is rarely a loss of consciousness. The attack is often alleviated by small doses of glyceryl trinitrate (see Chapter 5).

Vagotonia and Bronchial Asthma. The paroxysmal expiratory dyspnea of bronchial asthma, with its slow and labored breathing, is associated with excessive vagotonia. The phenomena, which in some cases constitute an allergic reaction, are produced by spasm of the unstriated bronchial muscles, innervated by parasympathetic fibers of the vagus. It is for this reason that many instances of asthma are found not to be of allergic origin

Abdomen and Pelvis In the section on Endocrine Disorders of the Pancreas (Chapter 14) under the heading Hypoglycemia are mentioned instances of hypoglycemia without other evidence of hyperinsulinism. In these patients there is no convulsive disorder associated with the hypoglycemia. This condition, in some, is thought to be due to an abnormal activity of the parasympathetic nerves to the pancreas.

Nervous Dyspepsias. Anxiety psychoneuroses are often associated with visceral symptoms and especially dyspepsia. In such cases, interference with the motor and secretory functions of the gastrointestinal tract may result from purely psychogenic causes, acting through the autonomic system.

Dyspepsias of nervous origin are often associated with hyperacidity and pyloric spasm, and excessively loud peristaltic rumbling noises. The rare condition known as acute dilatation of the stomach, and many of the symptoms of acute peritonitis, such as intestinal paralysis, meteorism, small pulse and general collapse, may be the result of acute paralysis of the parasympathetic fibers of the solar plexus Irritation of the solar plexus, and especially of its parasympathetic fibers, is exemplified in cases of lead colic, with its associated pain, constipation, and increased arterial tension The various visceral "crises" of tabes dorsalis—gastric, intestinal, renal and rectal—may be due to syphilitic changes in the autonomic fibers traversing the posterior spinal nerve roots, either irritative or causing defective inhibition. In sympathetic crises, pain is the main symptom which may be associated with cutaneous hyperesthesia of the abdominal wall.

Other digestive disorders associated with autonomic imbalance such as hypertrophic stenosis of the pylorus, spasm of the pylorus in adults giving symptoms resembling those of peptic ulcer, intussusception of the small intestine in children, chronic diarrhea and constipation and often indeterminate abdominal pains are described in Chapter 13.

The hypogastric plexus or presacral nerve, which supplies the pelvic viscera, receives its sympathetic fibers from the upper two lumbar ganglia and, after dividing into the two pelvic plexuses, one on each side of the rectum or vagina, receives sacral parasympathetic fibers through the second, third, and fourth sacral nerves, the combined strands constituting the nervus erigens on each side

The pelvic plexuses send nerve fibers to the terminal ganglia innervating the pelvic colon, rectum, bladder, uterus, fallopian tubes and internal genital organs

Many of the disorders which may arise in disturbances of the hypogastric plexus have been described with the diseases of the abdomen Among these disorders is hypertrophy and dilatation of the colon with constipation or Hirschsprung's disease (see Diseases of the Colon in Chapter 13).

There are syndromes manifested by pain (for instance, menstruation) associated with the normal physiologic functioning of the organs within the pelvis. Other syndromes are associated with a dissatisfaction with functioning of the distal colon, rectum and internal and external genitalia. These syndromes, many of them bizarre, are difficult to interpret. It is known, however, that the sympathetic nerves cause the uterus to contract, whereas the parasympathetic nerves inhibit contraction

Stimulation of the presacral nerve or the lumbar sympathetic fibers contracts the seminal vesicles, ejaculatory ducts and muscular septa of the prostate, which causes a pouring out of seminal fluid and prostatic secretion into the prostatic urethra. If

individual is hypersensitive. In those who have an allergic state by inheritance it may be associated with the intake of special articles of food. In some a crisis may occur which closely resembles anaphylactic attacks The attacks tend to recur for several months to years and then a long period, several years, may supervene without manifestations of the disorder.

When angioneurotic edema occurs in paroxysms the condition is known as Quincke's disease. Quincke's disease is characterized by paroxysmal attacks of sharply localized edema in various parts of the face, trunk, or limbs. After lasting a few hours, the swelling passes off spontaneously. The mucous membranes of the respiratory or gastrointestinal tract may be affected If the gastric mucous membrane is affected there is urgent vomiting, if the intestinal mucous membrane be affected a colic, and bloody diarrhea ensue, and if the mucous membrane of the larynx is severely affected death may result from edema of the glottis and asphyxia When the joints are affected, especially the knee joint, the condition is known as *intermittent hydrarthrosis*. The joint suddenly becomes distended with fluid, accompanied by a feeling of tightness and pain The swelling of the joint disappears in three or four days without residual disability to the joint and without fever though a leukocytosis may be present

Some varieties of urticaria are referable to affection of the vasomotor nervous mechanism, as in cases in which the characteristic itching wheals appear on sudden emotional excitement

In the hemiplegic state it is common to find edema of the hand or foot on the paralyzed side Permanent coldness and cyanosis are common in the paralyzed limbs of old poliomyelitics. Even in warm weather, the flaccid limb remains cold, and sometimes blue

The vasomotor fibers to the skin are not trophic fibers. The trophic nerve fibers seem to be closely associated with the vasomotor fibers and probably course with the latter to the skin Trophic disturbances follow aberrations in function of the autonomic nerves which may occur as sequelae of poliomyelitis, tabes dorsalis, and syringomyelia Disturbance of the functions of the urinary bladder is closely associated with trophic disturbances

HEART AND LUNGS. The sympathetic innervation of the heart is through the superior, middle and inferior cardiac nerves from the cervical ganglia similarly termed. There are additional innervations through rami from the sympathetic trunk in the thorax The efferent components are postganglionic fibers from the sympathetic ganglia The parasympathetic innervation is through three rami of the vagus nerve. The efferent components are preganglionic fibers from the cardiac plexuses

The proximal portions of the aorta, pulmonary artery and the cardiac wall, the cardio-aortic zones, are supplied in addition to the sympathetic fibers, by depressor nerves from the vagus Both afferent and efferent sensory cerebrospinal nerves are present in the cardio-aortic zones

Vasovagal Attacks. The paroxysms termed vasovagal attacks appear to be due to disorder of that part of the hypothalamic region which concerns the vagal distribution to the heart, lungs, and other viscera. The disorder is more frequent in women at the menopause and in younger women with pelvic disorders than in other persons

The attack generally begins with an epigastric aura, quickly followed in some instances by violent, irregular and rapid beating of the heart (*transient auricular* [illegible] constriction, *suffocative* dyspnea and [illegible] ases after the onset of the attack [illegible] ace is pale, and the limbs become cold. The pulse rate may fall to 30 per minute or less. This is followed either by burning flushes or clammy sweat, and by a tension of the muscles, sometimes amounting to tetany.

The paroxysms vary in duration from a few minutes to several hours and recur

INDEX

the lumbar sympathetics are bilaterally divided for the relief of congenital megacolon or of some angiospastic disorder in the lower limbs, the power of seminal ejaculation is lost, although in other respects the sexual reflex is unimpaired.

The sympathetic innervation retards the detrusor muscle of the bladder and excites the sphincter, while the parasympathetic innervation excites the detrusor muscle and inhibits the sphincter.

Examination. All through this book mention has been made in regard to the examination and significance of partial ptosis of the upper lids of the eyes, enophthalmos and miosis of the pupil. Dilatation of the pupil has many causes and not all dilatations are of autonomic origin

Aberrations of sweating over patches of the skin or in localized areas are always due to disturbances of the sympathetic nerves

A convenient method of mapping out sweating from nonsweating areas, according to Wright, is to paint the skin with a solution (the number of parts of some ingredients has been modified here) containing 1.5 gm. of pure iodine, 10 ml of oleum ricini and a sufficient quantity of alcohol (80 per cent) to make 100 ml After this has evaporated, leaving a thin film of oil and iodine, the skin is sprinkled with rice powder, and the powder is rubbed in; the excess is blown off with a fan. The patient is then exposed to a warm temperature Any sweating area will now appear as a deep blue-black color, the nonsweating areas remaining unchanged Another method of testing for abnormalities in sweating more convenient to the physician but uncomfortable to the patient is application of mustard to the patient's tongue which causes vasodilatation and sweating

The vasomotor reactions of the extremities to hot and cold water are described in association with diseases of the peripheral vascular system of the extremities (see Chapter 6)

A simple and practical method of examination of the skin of the extremities is to search for signs of cyanosis, pallor and scleroderma. Dermatographia is a sign of disordered vasomotor tone. Roughened, thickened, colorless nails, and other trophic changes may be present

By means of special thermometers differences in skin temperatures over localized areas or over extremities may be compared. This procedure is of great value in the diagnosis of the angioneuroses

Locally bony and soft tissue hypertrophy, Charcot joints with their increased mobility, are significant of autonomic disorders which accompany tabes dorsalis, syringomyelia, injuries and tumors.

In the syndrome of acroparesthesia there is present vasomotor disturbance of pale cold hands, paresthesias all of which may be an early stage of the cold wet cyanotic fingers and hands of Raynaud's phenomenon

The methods of examinations in the syndromes referable to the great autonomic plexuses are those commonly used for the detection of all manner of disease affecting the organs of the thorax, abdomen and pelvis

Diagnosis. The imbalances of the autonomic nervous system vary greatly in their clinical importance. These imbalances vary from manifestations which are accompanied by no ill health to those which are present in grave illnesses Since the autonomic nervous system is concerned with homeostasis no manifestation of imbalance can be taken lightly until it has been fully evaluated

In the diagnosis of autonomic disease it will be observed that sympathetic imbalances are more likely to be constant under any given conditions whereas parasympathetic imbalances are phasic and usually of short duration.
